Esophageal infections with human papillomavirus (HPV; Chapter 344) are typically asymptomatic. HPV lesions are most frequently found in the mid to distal esophagus as erythematous macules, white plaque, nodules, or exuberant frondlike lesions. The diagnosis is made by histologic demonstration of koilocytosis (an atypical nucleus surrounded by a ring), giant cells, or immunohistochemical stains. Treatment is usually not necessary, although large lesions may require endoscopic removal. Other treatments, such as interferon, bleomycin, and etoposide, have yielded varying results. HPV infection is a risk factor for esophageal squamous cell carcinoma (Chapter 178), but the value of endoscopic surveillance is not known.

MISCELLANEOUS ESOPHAGEAL CONDITIONS

Esophageal Emergencies

BOERHAAVE SYNDROME

Boerhaave syndrome, or spontaneous rupture of the esophagus, is a transmural full-thickness tear of the esophageal wall. A sudden rise in intraesophageal pressure during forceful vomiting is the cause in most cases. The tear is most commonly in the lower third of the esophagus, 2 to 3 cm proximal to the gastroesophageal junction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The classic presentation is vomiting, lower thoracic pain, and subcutaneous emphysema. Other findings may include pleural effusions, especially left-sided, tachypnea, abdominal rigidity, fever, and hypotension. Because the condition is rare and classic antecedent vomiting is not always reported, rupture is often recognized only after the development of mediastinitis.

The chest radiograph may demonstrate mediastinal widening, a unilateral pleural effusion, hydropneumothorax, and pneumomediastinum. The esophagram, typically with a water-soluble agent, reveals extravasation, although false-negative results may be encountered. Computed tomography (CT) scanning with an oral contrast agent, which is perhaps the best diagnostic option, typically demonstrates air in the mediastinum.

MALLORY-WEISS TEAR

A Mallory-Weiss tear (see Fig. 124-2) is a mucosal tear, often at the gastroesophageal junction, usually caused by severe vomiting or retching. The syndrome is more common in alcoholic patients. In about 85% of patients, it is associated with acute upper gastrointestinal bleeding, which requires transfusion in about 70% of patients and urgent intervention in about 10% of cases. Mortality is about 5%, similar to the mortality in severe bleeding ulcers. Most tears heal spontaneously within about 48 hours.

IATROGENIC PERFORATION

Esophageal perforation may occur as a result of a variety of iatrogenic causes, including endoscopy, dilation, endosonography, or surgery, as well as with foreign body ingestion. Typical symptoms include chest pain with or without abdominal pain, subcutaneous emphysema, and fever. Diagnosis may be made immediately at the time of endoscopy or radiography. Chest radiographs may show pneumomediastinum, subcutaneous emphysema, hydrothorax, or hydropneumothorax. A Gastrografin swallow may show a leak, and chest CT may show mediastinal air. Acute perforations are life-threatening emergencies that warrant immediate closure before contamination of the mediastinum. For acute perforation caused by endoscopy, endoscopic clips or stents are an option. Conservative therapy also is an option for well-contained perforations with minimal mediastinal, pleural, or peritoneal contamination and no obvious signs of sepsis. Prognosis is generally good if the perforation is recognized and treated early, preferably within 12 to 24 hours.

TREATMENT AND PROGNOSIS

Successful therapy depends on early recognition and the underlying condition of the patient. The classic approach is operative repair in conjunction with broad-spectrum antibiotics and nutritional support, especially if the diagnosis is made within the first 24 hours. Aggressive conservative therapy with percutaneous drains, broad-spectrum parenteral antibiotics, and nutrition also has been successful. In selected individuals, endoscopic insertion of self-expanding covered metallic stents or over the scope clips, with or without pleural drainage as needed, is an option. The mortality rate can be as high as 100% without treatment.

FOREIGN BODIES

Impaction of food or foreign bodies is a common gastrointestinal emergency. Meat impaction is most commonly seen in adults, but other foreign objects that also may be ingested accidentally or by design include batteries, coins, and bones. Many patients have an underlying esophageal abnormality, such as Schatzki ring, stricture, eosinophilic esophagitis, tumor, or achalasia. The clinical presentation includes dysphagia, odynophagia, foreign body sensation, chest pain, excessive salivation, and difficulty handling secretions. Immediate endoscopic extraction or gentle advancing of the bolus with concomitant airway protection is recommended because prolonged impaction may result in penetration into the esophageal wall followed by perforation and mediastinitis.

ESOPHAGEAL VARICES

Esophageal varices are described in Chapter 139.

ESOPHAGEAL FISTULA

Tracheoesophageal fistulas may arise from a variety of different causes, including trauma, infectious esophagitis, necrosis after prolonged endotracheal intubation, esophageal cancer, and radiation therapy. Patients are often critically ill and may not tolerate surgery. Metallic stents are a treatment option.

Atrial-esophageal fistulas are a rare complication after radio frequency ablation (Chapter 54) for atrial fibrillation. The clinical presentation is nonspecific and includes features such as dysphagia, fever, leukocytosis, bacteremia, massive intestinal bleeding, and septic shock. Diagnosis requires a high index of suspicion and is aided by a chest CT scan. Surgery is required; the

prognosis is excellent with early recognition and treatment but can be dire if treatment is delayed.

CONGENITAL ABNORMALITIES

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Children with congenital esophageal anomalies commonly survive into adulthood after successful surgery. As adults, these patients typically have gastroesophageal reflux that warrants proton pump inhibitor therapy. Strictures at prior surgical anastomoses are common, and patients may require periodic endoscopic dilation. Eosinophilic esophagitis may also occur.

HETEROTOPIC GASTRIC MUCOSA (INLET PATCH)

Inlet patches, which are areas of gastric columnar epithelium, are present in up to 4.5% of adults and are usually found incidentally at the time of routine endoscopy. Typically, a red columnar patch varying in size from a few millimeters to a few centimeters is seen just below the cricopharyngeus. Inlet patches can be associated with hoarseness, sore throat, and globus sensation. Strictures, ulcers, and rare malignant transformation also have been described. Treatment options include proton pump inhibitors (see Table 124-1) and endoscopic ablation.

OTHER CONGENITAL ESOPHAGEAL DISORDERS

Duplication cysts, which may be located anywhere in the esophagus, may be in continuity with or separate from the esophageal lumen. Symptoms, which may present initially in adulthood, include dysphagia owing to luminal compression, chest pain, and regurgitation. Treatment is surgical.

Dysphagia lusoria is caused by an aberrant right subclavian artery that originates from the right aortic arch and causes partial compression of the esophagus as it crosses over to the left side. Patients may complain of dysphagia. This condition is most commonly detected incidentally during barium radiography, where it is visualized as a crossing diagonal impression at the junction of the proximal and middle thirds of the esophagus. Surgery is rarely indicated because of the complexity of the operation and the difficulty in establishing a clear relationship between the radiographic findings and symptoms.

ACID PEPTIC DISEASE

ERNST J. KUIPERS

Acid peptic diseases can involve the esophagus (Chapter 124), the stomach, and the duodenum. Dyspeptic symptoms also can occur in patients who have no endoscopic abnormalities, in whom it is termed *nonulcer dyspepsia* (Chapter 123).

DEFINITIONS

Gastric and duodenal ulcers usually occur in an area of inflamed mucosa. This inflammation, termed *gastritis, duodenitis*, or *bulbitis*, can be recognized by endoscopic signs of edema and erythema of the mucosa, but microscopic evaluation of endoscopic biopsy specimens is required for a definitive diagnosis of mucosal inflammation.

Gastritis is categorized by endoscopic and histologic criteria, with granulocytes predominating in active gastritis and mononuclear cells in chronic gastritis. Gastritis is classified further by the segment of the involved stomach: antral-predominant gastritis, corpus-predominant gastritis, or pangastritis. Finally, the absence or presence of premalignant stages of damage to the mucosa as a result of long-standing inflammation defines the categories of nonatrophic and atrophic gastritis, respectively. High-definition endoscopy, when combined with magnification and image enhancement, allows adequate visualization of features of gastritis, atrophy, and intestinal metaplasia. Gastritis features include antral nodularity, absence of connecting venules, and enlarged gastric folds. Sometimes, the mucosa has a typical miniature cobblestone appearance, termed *nodular gastritis* (a finding particularly in children colonized by *Helicobacter pylori*), or grossly enlarged folds without evidence of cancer, termed *hypertrophic gastritis*. Disappearance of gastric folds and enhanced mucosal vasculature are findings of *atrophic gastritis*. Atrophy may be accompanied by *intestinal metaplasia*, which appears as gray-white patches (white-light endoscopy) or light-blue lines ("light-blue crests") on the mucosal surface (narrow-band imaging).

A *peptic ulcer* is a mucosal defect at least 0.5 cm in diameter that penetrates the muscularis mucosae. Smaller mucosal defects are called *erosions* (Fig.125-1). Gastric ulcers are subdivided into proximal ulcers, located in the body of the stomach, and distal ulcers, located in the antrum and angulus of the stomach. Gastric ulcers are located mainly along the lesser curvature, in particular at the transitional zone of corpus- to antral-type mucosa. This transitional zone is often in the area of the angulus but may shift proximally. Duodenal ulcers usually are located on the anterior or posterior wall of the duodenal bulb (Fig. 125-2) or occasionally at both sites ("kissing" ulcers). Lesions distal

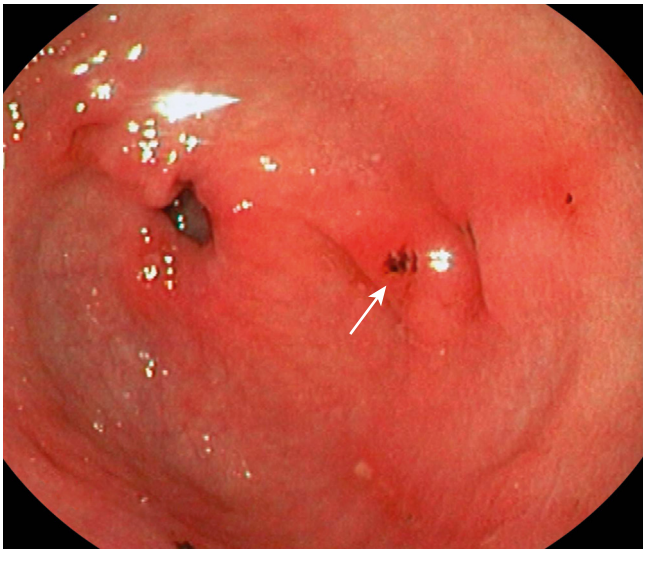

FIGURE 125-1. Endoscopic view of uncomplicated erosive gastritis. The erosion appears as a small, superficial mucosal break with a black base (*arrow*).

ABSTRACT

Gastroduodenal acid peptic diseases, in particular, gastritis and peptic ulcer, are predominantly caused by *Helicobacter pylori* infection and by use of aspirin and nonsteroidal anti-inflammatory drugs, but their pathobiology includes a wide range of other conditions. Patients with suspected acid peptic disease are often first treated empirically with acid suppression. Patients with persistent or recurrent symptoms, with new-onset symptoms at an older age, or with alarm symptoms should have *H. pylori* testing and upper gastrointestinal endoscopy to confirm the anatomic abnormality and its cause, as well as to exclude other potential causes of symptoms. Treatment should be targeted to heal mucosal breaks, address the underlying cause, and prevent recurrence. Peptic ulcer disease can be complicated by bleeding, perforation, and stenosis, each of which requires specific assessment and treatment by endoscopy, interventional radiology, or surgery.

to the duodenal bulb are termed *postbulbar ulcers*. Patients who previously underwent a distal gastric resection (Billroth I or II procedure) or a gastric bypass (Chapter 201) can develop ulceration at the anastomosis (*anastomotic* or *marginal ulcer*). However, ulcers occurring after Billroth II resection are located predominantly in the jejunal mucosa at the junction between the afferent and efferent loops. Other peptic ulcers can occur at sites of metaplastic or heterotopic gastric mucosa, for example, in Meckel diverticulum, the rectum, or Barrett esophagus. Patients with a large hiatal hernia can develop gastric ulceration, known as *Cameron ulcers*, at the herniation. *Dieulafoy ulcers*, which are small mucosal defects over an intramural arteriole, can lead to severe bleeding. Although these lesions can occur throughout the gastrointestinal tract, two thirds occur in the stomach.

EPIDEMIOLOGY

The worldwide prevalence of gastritis reflects the prevalence of *H. pylori*. Colonization with this bacterium is virtually always associated with chronic active gastritis, which persists as long as an individual remains colonized and only slowly disappears 6 to 24 months after bacterial eradication. An estimated 4.4 billion people worldwide are colonized with *H. pylori*.[1] Colonization usually occurs in the first decade of life and then remains lifelong. In developing countries, high colonization rates result in a high prevalence of *H. pylori* gastritis (often ≥75%) in all age groups, including children. In Western countries, the colonization pressure in children has decreased markedly in recent decades, thereby leading to a birth-cohort phenomenon for the prevalence of *H. pylori* gastritis—currently less than 20% in young adults but 40 to 60% in elderly persons. Some recent studies suggest that this decrease in *H. pylori* prevalence in children may be slowed by factors such as the increasing use of daycare facilities. Nevertheless, the decline of *H. pylori* in developed country populations has been inexorable.

Although peptic ulcer disease is strongly related to *H. pylori* gastritis and duodenitis, the epidemiology of ulcer disease has shown secular variation even when *H. pylori* was ubiquitous. The incidence of peptic ulcer disease rose steeply in Western countries in the late 19th and early 20th centuries and has decreased over the past 40 years; nevertheless, peptic ulceration remains a common disorder. The decline in incidence, associated with a decrease in hospital admissions and surgery for ulcer disease, is believed mostly to reflect the decreasing prevalence of gastric colonization with *H. pylori*. It also results from the widespread application of eradication therapy, which strongly reduced recurrent ulcers in *H. pylori*–positive patients, and the widespread use of acid-suppressive medications. Nevertheless, hospital admissions for complications of ulcers and mortality from ulcer disease have shown a far less marked decline in both the United States and other countries because the reduction in *H. pylori*–associated ulcers in younger persons has been partly counterbalanced by an increase in ulcers related to nonsteroidal anti-inflammatory drugs (NSAIDs) in older persons.

In Western countries, duodenal ulcers occur more frequently than gastric ulcers. The predominant age at which duodenal ulcers occur is between 20 and 50 years, whereas gastric ulcers most commonly occur in patients older than 40 years. The incidence of gastroduodenal ulcer disease is approximately 1 to 2 per 1000 inhabitants per year. Although the prevalence of *H. pylori* colonization is nearly identical in males and females, two thirds of patients with ulcers are male. More than 50% of patients have a recurrent ulcer within 12 months of healing in the absence of treatment. Maintenance acid-suppressive therapy reduces this recurrence rate, but only therapeutic measures that remove the underlying cause of the ulcer can prevent most ulcer recurrences.

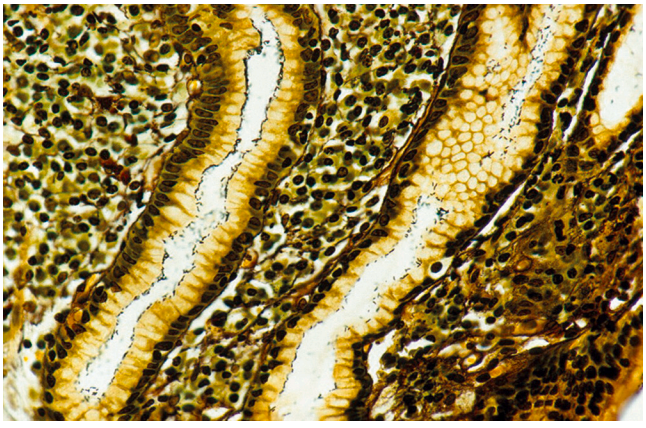

FIGURE 125-3. Gastric mucosa colonized with *Helicobacter pylori* appearing as curved bacilli on the mucosal surface.

PATHOBIOLOGY

Helicobacter pylori

Most peptic ulcers are associated with colonization with *H. pylori* (Fig. 125-3).[2] However, most persons who are *H. pylori* positive do not have any specific complaints, nor do they develop ulcer disease. The estimated risk for the development of ulcer disease during persistent *H. pylori* colonization is 5 to 15%—that is, three-fold to eight-fold higher than the risk in patients who are *H. pylori* negative. The risk for the development of an ulcer in the presence of *H. pylori* is determined by a combination of host- and bacteria-related factors. Host factors include immune response, smoking, and stress. Genome-wide association studies have identified a relationship between polymorphisms in the toll-like receptor gene and the interleukin-1β gene with the prevalence of *H. pylori*. This relationship may in part explain the variation in risk for *H. pylori* colonization and thus the risk for *H. pylori*–associated disease, including peptic ulcer. Bacterial factors that enhance mucosal inflammation and increase the risk for ulcer include a high production of the *VacA* product, which reflects the presence of the s1m1 genotype; a high level of cytokine induction, owing to the presence of genes in the *cag* pathogenicity island; and enhanced adherence to the gastric epithelium as a result of bacterial expression of *babA* and *oipA*.

Nonsteroidal Anti-inflammatory Drugs and Aspirin

The other common cause of gastroduodenal ulcer disease is the use of NSAIDs. At least 2 to 4% of the population in many countries use acetylsalicylic acid, acetic acid derivatives (diclofenac, indomethacin, sulindac), or propionic acid derivatives (ibuprofen, ketoprofen, naproxen) on a daily basis. The risk for ulcer disease is dose and duration dependent. Within 14 days after the start of such treatment, about 5% of patients develop erosions or ulcers. In patients who continue therapy for 4 weeks or longer, this proportion increases to 10%, but many are clinically silent. The concomitant presence of *H. pylori* infection increases the incidence of NSAID-related ulcers.

The risk for an ulcer during NSAID use is higher in patients who are older than 60 years; patients with a previous ulcer; patients who use corticosteroids, selective serotonin reuptake inhibitors, or aldosterone antagonists; and patients with major comorbid diseases. In patients who use anticoagulants, such as warfarin and new oral anticoagulants (thrombin and factor Xa inhibitors), or who have severe comorbid disease, an NSAID-induced ulcer is more likely to lead to life-threatening gastroduodenal hemorrhage.

On the basis of their activities, NSAIDs are divided into cyclooxygenase 1 (COX1) and COX2 inhibitors (Chapter 26). The COX1 enzyme is involved in the production of prostaglandins, which play a role in normal cell regulation. The COX2 enzyme, which is also involved in the production of prostaglandins, is induced by inflammatory responses. Most NSAIDs have a nonselective

COX inhibitory effect; selective COX2 inhibitors are associated with fewer gastroduodenal ulcers, but their use has been limited because of their adverse coronary effects (Chapter 26). The strong association between NSAIDs and ulcer disease and the risk for recurrence of ulcers with their continued use require that patients with ulcers be thoroughly assessed for any use of NSAIDs.

Helicobacter pylori–Negative, Non-NSAID Ulcer Disease

In most series, *H. pylori* and NSAID use account for 80 to 95% of cases of ulcer disease. The remaining cases are often referred to as *idiopathic* or *H. pylori–negative, non-NSAID* acid peptic disease. The proportion of ulcer disease that is idiopathic is increasing throughout the world as the prevalence of *H. pylori* decreases. Further, it is likely that some ulcers in *H. pylori*–positive patients were not caused by *H. pylori*. Consistent with this notion is the fact that some *H. pylori*–positive patients develop recurrent ulcers after successful bacterial eradication, so presumably their ulcer disease was idiopathic. It is not known whether the increase in idiopathic ulcer disease is simply proportional to the decrease in *H. pylori*–associated ulcers or whether it reflects a true increase in the incidence of idiopathic ulcers.

In patients with idiopathic ulcer disease, specific clues to the underlying cause are often provided by the medical history, including comorbidity and drug use; the endoscopic appearance of the ulcer; and the histologic features of the ulcer's margins and surroundings. In most cases, these initial data can be used to direct further diagnostic studies (Table 125-1).

Malignant Ulcer Disease

Gastroduodenal ulcers can result from underlying malignancies. In the stomach, such tumors are related to gastric adenocarcinoma and, rarely, to mucosa-associated lymphoid tissue (MALT) lymphomas (Chapter 178). Malignant ulcers in the duodenum may result from primary duodenal carcinomas or from penetrating pancreatic cancers. Duodenal cancers have an association with polyposis syndromes, especially familial adenomatous polyposis and, to a much lesser extent, *MUTYH*-associated polyposis and Peutz-Jeghers syndrome (Chapter 179). In both the stomach and the duodenum, ulcer disease also may be caused by metastatic tumors, including cancers of the breast, colon, thyroid, or kidney, or by melanoma, disseminated lymphoma, or Kaposi sarcoma. Malignant ulcers are characteristically irregular in shape with heaped borders, but they also may be flat or depressed. Current high-resolution and magnification endoscopes allow visualization of the altered mucosal structure surrounding an ulcer, including changes in the microvascular pattern. Primary gastric adenocarcinomas often occur in mucosal areas with atrophic and intestinal metaplastic changes. For a definite diagnosis of malignancy, multiple biopsy specimens are needed, usually from the ulcer margins.

Systemic Inflammatory Disorders

A few gastroduodenal ulcers are caused by systemic inflammatory diseases, in particular, Crohn disease (Chapter 127). Patients with Crohn disease affecting

TABLE 125-1 DIFFERENTIAL DIAGNOSIS OF PEPTIC ULCER DISEASE

ORIGIN	CONDITION	FREQUENCY*	DIAGNOSTIC TEST	FINDINGS
Microbes	*Helicobacter pylori*	Very common	*H. pylori* tests	Bacteria, enzymes, antigens, antibodies
			Histology	Gastritis
	Helicobacter heilmannii	Rare	Histology	Spiral bacteria, gastritis
	Treponema pallidum	Very rare	Serology	Antibodies
	Mycobacterial infection	Very rare	Histology, immune response testing, chest radiograph	Acid-fast bacteria, granuloma, immune response, pulmonary infiltrate
	Cytomegalovirus, herpes simplex virus type 1, Epstein-Barr virus	Rare	Histology, serology	Virus inclusions, antibodies
Drug use	NSAIDs, aspirin	Very common	History, urine test	NSAID use
	Bisphosphonates	Rare	History	Bisphosphonate use
	Corticosteroids	Rare	History	Corticosteroid use, comorbidity
	Amphetamines, cocaine	Rare	History, drug testing	Drug use
	Anticoagulants, coagulopathy	Rare	Endoscopy	Ulcer after intramural bleed
	Immune checkpoint inhibitors	Rare	Endoscopy	Ulceration
	Calcium polystyrene sulfonate	Rare	Endoscopy	Ulceration
Malignancy	Gastric cancer	Common	Histology	Malignancy
	Duodenal cancer	Rare	Histology, CT	Malignancy
	Pancreatic cancer	Common	Histology, CT	Malignancy
	Mucosa-associated lymphoid tissue lymphoma	Rare	Histology	Malignancy
	Metastatic cancer	Rare	Histology	Malignancy
	Gastric sarcoma	Very rare	Histology	Malignancy
Gastritis syndromes	Eosinophilic gastritis	Rare	Histology	Eosinophilic infiltration
	Lymphocytic gastritis	Rare	Histology, celiac disease screening	Lymphocytic infiltration, villous atrophy
Hyperacidity syndromes	Zollinger-Ellison syndrome	Rare	Serum gastrin, secretin test	Extreme hypergastrinemia, positive secretin test
	Antral G-cell hyperfunction	Very rare	Serum gastrin, secretin test	Moderate hypergastrinemia, negative secretin test
	Retained gastric antrum	Very rare	Medical history, gastrin	Billroth II resection, hypergastrinemia
	Systemic mastocytosis	Very rare	Histology of affected sites	Mast cell infiltration
	Chronic myelogenous leukemia	Very rare	Leukemia evaluation	Leukemia
Ischemia	Mesenteric vascular occlusion	Common	Angiography	Vascular disease
	Polycythemia vera	Rare	Blood counts	Polycythemia
Specific ulcer types	Cameron ulcer	Common	Endoscopy	Ulcer in large hiatal hernia
	Marginal ulcer	Common	Endoscopy	Ulcer at anastomosis
	Dieulafoy ulcer	Common	Endoscopy	Singular bleeding focus with minimal mucosal disruption
Systemic inflammation	Crohn disease	Common	Histology, ileocolonoscopy	Inflammation, granulomas
	Vasculitides	Rare	Histology, systemic evaluation	Vasculitis, signs of systemic disease
	Gastric amyloidosis	Very rare	Histology	Amyloid deposition
Other conditions	Stress ulcer	Fairly common in patients in intensive care units	Endoscopy	—
	Radiation therapy, chemotherapy	Rare	Endoscopy, history	—

*Frequency as a cause of gastroduodenal ulcer disease.
CT = computed tomography; NSAID = nonsteroidal anti-inflammatory drug.

the proximal gastrointestinal tract often have multiple ulcers characterized by irregular longitudinal shapes. Ulcers in the duodenum occur on top of Kerckring folds. Patients with gastroduodenal ulcers from Crohn disease do not invariably have evidence of disease elsewhere in the digestive tract, nor do blood tests always suggest an active inflammatory bowel disorder. The demonstration of ulcerative inflammation elsewhere in the digestive tract, in particular in the terminal ileum and colon, strongly supports the diagnosis of Crohn disease, as do noncaseating granulomas on biopsy specimens. However, the absence of granulomas does not exclude Crohn disease, and these lesions are not specific for Crohn disease; they also are associated with *H. pylori* gastritis and other conditions, particularly sarcoidosis (Chapter 83). Sarcoidosis can also lead to gastroduodenal ulcer disease.

Other inflammatory disorders that can cause gastritis or gastroduodenal ulcers include various forms of vasculitis affecting the mesenteric system, in particular, Behçet disease (Chapter 249), Henoch-Schönlein purpura (Chapter 249), Takayasu arteritis (Chapters 63 and 249), polyarteritis nodosa (Chapter 249), systemic lupus erythematosus (Chapter 245), Churg-Strauss syndrome (Chapter 249), and granulomatosis with polyangiitis (Chapter 249). Lymphocytic gastroduodenitis, which is strongly associated with celiac disease (Chapter 126), may lead to duodenal ulceration and subsequent stenotic web formation. Ulcer disease also may occur in patients with polycythemia vera (Chapter 152), possibly in relation to reduced mucosal blood flow. Vasculitis underlying ulcer disease should be considered in patients with chronic or recurrent ulceration in whom other causes have been excluded. Lymphocytic phlebitis, which is a rare vasculitic inflammatory disorder that affects the mesenteric veins, may cause gastric ulcers. Systemic amyloidosis (Chapter 174) affecting the stomach wall may lead to gastric ulcers. Rare cases of duodenal ulceration have been described in the presence of annular pancreas or congenital bands obstructing the descending duodenum.

Hypergastrinemic Syndromes

Peptic ulcers can result from chronic gastric hyperacidity related to hypergastrinemia. The most important hypergastrinemic disorder is Zollinger-Ellison syndrome (Chapter 213), a condition of marked hyperacidity leading to severe peptic ulcer disease caused by a gastrin-producing endocrine tumor. These patients usually have multiple bulbar and postbulbar duodenal ulcers that are resistant to conventional acid-suppressive therapy. The diagnosis can be confirmed by the presence of a high fasting serum gastrin level (often, but not always, ≥10-fold increased and >1000 pg/mL). Similar gastrin levels are sometimes seen in patients treated for chronic ulcer disease with high-dose proton pump inhibitors. For clarification, secretin testing can be performed: in patients with Zollinger-Ellison syndrome, the injection of secretin (1 U/kg) increases serum gastrin levels by more than 50%, or 120 pg/mL or greater, in persons with fasting gastrin levels less than 10-fold above normal. Imaging techniques, such as computed tomography (CT), magnetic resonance imaging, isotope scanning, endoscopic ultrasonography, videocapsule endoscopy, and balloon-assisted enteroscopy, may be used to detect the primary tumor, which is often located in either the pancreas or the proximal small bowel. In some patients, Zollinger-Ellison syndrome occurs as part of the multiple endocrine neoplasia syndrome (Chapter 212), particularly in association with hyperparathyroidism. Other hypergastrinemic hyperacidity syndromes are retained gastric antrum syndrome (see later) and antral G-cell hyperfunction. In the latter, fasting serum gastrin levels are only modestly increased and do not rise after the injection of secretin, but they respond in an exaggerated way to meals, thereby leading to hyperacidity. When the condition occurs in an *H. pylori*–positive patient, bacterial eradication therapy may be curative. However, some patients with G-cell hyperfunction are *H. pylori* negative.

Ischemia

Stenosis or occlusion of the celiac trunk or the superior mesenteric artery (Chapter 129) also can lead to ulceration in the mucosa of the proximal digestive tract (Fig. 125-4). These ulcers typically occur in elderly patients who have known severe atherosclerosis or risk factors for it, but they can also occur in younger subjects with mesenteric obstruction due to other causes, as well as in patients with marked chronic heart failure. Ischemic ulcers tend to heal slowly and to recur. Pallor of the mucosa, consistent with decreased mucosal blood flow, may be noted at endoscopy. Upper mesenteric ischemia is often associated with upper abdominal pain, which can be elicited by a meal or by physical activity. These symptoms may cause patients to decrease their food intake, leading to weight loss before their clinical presentation. The prevalence of upper mesenteric ischemia with secondary ulcer disease is unknown, in part owing to its variable presentation, often with a history of gradual symptoms; the lack of standardized and reliable diagnostic tests; and clinicians' unfamiliarity with the condition.[3] Diagnostic evaluation includes a duplex ultrasound scan for vascular flow and conventional or CT angiography of the affected arteries. Gastroduodenal mucosal perfusion can be functionally measured by means of tonometry and by directly measuring mucosal oxygen saturation during endoscopy; however, these tests are not widely available.

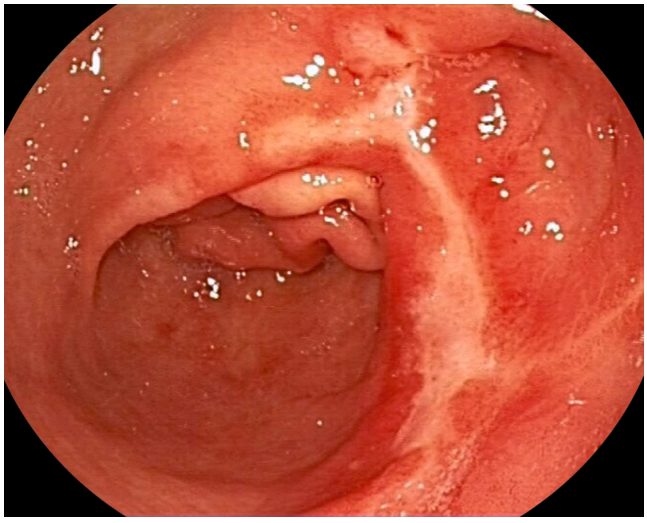

FIGURE 125-4. Endoscopic view of an irregular gastric ulcer at the posterior wall and smaller curvature in a patient with chronic mesenteric ischemia due to subtotal stenosis of the celiac trunk.

Stress Ulcers

Patients with severe medical conditions, such as major trauma, sepsis, extensive burns, head injury, or multiorgan failure, can develop stress ulcers in the stomach or duodenum. Major risk factors for stress ulceration in severely ill patients include mechanical ventilation, coagulopathy, and hypotension, but factors such as hepatic and renal failure and the use of ulcerogenic medications may contribute. Stress ulcers occur independently of *H. pylori* colonization. Ulcers associated with head injury are known as Cushing ulcers, and ulcers associated with extensive burns are known as Curling ulcers. Stress ulcers were once common in patients in intensive care units, but improvements in overall management, including respiratory and hemodynamic care, acid inhibition, and emphasis on adequate feeding, have reduced the incidence of these ulcers, which currently affect 1 to 2% of these patients. Stress ulcers may be asymptomatic, but they can also cause complications, especially bleeding.

Other Factors

Cameron Ulcer

Patients with large hiatal hernias (Chapter 124) may present with proximal gastric ulcers, termed *Cameron ulcers*, at the level of the hiatus, where the stomach is compressed. These ulcers are usually asymptomatic but may cause occult or overt bleeding. During upper gastrointestinal endoscopy, patients with large hiatal hernias and iron deficiency anemia should be carefully examined in normal and retroverted positions for the presence of Cameron ulcers.

Anastomotic or Marginal Ulceration

Patients who have undergone partial gastrectomy sometimes develop recurrent ulcers, often located at the anastomosis or within the jejunum immediately opposite the anastomosis. Ischemia and chronic inflammation, in particular resulting from biliary reflux, may cause such ulcers. If biopsies exclude cancer, treatment includes acid suppression and *H. pylori* eradication, if needed. Anastomotic ulcers after bariatric gastric surgery appear to be related to local ischemia. They have no clear correlation with *H. pylori*, and preoperative *H. pylori* eradication does not appear to reduce the incidence of such ulcers. However, proton pump inhibitor therapy may reduce their incidence. Peptic ulcer disease can also be associated with the retained gastric antrum syndrome when the antrum is not completely excised from the detached duodenum during partial gastrectomy surgery. Because it then lacks exposure to acid and therefore is not physiologically downregulated, it continues to secrete gastrin despite normal or even high acid levels. Marginal ulcers can also occur after bariatric Roux-en-Y gastric bypass surgery.

Other Microbial Organisms

Colonization with *Helicobacter heilmannii* (formerly known as *Gastrospirillum hominis*), which is probably a zoonotic organism, is associated with mild gastritis and sometimes with transient ulcer disease. Ulcer disease also may be infectious, resulting from secondary syphilis (Chapter 295), mycobacterial infection (Chapter 299), infection with herpes simplex virus type 1 (Chapter 371), varicella-zoster virus (Chapter 346), cytomegalovirus infection (Chapter 347), or Epstein-Barr virus (Chapter 348).

Alcohol

Short-term heavy alcohol use or long-term moderate to heavy alcohol use can lead to signs of acute and chronic gastritis. No evidence indicates that this type of gastritis is associated with a significant risk for peptic ulceration, although alcohol use increases the risk for bleeding in patients with peptic ulcer disease.

Hyperhistaminic Syndromes

Similar to the hypergastrinemic syndromes, persistent elevation of histamine can lead to hyperacidity as a result of the chronic stimulation of parietal cells. Elevated histamine levels are observed in two rare syndromes. *Systemic mastocytosis* (Chapter 235) is characterized by a proliferation of mast cells in the bone marrow, skin, liver, spleen, and gastrointestinal tract, often associated with both spontaneous and trigger-induced (e.g., alcohol) release of histamine and other vasoactive substances. Patients with systemic mastocytosis often have gastrointestinal symptoms, including pain, diarrhea, and blood loss. Ulceration results from chronic gastric acid hypersecretion. Clues to the diagnosis include symptoms of pruritus, urticaria, or rash. The bone marrow and affected organ mast cell infiltrates carry a specific *C-kit* mutation and express CD2 and CD25. Histamine hypersecretion leading to peptic ulcer disease also can occur in *chronic myelogenous leukemia* (Chapter 170) with basophilia.

Other Drugs

Oral bisphosphonates, used widely for osteoporosis (Chapter 225), may induce gastric erosions and ulcerations in an estimated 3 to 10% of treated patients. The risk for ulcer disease may be synergistically increased by NSAID use but is probably independent of *H. pylori* colonization. Although corticosteroid treatment can be complicated by peptic ulcer disease, the relative risk is only slightly increased, except in patients with serious comorbid diseases, patients using long-term or high-dose therapy, or patients with prior ulcers. Other patients who use corticosteroids are not at serious risk for ulcer disease and therefore do not require measures to prevent ulcers. Similarly, the use of aldosterone antagonists is also associated with an increased risk for peptic ulcer and ulcer bleeding, likely related to impaired mucosal healing.

Persons who use amphetamines and crack cocaine (Chapter 365) frequently develop ulcer disease, often with perforation, possibly as a result of vascular insufficiency. Chemotherapy, particularly when given selectively as a high-dose intra-arterial infusion in the celiac system, can be complicated by ulcer disease. Patients on anticoagulant therapy and those with other coagulopathies may rarely develop intramural hematoma of the gastrointestinal tract. Depending on the location, these hematomas may cause obstruction, but they can also leave large ulcers when they rupture into the lumen. Radiation therapy of the upper abdomen is sometimes complicated by chronic ischemic ulceration, especially as a late complication.

CLINICAL MANIFESTATIONS

The clinical manifestations of acid peptic disease (Table 125-2) do not always predict the various morphologic presentations found at endoscopy. Indeed, a silent ulcer may be recognized only when it presents abruptly with a complication, most commonly hemorrhage or perforation, or it may be discovered incidentally when a diagnostic test is performed for other reasons. Nevertheless, the typical presentation of acid peptic disease is recurrent episodes of pain. The pain is almost invariably located in the epigastrium and may radiate to the back or, less commonly, to the thorax or other regions of the abdomen (see Table 125-2). Some patients describe the pain as burning or piercing, whereas others describe it as an uncomfortable feeling of emptiness of the stomach, referred to as *painful hunger*. Indeed, the pain may improve with the ingestion of food, only to return in the postprandial period. The timing of the pain in relation to meals and to the soothing effects of food is nonspecific, however, and may also occur in patients with functional dyspepsia without ulcer. Nocturnal epigastric pain that awakens a patient several hours after a late meal is more likely to represent ulcer pain.

TABLE 125-2 KEY SYMPTOMS AND SIGNS OF PEPTIC ULCER

UNCOMPLICATED ULCER
No symptoms ("silent ulcer" in up to 40% of cases)
Epigastric pain
Pain may radiate to the back, thorax, other parts of the abdomen (cephalad most likely, caudad least likely)
Pain may be nocturnal (most specific), "painful hunger" relieved by food, or continuous (least specific)
Nausea
Vomiting
Heartburn (mimics or associated with gastroesophageal reflux)
COMPLICATED ULCER
Severe abdominal pain
Shock
Abdominal boardlike rigidity (and rebound and other signs of peritoneal irritation)
Free intraperitoneal air
Hemorrhage
Hematemesis and/or melena
Hemodynamic changes, anemia
Previous history of ulcer symptoms (80%)
Gastric outlet obstruction
Satiation, inability to ingest food, eructation
Nausea, vomiting (and related disturbances)
Weight loss

Aside from the pain during symptomatic episodes, patients may complain of retrosternal burning (heartburn) or acidic regurgitation into the throat, symptoms that reflect associated gastroesophageal reflux (Chapter 124), which is aggravated by hyperacidity or delayed gastric emptying. Nausea and vomiting may also occur but are nonspecific. The presence of significant diarrhea should raise the possibility of Zollinger-Ellison syndrome (Chapter 213), but diarrhea also may result from the intensive use of magnesium-containing antacids. In untreated patients, symptoms tend to be intermittent, with flares of daily pain lasting 2 to 8 weeks, separated by prolonged asymptomatic intervals. During periods of remission, patients may feel well and may be able to eat even heavy or spicy meals without apparent discomfort.

Physical Examination

The physical examination is usually unrevealing. If significant bleeding has occurred (Chapter 121), the patient may present with pallor and may be hypovolemic (Chapter 92). It is always useful to inquire about the characteristics of the stool because ulcer-related bleeding may manifest not only obviously in the form of hematemesis but also insidiously as melena (black feces). In the case of massive ulcer bleeding with the rapid bowel passage of blood, patients may also present with red rectal blood loss. When a patient has acute perforation, severe epigastric and abdominal pain usually develops, and the patient appears distressed. Characteristically, intense contracture of the abdominal muscles is apparent on palpation, together with rebound tenderness and other signs of peritoneal irritation. With large amounts of intra-abdominal air, percussion may reveal hypertympany over the liver.

DIAGNOSIS

In a patient who presents with symptoms consistent with ulcer disease, the diagnostic evaluation should proceed along two different but complementary paths: confirmation of the anatomic abnormality and investigation of its cause (Table 125-3). In most patients, it is advisable to follow both diagnostic paths simultaneously, but sometimes it is reasonable to skip the anatomic verification as a cost-saving strategy and proceed to management based on probable cause.

Anatomic Diagnosis

Upper gastrointestinal endoscopy (Chapter 120) is the primary investigative tool in patients suspected of having acid peptic disease. This technique can detect erosive gastritis (see Fig. 125-1) or an ulcer in the gastric wall or duodenal bulb (see Fig. 125-2). Because of the high prevalence and the spontaneous improvement of dyspeptic symptoms, endoscopy generally should not be performed immediately; rather, its use should be restricted to patients with persistent or recurrent symptoms. However, immediate endoscopy is indicated in patients with alarm symptoms such as weight loss, dysphagia, anorexia, considerable vomiting, anemia, or signs of occult or overt bleeding.

TABLE 125-3 DIAGNOSTIC PATHS AND TOOLS IN ULCER DISEASE

PATH 1: MORPHOLOGIC DIAGNOSIS
Gastroduodenoscopy Barium contrast (inferior alternative) Endoscopic ultrasound (selected cases only) Computed tomography (useful in selected cases)
PATH 2: ETIOLOGIC DIAGNOSIS
***Helicobacter pylori* Testing**
Histologic examination of gastric mucosa with appropriate stains Serum antibodies Stool antigen test Carbon-13 urea breath test
Ulcer Associated with Nonsteroidal Anti-inflammatory Drug Use
History of drug ingestion Decreased platelet aggregation Molecular identification of drugs, pro-drugs, metabolites (complex, expensive)
Acid Hypersecretory Syndromes
Serum gastrin elevation Gastrin provocative tests (intravenous secretin, meal) Gastric analysis (acid titration)

Endoscopy, which is the gold standard for diagnosis, is both highly sensitive and highly specific for the detection of ulcer disease. The most common locations for a peptic ulcer are the stomach and duodenal bulb, but peptic ulcers sometimes occur in the esophagus, the small bowel, and a Meckel diverticulum lined with heterotopic gastric mucosa. Endoscopic ultrasound may detect an unsuspected submucosal component or enlarged lymph nodes, such as may occur in gastric neoplasia, especially lymphoma and linitis plastica (Chapter 178). Ulcers in the dorsal wall of the duodenal bulb, especially at the transition from the bulb to the postbulbar descending portion of the duodenum, are most difficult to visualize. They sometimes require a side-viewing endoscope, particularly when endoscopic treatment is needed. Other regions where gastroduodenal ulcers can be easily missed are the cardia and the gastric angulus. Dieulafoy lesions may be difficult to diagnose because of their small mucosal defects and intermittent bleeding. Some patients require more than one endoscopy, preferably during acute bleeding, to localize the lesion. Endoscopy is also useful for ascertaining the presence of concomitant disorders, including esophagitis and duodenitis, or complications, such as bleeding or a visible vessel (see Fig. 125-2); obtaining biopsy specimens for histologic examination and to assess for *H. pylori* (see Fig. 125-3); and performing therapeutic interventions.

In rare cases, such as stenosis that blocks the advancing endoscope, conventional barium contrast radiographs (Chapter 119) are indicated. Additional investigations by endosonography or CT are needed when underlying malignant disease is suspected. The endoscopist should obtain biopsy samples from all gastric ulcers, especially those with a suspicious appearance, to exclude potential malignant disease. Because duodenal ulcers are less likely to be malignant, biopsies are usually not required unless malignancy is specifically suspected.

Etiologic Diagnosis

Diagnosis must focus on establishing the cause of the ulcer. The first step is to determine whether *H. pylori* or NSAID use is present because these are the major risk factors for peptic ulcers and can be contributing factors in ulcers with other precipitating causes.

Testing for *Helicobacter pylori*

In populations with high *H. pylori* prevalence, nearly all patients with peptic ulcer disease are positive for *H. pylori*, so diagnostic testing has little value except when antimicrobial susceptibility testing is needed. The prevalence of *H. pylori* remains high in immigrants from developing countries, where most people become *H. pylori* positive in youth. In Western countries, approximately 50% of individuals who are older than 65 years are colonized with *H. pylori*, but the prevalence is less than 20% in those younger than 30 years. In these younger persons, the proportion of patients with ulcers who are *H. pylori* negative is higher than in older patients, making diagnostic testing for *H. pylori*, followed by targeted therapy in those who are positive for the bacterium, more attractive than empirical therapy.

The presence of *H. pylori* can be ascertained by four possible approaches: gastric biopsies, serum, stool, or breath test.[4] The first method, *gastric mucosal biopsies*, is the standard procedure when diagnostic endoscopy is initially performed. Routine hematoxylin and eosin staining is sensitive and specific for *H. pylori*. However, the accuracy of this technique may be affected by sampling error, improper orientation of the specimen, and recent therapy with proton pump inhibitors or antibiotics. The presence of *H. pylori* in gastric mucosal biopsies also can be assessed by rapid urease testing, which has a high positive predictive value, although false-negative tests occur in patients using proton pump inhibitors or antibiotics and in patients with marked atrophic gastritis and intestinal metaplasia. Finally, biopsies can be cultured for *H. pylori* when it is important to assess antimicrobial resistance in patients with recurrent disease after previous antibiotic treatment.

A second option is *serology*, which is simple, inexpensive, and accurate, although its predictive value is lower in areas where the prevalence of *H. pylori* is low. Serology is not helpful to verify whether *H. pylori* has been eradicated with antibiotics because it may take more than 6 months or even 1 to 2 years for *H. pylori* antibodies to decrease to undetectable levels.

A third option is a *stool H. pylori antigen test*, which is similar in accuracy to standardized serologic testing. Finally, the *carbon-13* or *carbon-14 urea breath test*, which relies on the detection of *H. pylori* urease activity, is a noninvasive and relatively simple test, but it is more expensive than stool or blood testing. Although the test usually becomes negative as soon as *H. pylori* treatment is begun, a minimum interval of 6 to 8 weeks after therapy has ended is recommended to reduce false-negative results.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are usually established as the putative cause of an ulcer based on information obtained from the patient. Assessment of NSAID use in an individual patient presenting with ulcer disease can be difficult both because NSAID use is common and often intermittent and because many different NSAIDs are widely available over the counter in most countries. NSAID use is usually evaluated by detailed medical history, focusing not only on current and recent drug use, and especially over-the-counter treatments, but also on symptoms of pain, including musculoskeletal complaints. Further information from family members, family practitioners, and pharmacists is sometimes helpful. If surreptitious use of NSAIDs is suspected, direct serum and urine testing for aspirin and NSAID derivatives is feasible, or aspirin use can be assessed indirectly by a platelet adherence assay; however, these tests are not commonly used in clinical practice.

Hypersecretory Syndromes

Hypersecretory syndromes not related to *H. pylori* or NSAIDs are rare causes of ulcer disease and are diagnosed by special tests (see Table 125-3). Zollinger-Ellison syndrome should be strongly considered in patients with multiple ulcers, particularly in atypical locations such as distal to the duodenal bulb, and when diarrhea is present because these findings are uncommon in *H. pylori*–related peptic ulcer disease. Hypergastrinemic syndromes (e.g., Zollinger-Ellison syndrome, antral G-cell hyperplasia) are best diagnosed by a determination of serum gastrin levels, both basal and after stimulation with intravenous secretin (gastrinoma detection) or a test meal (antral G-cell hyperplasia detection). When detected early, gastrinomas may be resectable (Chapter 213).

Gastric analysis, by quantified aspiration of gastric juice through a nasogastric tube (both basal and after stimulation with subcutaneous pentagastrin), is indicated in only two rare circumstances: patients with elevated serum gastrin levels suggestive of Zollinger-Ellison syndrome or antral G-cell hyperplasia but with equivocal responses to standard gastric provocative tests, and patients with indirect signs of gastric hypersecretion (e.g., enlarged folds and abundant clear fluid at endoscopy), normal gastrin levels, and negative provocative gastrin tests but who may still be hypersecretors, such as patients with recurrent ulcer disease despite a prior vagotomy with or without antrectomy. A basal acid output greater than 15 mEq/hour or greater than 5 mEq/hour in a postoperative patient is considered a positive test result.

The diagnosis of Zollinger-Ellison syndrome is best confirmed by gastric analysis showing a basal acid output greater than 15 mEq/hour in conjunction with a fasting serum gastrin level exceeding 1000 pg/mL in the presence of gastric pH less than 2. To bypass the cumbersome gastric analysis, a gastric pH determination showing a fasting pH of 2 or less is adequate. For serum gastrin levels in the range of 100 to 1000 pg/mL and intragastric pH>2, an increase in the serum gastrin to more than 200 pg/mL after a secretin stimulation test is suggestive of the diagnosis. An elevated serum gastrin level alone is not sufficient to diagnose Zollinger-Ellison syndrome because serum gastrin levels

tend to increase over time with atrophic gastritis and also can be markedly increased in patients receiving proton pump inhibitor therapy.

Other Causes

In patients in whom a gastroduodenal ulcer cannot be ascribed to colonization with *H. pylori*, use of NSAIDs, or a hypersecretory syndrome, the establishment of a definite etiologic diagnosis may require a more thorough evaluation, starting with a medical history that focuses on the use of other ulcerogenic agents and the presence of symptoms that could suggest an underlying systemic disease. The next step is to evaluate biopsy samples from ulcer borders and from the antrum, corpus, and duodenum. The ulcer specimens may reveal overt or suspicious signs of malignancy, in particular adenocarcinoma (Chapter 178) or lymphoma. In these cases, further diagnostic evaluation should include staging of the malignancy. Alternatively, the biopsies may provide evidence of other infectious conditions, specific types of gastritis, celiac disease, ischemia, amyloidosis, or a systemic inflammatory condition. These data can be combined with clues provided by the endoscopic evaluation, including the character and location of the ulcer, signs of ischemia, and signs of inflammation at other locations. Further evaluation should focus on the presence of systemic disorders and may include a chest radiograph, angiography, colonoscopy, and abdominal CT.

Differential Diagnosis

The differential diagnosis of ulcer-like symptoms includes many disorders of the upper abdominal organs, including malignant diseases of the stomach (Chapter 178), duodenum (Chapter 179), pancreas (Chapter 180), or bile ducts (Chapter 181). The differential diagnosis of upper abdominal symptoms also includes liver and gallstone disease (Chapter 141), pancreatitis (Chapter 130), and motility disorders (Chapter 122). In many patients with upper abdominal dyspeptic complaints, no underlying cause can be identified. In this "nonulcer" or functional dyspepsia group, complaints characteristic of gastroesophageal reflux, ulcer symptoms, or dysmotility symptoms may be prominent. Some patients (generally 5%) benefit from eradication of *H. pylori*, with a slow decrease of dyspeptic complaints over 12 to 24 months, but functional dyspepsia is not a proven or widely accepted indication for treatment of *H. pylori*. If such treatment is considered, both the patient and the physician should be prepared for persistent symptoms despite eradication of *H. pylori* and potentially for the emergence of antimicrobial-resistant *H. pylori*, which may result in a spiral of multiple courses of therapy in an attempt to remove resistant organisms.

Diagnostic Scenarios: Acute or Initial Clinical Presentation

Younger (≤45 years old) patients without alarm symptoms or signs such as anemia, rapid weight loss, or other evidence of serious disease do not necessarily require endoscopy, and malignant gastric disease is unlikely. When a physician is treating a patient who lives in an area of the world with a relatively high prevalence of *H. pylori* infection (>10% of the population is positive), a test-and-treat approach can begin with an *H. pylori* stool antigen determination, urea breath test, or *H. pylori* serologic examination. However, although commonly practiced, the test-and-treat approach has never been documented to improve outcomes, except in the setting of endoscopically confirmed peptic ulcer disease. If the *H. pylori* test is positive, the patient can be treated with the appropriate *H. pylori* eradication drugs (see later) and observed for 4 to 6 weeks. If a patient with dyspeptic symptoms is taking an NSAID, either orally or parenterally, the first therapeutic approach is to discontinue these drugs and to prescribe a proton pump inhibitor for 4 to 6 weeks. In patients who test negative for *H. pylori* and who are not taking NSAIDs or who do not improve after these drugs are discontinued, endoscopy is indicated to determine whether an ulcer is present.

Conversely, gastroenterologists more commonly proceed directly to endoscopy. If no abnormalities are apparent or the endoscopic study shows only "gastritis" without an overt ulcer, a biopsy should be obtained to ascertain by histologic examination or urease testing whether *H. pylori* is present. If *H. pylori* is present, then eradication treatment may be pursued. However, the efficacy of *H. pylori* eradication for the relief of functional dyspeptic symptoms is only about 6 to 12% greater than with placebo,[A1] and eradication therapy increases the risk for reflux-related symptoms (Chapter 124), especially in Asian patients.

If endoscopic examination reveals an ulcer, its location determines the subsequent approach. An ulcer in the duodenal bulb has only a remote chance of representing a malignant lesion and need not routinely be examined by biopsy. By contrast, biopsy is mandatory for a gastric ulcerative lesion identified at endoscopy because malignant gastric disease may present with similar clinical manifestations and may resemble benign ulcer disease morphologically. Even if histologic assessment does not identify a malignant process, repeat endoscopy is recommended about 1 month after therapy to verify complete healing and for biopsy of the scar.

TREATMENT

Helicobacter pylori–Associated Ulcers

H. pylori–associated ulcers often heal spontaneously, but acid-suppressive therapy accelerates healing and ameliorates symptoms. Four weeks of acid-suppressive therapy heals 70 to 80% of ulcers, and this number increases to more than 90% after 8 weeks of therapy. If *H. pylori* colonization persists, however, ulcers recur in 50 to 90% of patients within 12 to 24 months; this rate can be reduced to 20 to 30% with maintenance acid suppression and to less than 5% with *H. pylori* eradication.[A2] Eradication treatment is therefore mandatory (Table 125-4).[5,6] The success of eradication treatment strongly depends on therapy adherence and antimicrobial resistance.[7,8] Resistance of *H. pylori* to metronidazole varies between 20 and 80% throughout the world. Clarithromycin resistance is increasing and ranges between 10 and 50% in many regions owing to the widespread use of macrolides to treat upper respiratory infections. Resistance to amoxicillin and tetracycline is rare and is not usually relevant in clinical practice. Levofloxacin resistance was very rare a decade ago, but it now ranges between 10 and 50% in many regions of the world. Because of this worldwide increase in prevalence of antimicrobial resistance, *H. pylori* eradication regimens continue to evolve.

The conventional regimen is empiric "triple" therapy for 14 days.[9,10] This treatment remains a standard regimen for regions and populations with a clarithromycin resistance below 15%, such as in Northern Europe and North America. Triple therapy combines a proton pump inhibitor or potassium-competitive acid blocker (vonoprazan 20 mg twice daily)[A3] with two antibiotics, usually combinations of amoxicillin, a nitroimidazole, and clarithromycin, with the latter sometimes being replaced by levofloxacin.[A4] Double-dose proton pump inhibitor therapy (dose equivalent to omeprazole 40 mg twice daily) also increases eradication rates by approximately 10% and is preferred. For patients in whom such therapy fails, a 14-day course of quadruple therapy (see later) eradicates *H. pylori* in an additional 80% of patients (Fig. 125-5). Adding probiotic capsules to standard triple therapy appears to hasten the resolution of symptoms and increase the eradication of *H. pylori*.[A5]

Because of the increased prevalence of antimicrobial resistance, initial empiric "quadruple" therapies[A6] or susceptibility-guided antibiotic treatment[A7] are increasingly being recommended over initial empiric "triple therapy" because of their better first-line efficacy. Bismuth-based quadruple therapy consists of a proton pump inhibitor, a bismuth compound, and two antibiotics, usually tetracycline and a nitroimidazole (see Table 125-4). This regimen leads to eradication in about 85 to 90% of patients. Non–bismuth-based quadruple therapies consist of a proton pump inhibitor plus three antibiotics, usually given for 14 days (see Table 125-4). The three forms of non–bismuth-based quadruple therapy (sequential, hybrid, and concomitant therapy) differ in their antibiotic dosing schedule. Sequential therapy consists of a proton pump inhibitor with amoxicillin, usually given for 5 days, followed by a proton pump inhibitor with clarithromycin and a nitroimidazole for another 5 days. Ten-day sequential therapy is equally effective as 14-day triple therapy.[A8] Hybrid therapy starts with the same 5-day combination of a proton pump inhibitor with amoxicillin and then continues the amoxicillin for the next 5 days together with clarithromycin and metronidazole. Concomitant therapy, which gives these same drugs all together for 14 days, is the most effective, in particular when given for 14 days with a proton pump inhibitor in a dose of 40 mg twice daily.

Continuation of acid-suppressive therapy after antibiotic treatment is needed only when symptoms persist or in cases of complicated ulcer disease until eradication of *H. pylori* has been confirmed. Ascertainment of therapeutic efficacy must be delayed at least 1 month after the end of treatment to prevent false-negative results related to the organism's temporary suppression but not eradication. When repeat endoscopy is needed (e.g., a gastric ulcer requires repeated histologic examination to exclude underlying malignancy), repeat screening for *H. pylori* can be performed using gastric biopsy specimens for histologic examination, culture, or urease testing. If no clinical indication exists for repeat endoscopy, *H. pylori* status can be determined by a carbon-13 urea breath test, stool *H. pylori* antigen, or repeated serology. Serologic determination is based on a more than 40 to 50% decrease in immunoglobulin G antibody levels in the first 6 months after treatment compared with pretreatment levels in that patient; ideally, the (frozen) pretreatment and post-treatment specimens should be examined simultaneously by the same laboratory using the same assay.

After successful *H. pylori* eradication, the risk for recurrent infection in most populations is less than 1% per year. In a minority of patients, ulcers recur either owing to reinfection or in the presence of another ulcerogenic factor, particularly NSAID use. Quinolone-based quadruple therapy (including bismuth) for 10 or more days is an excellent second-line therapy for patients who do not respond to initial therapy.[11]

Disease Related to Nonsteroidal Anti-inflammatory Drug Use

In patients who are diagnosed with acid peptic disease while they are taking NSAIDs or aspirin, the first step is to stop such therapy. Acid suppression with a proton pump inhibitor (in doses similar to those used for *H. pylori*) leads

to healing of 85% of NSAID-induced gastric ulcers and more than 90% of duodenal ulcers within 8 weeks of therapy, whereas acid suppression with a histamine-2 (H_2)-receptor blocker, equivalent to ranitidine 300 mg twice daily (see Table 125-1), heals approximately 70% of ulcers within 8 weeks. The mucosal-protective drug misoprostol (200 mg four times daily) has a similar effect to the H_2 blockers. Treatment must be continued for at least 8 weeks, and maintenance therapy is needed in patients who continue to take NSAIDs. Gastric ulcers, larger lesions, and recurrent lesions heal more slowly.

Ulcer occurrence during NSAID therapy suggests a causal relationship, but patients should also be tested for *H. pylori*. In patients who are *H. pylori* positive, eradication therapy should be considered because there are no clear clinical parameters distinguishing between these etiologic factors.

Idiopathic Ulcer Disease

Patients with idiopathic ulcer disease despite a thorough assessment for underlying causes are treated primarily with an acid suppressant, usually a proton pump inhibitor, because they are at considerable risk for recurrent ulcer disease. After the underlying cause is identified and adequately treated, acid-suppressive therapy can be withdrawn if there are no additional risk factors for ulcer disease, such as NSAID therapy or *H. pylori* infection. If the cause of the idiopathic ulceration is not clarified and there is doubt about the adequacy of the diagnostic testing for *H. pylori*, empirical eradication therapy can be considered, especially when there is histologic evidence of chronic active gastritis without further explanation. If related to unidentified *H. pylori*, gastritis should slowly disappear after successful eradication therapy.

PREVENTION

Primary Prevention

A test-and-treat strategy for *H. pylori* colonization is sometimes considered for patients with dyspeptic symptoms, but there is no specific way to prevent *H. pylori*–associated ulcer disease. By contrast, primary prevention of NSAID-associated ulcer disease is widely advocated for patients at high risk because of a prior ulcer, severe concomitant disease, or use of warfarin or high-dose corticosteroids as well as for critically ill patients in intensive care units. H_2 blockers (at a dose equivalent to ranitidine 300 mg twice daily; Table 124-1) partially prevent duodenal ulcer disease during NSAID therapy but have no effect on preventing gastric ulcers unless a higher dose (equivalent to famotidine 40 mg twice daily) is given. Proton pump inhibitors[A9] (at a dose equivalent to omeprazole 20 mg once daily; Table 124-1) and misoprostol (in doses varying between 400 and 800 mg/day) partially protect against both gastric and duodenal ulcers during NSAID use. Misoprostol and proton pump inhibitors are equally effective, but adherence with therapy is lower with misoprostol owing to its side effects. Patients should be advised of the importance of adherence because less than 80% adherence to gastroprotection is associated with a more than two-fold increased risk for ulcer disease compared with those who are fully adherent. During low-dose aspirin therapy, primary prevention of ulcers is advocated for the same risk groups, using a proton pump inhibitor or an H_2-receptor antagonist.[A10] *H. pylori* eradication also can reduce aspirin-associated peptic ulcer bleeding.[A11] For the prevention of stress ulcers in patients in intensive care units,[12] proton pump inhibitors and histamine-2 receptor blockers are approximately equally effective, but some data suggest that proton pump inhibitors may be preferred.[A12]

Secondary Prevention

Secondary prevention of *H. pylori*–associated ulcer disease is mandatory and consists of successful bacterial eradication. Testing to ascertain *H. pylori* status after eradication therapy is indicated in patients with prior complicated ulcer disease or with persistent or recurrent symptoms after therapy, as well as in patients who fail to complete the therapeutic course.

Secondary prevention of NSAID-related ulcer disease is preferentially achieved by the withdrawal of NSAIDs. In patients who must continue taking NSAIDs, a change to a selective COX2 inhibitor[A13] in combination with a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily is advocated, especially for patients with complicated ulcer disease. This combination is associated with a lower risk for secondary peptic ulcer complications than treatment with a COX2 inhibitor alone.

Secondary prevention of recurrent ulcers in patients who use aspirin may depend on *H. pylori* status. In *H. pylori*–positive patients, *H. pylori* eradication is as effective as a proton pump inhibitor for the prevention of recurrent ulcers. *H. pylori*–negative patients require additional acid-suppressive therapy at a dose equivalent to esomeprazole 20 mg twice daily.[A14] Secondary prevention of idiopathic ulcer disease consists primarily of maintenance therapy with a proton pump inhibitor and treatment of the underlying condition. When there is doubt about the accuracy of the diagnostic assessment for *H. pylori*, an empirical course of eradication treatment can be considered.

Complications

Hemorrhage

Hemorrhage (Chapter 121), which is the most common complication of peptic ulcer disease, occurs in about one in six patients with ulcers over the course of their ulcer activity. Ulcers caused by NSAIDs account for a larger proportion of these hemorrhages. Peptic ulcer is thus the most common cause of nonvariceal upper gastrointestinal bleeding, accounting for 40 to 60% of cases in most populations. Bleeding is associated with a 5 to 15% risk for rebleeding and up to a 10% risk for mortality. Hemorrhage may occur along a continuum from a serious acute event associated with hemodynamic shock and high mortality to slow or intermittent blood loss leading to chronic anemia. Approximately 80% of patients with bleeding ulcers describe a prior history of symptomatic disease, and about 20 to 30% have suffered a previous hemorrhage. Assessment of the magnitude of bleeding is of paramount importance in determining the need for transfusion and subsequent management (Table 125-5). Initial hematocrit levels may be misleading and are likely to

*The Blatchford (Stanley AJ, Ashley D, Dalton HR, et al. Outpatient management of patients with low-risk upper-gastrointestinal haemorrhage: multicentre validation and prospective evaluation. *Lancet*. 2009;373:42-47) and AIMS65 (Saltzman JR, Tabak YP, Hyett BH, et al. A simple risk score accurately predicts in-hospital mortality, length of stay, and cost in acute upper GI bleeding. *Gastrointest Endosc*. 2011;74:1215-1224) systems are pre-endoscopy scoring systems; the Rockall system (Rockall TA, Logan RF, Devlin HB, et al. Risk assessment after acute upper gastrointestinal haemorrhage. *Gut*. 1996;38:316-321) has a pre- and post-endoscopy component. The Blatchford system is a tool to select patients for early discharge and later endoscopy during office hours. The Rockall score can help to assess the risk for rebleeding and mortality. The AIMS65 predicts mortality.

†Scores before and after endoscopy. Low risk defined as scores of ≤2, high risk defined as scores ≥6.

fall because of hemodilution. Rapid bleeding is usually apparent on the basis of clinical signs (pallor, systolic blood pressure ≤100 mm Hg, pulse ≥100 beats/minute); immediate fluid resuscitation is indicated to prevent circulatory collapse. Transfusion is needed in patients with marked anemia. Restrictive transfusion using a hemoglobin threshold of 70 to 80 g/L is associated with fewer transfusions and lower risks for rebleeding and mortality.[A15] Mortality is particularly related to complications of the bleed, such as aspiration, and exacerbation of underlying disease, such as pulmonary, cardiovascular, renal, and hepatic disease. On rare occasions, patients may actually bleed to death, especially when a larger artery is affected, such as when an ulcer in the posterior wall of the duodenal bulb perforates the gastroduodenal artery. The stopping of such bleeding is therefore a medical emergency.[13]

Initial treatment aims at hemodynamic stabilization. Endoscopy is the mainstay of therapy and should be performed emergently or within 24 hours of presentation in high-risk cases, especially patients who are hemodynamically unstable, require transfusion, or have more severe comorbidities.[14] Endoscopy can be performed to ascertain the origin of the bleeding and, if necessary, provide therapy to stop the bleed and reduce the risk for rebleeding.

The appearance of the ulcer determines the need for endoscopic treatment and the risk for rebleeding (Table 125-6) and mortality. "Clean base" ulcers and those with flat and pigmented spots carry a low risk for rebleeding and do not require endoscopic treatment. In contrast, ulcers with active bleeding or stigmata of recent bleeding, in particular a visible vessel or adherent clot, require treatment to stop the bleed and reduce the otherwise high risk for recurrence.

Endoscopic therapy may lead to a three-fold reduction in episodes of recurrent bleeding and in the need for surgical intervention, as well as a 40% reduction in mortality. Treatment modalities include injection therapy with epinephrine or a sclerosant, thermocoagulation, and mechanical pressure by means of clips. Thermocoagulation can be performed by direct contact, such as with a heater probe, or by a noncontact method, such as argon plasma coagulation. The efficacy of these methods is generally comparable, except that epinephrine injection alone is inferior to the other modalities but can be useful when combined with any of the others. If an adherent clot is found, an attempt should be made to remove it by water flushing or snaring to allow an assessment of the underlying ulcer base and the treatment of any underlying visible vessels to reduce the risk for rebleeding.

Pre-endoscopy administration of intravenous proton pump inhibitor therapy (at a dose equivalent to a bolus of 80 mg esomeprazole, followed by a continuous infusion of 8 mg/hour until endoscopy) reduces bleeding and the need for emergent endoscopic treatment, but it has no effect on the need for transfusion or the occurrence of rebleeding or death. For patients with active bleeding or stigmata of recent bleeding, endoscopic treatment should be followed by an intravenous proton pump inhibitor given as a bolus at a dose equivalent to 80 mg esomeprazole over 30 minutes, followed by a continuous infusion at a dose equivalent to esomeprazole 8 mg/hour for 72 hours to reduce rebleeding and the need for further intervention. Intermittent oral or intravenous therapy at 6- to 12-hour intervals in a cumulative daily dose equivalent to 80 to 160 mg esomeprazole may be equally effective, although more evidence is needed in patients from Western countries. Other therapies, including tranexamic acid, vasopressin, somatostatin, and octreotide, should be considered experimental (Chapter 121). Second-look endoscopy is not routinely indicated but can be considered in very high-risk cases, particularly when there is doubt about the adequacy of initial visualization or treatment.

About 70 to 80% of rebleeds occur within the first 3 days and generally should be managed by repeat endoscopy. If endoscopy fails to stop the bleed or prevent further rebleeding, surgery and interventional radiology are equivalent options. Surgery includes stitching of the ulcer and occlusion of the feeding artery, usually the gastroduodenal artery. Interventional radiology uses angiography to insert coils in the culprit vessel at the site of the bleed. Single-center observational experience suggests that each of these methods is equally effective in the hands of experienced clinicians, and the choice depends on local availability and expertise.

The risk for a fatal outcome of an upper gastrointestinal hemorrhage can be estimated based on five clinical and endoscopic parameters (see Table 125-5). In several studies, mortality in patients with a bleeding peptic ulcer was less than 2% among those with a score of 2 points or less, 10% in those with 3 to 5 points, and up to 46% in those with 6 points or more. Management of patients who recover after a peptic ulcer hemorrhage is similar to the treatment of patients with uncomplicated ulcers. Eradication of *H. pylori* provides excellent protection against both recurrence and rebleeding of *H. pylori*–related ulcers. NSAID-induced ulcers are preferentially managed by the withdrawal of NSAIDs or, if this is not feasible, by the combination of a COX2 inhibitor and a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily. In patients with a history of ulcer bleeding and concomitant cardiovascular disease requiring antiplatelet therapy, the combination of low-dose aspirin and a proton pump inhibitor at a dose equivalent to esomeprazole 20 mg twice daily is associated with a lower risk for complicated ulcer than is clopidogrel monotherapy. If a patient who requires antiplatelet therapy presents with a bleeding ulcer, antiplatelet therapy should be continued or restarted as soon as possible if the risk for a cardiovascular event outweighs the risk for recurrent bleeding.

Perforation

Perforation may manifest as an acute event, whereby gastric contents spill into the peritoneal cavity, or more insidiously as the ulcer slowly penetrates into surrounding tissues. Acute free perforation typically causes abrupt and severe abdominal pain associated with abdominal muscular spasm that produces boardlike rigidity of the abdomen and other manifestations of peritoneal irritation. Secondary hemodynamic shock is common. The clinical diagnosis can be confirmed in approximately 80% of patients by a plain chest radiograph with the patient standing (Fig. 125-6); a CT scan can be obtained if doubt persists. Leukocytosis and elevated C-reactive protein levels develop rapidly, and mild hyperamylasemia may occur. Treatment begins by correcting hemodynamic, fluid, and electrolyte imbalances. Nasogastric suction is helpful, and prophylactic antibiotics (e.g., amoxicillin-clavulanic acid 1 g every 8 hours intravenously) are usually administered. Unless a specific contraindication exists, emergency surgery is usually indicated,[15] although more conservative approaches are sometimes appropriate. Given the success in achieving the long-term cure of ulcer disease through the eradication of *H. pylori* and the

TABLE 125-6 ENDOSCOPY RESULTS IN PATIENTS WITH BLEEDING ULCERS

ENDOSCOPY RESULT	ULCER CHARACTERISTICS*	RISK FOR RECURRENT BLEEDING (%)

withdrawal of NSAIDs, suturing of the perforated ulcer may be adequate, permitting the patient to avoid a more radical vagotomy with or without gastric resection.

Intractability

Intractability is a term strictly applied to an ulcer that persists even after intensive and prolonged proton pump inhibitor therapy. Symptoms may or may not be present. These rare cases may result from poor compliance with recommended treatment, surreptitious use of ulcerogenic drugs, or other diseases (e.g., Crohn disease, ischemia, infection with bacteria other than *H. pylori*, viral infection). If these issues are recognized and these diagnoses are pursued, further complications and interventions such as surgical vagotomy and pyloroplasty can almost always be avoided.

Acid peptic disease related to alcohol or bisphosphonates should be addressed by discontinuing the precipitating agent. Treatment of Zollinger-Ellison syndrome requires high-dose proton pump inhibitors and/or surgery (Chapter 213). Rare ulcers caused by Crohn disease (Chapter 127), vasculitis (Chapter 249), sarcoidosis (Chapter 83), polycythemia vera (Chapter 152), amyloidosis (Chapter 174), and other rare disorders should be addressed by treating the underlying condition. Stress ulcers and Cameron ulcers are treated by potent acid-suppressive therapy (e.g., omeprazole 20 mg twice daily).

Stenosis

Gastric outlet obstruction is now a rare complication of ulcer disease because of the early detection and treatment of most ulcers. Most patients who develop clinically relevant gastric outlet obstruction have had an ulcer in the duodenal bulb and/or pyloric channel. Edema and inflammation play an important role, and occasionally a patient with active disease presents with symptoms of outlet obstruction as manifested by nausea, vomiting, and gastric stasis without a tight, chronic stenosis. Management therefore involves three key steps. The first is nasogastric tube aspiration and gastric lavage to clear the stomach of retained debris, followed by early endoscopy. This step facilitates an accurate diagnosis. Nasogastric suction may need to be maintained for several days if vomiting resumes when the tube is clamped. The second step consists of intense antisecretory therapy using intravenous proton pump inhibitors in a dose equivalent to a bolus of 80 mg esomeprazole over 30 minutes, followed by a continuous infusion of 8 mg/hour. Finally, the cause of the ulcer needs to be addressed, usually by eradicating *H. pylori* and withdrawing NSAIDs. If the initial treatment resolves the clinical situation and the patient can resume eating, it is often not necessary to undertake further treatment of the outlet stenosis; however, tight, fibrous scarring may require endoscopic balloon dilation or surgery.

PROGNOSIS

Most peptic ulcers heal spontaneously within weeks to months. However, if the underlying condition is not adequately treated, a large proportion of ulcers recur. Both initial and recurrent ulcers can give rise to complications. The four major complications are intractability, perforation, hemorrhage, and stenosis. Each distinct situation requires specific management approaches. Patients with complicated ulcer disease are at particular risk for recurrent complications and need careful assessment for secondary prevention. In patients who take long-term acid suppressive therapy, especially with proton pump inhibitors, the risks for community-acquired pneumonia and vitamin B_{12} deficiency (Chapters 150 and 199) are increased but overall mortality is not.[16] The treatment of *H. pylori* infection appears to reduce the risk of gastric cancer.[17,A16]

126 APPROACH TO THE PATIENT WITH DIARRHEA AND MALABSORPTION

CAROL E. SEMRAD

DEFINITIONS

Normal stool frequency ranges from three times per week to three times per day. As a symptom, diarrhea can be described as a decrease in stool consistency (increased fluidity), stools that cause urgency or abdominal discomfort, or an increase in the frequency of stool. Consistency is defined as the ratio of fecal water to the water-holding capacity of fecal insoluble solids, which are composed of bacterial mass and dietary fiber. Because it is difficult to measure stool consistency and because stool is predominantly (60 to 85%) water, stool weight becomes a reasonable surrogate of consistency.

As a sign, diarrhea is defined by the weight or volume of stool measured over a 24- to 72-hour period. Daily stool weights of children and adults are less than 200 g, and greater stool weights are an objective definition of diarrhea; however, this definition misses 20% of diarrheal symptoms in patients who have loose stools that are less than this daily weight.

Acute diarrheas persist for less than 2 to 3 weeks or, rarely, 6 to 8 weeks. The most common cause of acute diarrhea is infection. Chronic diarrheal conditions persist for at least 4 weeks and, more typically, 6 to 8 weeks or longer. The four mechanisms of diarrhea are osmotic, secretory, exudative, and altered motility. Because many diarrheal diseases are due to more than one of these mechanisms, it is clinically useful to categorize diarrhea as malabsorptive (fatty), watery, and inflammatory.

EPIDEMIOLOGY

Diarrhea is a leading cause of mortality worldwide and is particularly problematic for elderly people and for children younger than 5 years of age in developing nations. Infectious diarrheal conditions cause approximately 445,000 worldwide childhood deaths annually, despite the improved use of oral rehydration solutions, zinc, and vitamin A supplements. Rotavirus infection (Chapter 350) is the most common cause of fatal childhood diarrhea, but the introduction of the oral monovalent rotavirus vaccine has significantly decreased its mortality rate in both developing and developed nations.

withdrawal of NSAIDs, suturing of the perforated ulcer may be adequate, permitting the patient to avoid a more radical vagotomy with or without gastric resection.

Intractability

Intractability is a term strictly applied to an ulcer that persists even after intensive and prolonged proton pump inhibitor therapy. Symptoms may or may not be present. These rare cases may result from poor compliance with recommended treatment, surreptitious use of ulcerogenic drugs, or other diseases (e.g., Crohn disease, ischemia, infection with bacteria other than *H. pylori*, viral infection). If these issues are recognized and these diagnoses are pursued, further complications and interventions such as surgical vagotomy and pyloroplasty can almost always be avoided.

Acid peptic disease related to alcohol or bisphosphonates should be addressed by discontinuing the precipitating agent. Treatment of Zollinger-Ellison syndrome requires high-dose proton pump inhibitors and/or surgery (Chapter 213). Rare ulcers caused by Crohn disease (Chapter 127), vasculitis (Chapter 249), sarcoidosis (Chapter 83), polycythemia vera (Chapter 152), amyloidosis (Chapter 174), and other rare disorders should be addressed by treating the underlying condition. Stress ulcers and Cameron ulcers are treated by potent acid-suppressive therapy (e.g., omeprazole 20 mg twice daily).

Stenosis

Gastric outlet obstruction is now a rare complication of ulcer disease because of the early detection and treatment of most ulcers. Most patients who develop clinically relevant gastric outlet obstruction have had an ulcer in the duodenal bulb and/or pyloric channel. Edema and inflammation play an important role, and occasionally a patient with active disease presents with symptoms of outlet obstruction as manifested by nausea, vomiting, and gastric stasis without a tight, chronic stenosis. Management therefore involves three key steps. The first is nasogastric tube aspiration and gastric lavage to clear the stomach of retained debris, followed by early endoscopy. This step facilitates an accurate diagnosis. Nasogastric suction may need to be maintained for several days if vomiting resumes when the tube is clamped. The second step consists of intense antisecretory therapy using intravenous proton pump inhibitors in a dose equivalent to a bolus of 80 mg esomeprazole over 30 minutes, followed by a continuous infusion of 8 mg/hour. Finally, the cause of the ulcer needs to be addressed, usually by eradicating *H. pylori* and withdrawing NSAIDs. If the initial treatment resolves the clinical situation and the patient can resume eating, it is often not necessary to undertake further treatment of the outlet stenosis; however, tight, fibrous scarring may require endoscopic balloon dilation or surgery.

PROGNOSIS

Most peptic ulcers heal spontaneously within weeks to months. However, if the underlying condition is not adequately treated, a large proportion of ulcers recur. Both initial and recurrent ulcers can give rise to complications. The four major complications are intractability, perforation, hemorrhage, and stenosis. Each distinct situation requires specific management approaches. Patients with complicated ulcer disease are at particular risk for recurrent complications and need careful assessment for secondary prevention. In patients who take long-term acid suppressive therapy, especially with proton pump inhibitors, the risks for community-acquired pneumonia and vitamin B_{12} deficiency (Chapters 150 and 199) are increased but overall mortality is not.[16] The treatment of *H. pylori* infection appears to reduce the risk of gastric cancer.[17,A16]

126 APPROACH TO THE PATIENT WITH DIARRHEA AND MALABSORPTION

CAROL E. SEMRAD

DEFINITIONS

Normal stool frequency ranges from three times per week to three times per day. As a symptom, diarrhea can be described as a decrease in stool consistency (increased fluidity), stools that cause urgency or abdominal discomfort, or an increase in the frequency of stool. Consistency is defined as the ratio of fecal water to the water-holding capacity of fecal insoluble solids, which are composed of bacterial mass and dietary fiber. Because it is difficult to measure stool consistency and because stool is predominantly (60 to 85%) water, stool weight becomes a reasonable surrogate of consistency.

As a sign, diarrhea is defined by the weight or volume of stool measured over a 24- to 72-hour period. Daily stool weights of children and adults are less than 200 g, and greater stool weights are an objective definition of diarrhea; however, this definition misses 20% of diarrheal symptoms in patients who have loose stools that are less than this daily weight.

Acute diarrheas persist for less than 2 to 3 weeks or, rarely, 6 to 8 weeks. The most common cause of acute diarrhea is infection. Chronic diarrheal conditions persist for at least 4 weeks and, more typically, 6 to 8 weeks or longer. The four mechanisms of diarrhea are osmotic, secretory, exudative, and altered motility. Because many diarrheal diseases are due to more than one of these mechanisms, it is clinically useful to categorize diarrhea as malabsorptive (fatty), watery, and inflammatory.

EPIDEMIOLOGY

Diarrhea is a leading cause of mortality worldwide and is particularly problematic for elderly people and for children younger than 5 years of age in developing nations. Infectious diarrheal conditions cause approximately 445,000 worldwide childhood deaths annually, despite the improved use of oral rehydration solutions, zinc, and vitamin A supplements. Rotavirus infection (Chapter 350) is the most common cause of fatal childhood diarrhea, but the introduction of the oral monovalent rotavirus vaccine has significantly decreased its mortality rate in both developing and developed nations.

ABSTRACT

Diarrhea is one of the most common gastrointestinal problems encountered in the outpatient, emergency department, and hospitalized settings. There are many infectious, dietary, drug, gastrointestinal, extraintestinal, and surgical causes. An understanding of the physiology and pathophysiology of nutrient digestion and intestinal absorption can guide the diagnostic approach. This chapter provides an understanding of key concepts of intestinal physiology, pathophysiology, and clinical presentation to make a specific diagnosis in patients who present with diarrhea or suspected malabsorption.

KEYWORDS

diarrhea
malabsorption
celiac disease
pathobiology

In the United States, norovirus has surpassed rotavirus as the leading cause of gastroenteritis requiring medical care. Approximately 48 million Americans suffer from food-borne illness each year, including about 128,000 annual hospitalizations and 3000 deaths, most in elderly people. The major pathogens that cause diarrhea result in an estimated $17.6 billion in annual health care costs and days lost from work.

PATHOBIOLOGY

Fluid and Electrolyte Transport

Whether a hypotonic meal, such as a steak and water, or a hypertonic meal, such as milk and a doughnut, is consumed, the volume of the meal is augmented by gastric, pancreatic, biliary, and duodenal secretions. The permeable duodenum then renders the meal approximately isotonic with an electrolyte content similar to that of plasma by the time it reaches the proximal jejunum. As the intestinal slurry moves toward the colon, the Na^+ concentration in the luminal fluid remains constant, but Cl^- is reduced to 60 to 70 mmol/L, and bicarbonate (HCO_3^-) is increased to a similar concentration as the result of Cl^- and HCO_3^- transport mechanisms in the enterocyte and HCO_3^- secretion in the ileum (E-Fig. 126-1A and B). In the colon, K^+ is secreted, and the Na^+ transport mechanism of the colonocyte, together with the low epithelial permeability, extracts Na^+ and fluid from the stool. As a result, the Na^+ content of stool decreases to 30 to 40 mmol/L; K^+ increases from 5 to 10 mmol/L in the small bowel to 75 to 90 mmol/L; and poorly absorbed divalent cations, such as Mg^{2+} and Ca^{2+}, are concentrated in stool to values of 5 to 100 mmol/L. The anion concentrations in the colon change drastically because bacterial degradation of carbohydrate (i.e., unabsorbed starches, sugars, and fiber) creates short-chain fatty acids that attain concentrations of 80 to 180 mmol/L; at colonic pH, organic anions, such as acetate, propionate, and butyrate, are present. In the setting of carbohydrate malabsorption, the generation of high concentrations of these short-chain fatty acids may decrease stool pH to 4 or lower. The osmolality of the stool is approximately that of plasma (280 to 300 mOsm/kg H_2O) when it is passed.

At the cellular level, Na^+ transport by the epithelium from lumen to blood (by Na^+-coupled sugar and amino acid transport in the small intestine, by Na^+/H^+ exchange proteins in the small intestine and proximal colon, and by aldosterone-regulated Na^+ channels [ENaC] in the distal colon) creates a favorable osmotic gradient for absorption (see E-Fig. 126-1A and C). Chloride transport by the epithelium from blood to lumen (by cystic fibrosis transmembrane conductance regulator [CFTR] and the calcium-activated chloride channel in the small intestine and colon) creates an osmotic gradient for secretion (see E-Fig. 126-1B). Normally, the intestine is in a net absorptive state, regulated by extrinsic adrenergic nerves and proabsorptive neuropeptides and hormones (see E-Fig. 126-1D). Stimulation of secretion by neurotransmitters, hormones, and inflammatory mediators (Table 126-1) can offset this balance. A heterozygous missense mutation (c.2519 G→T) in GUCY2C on chromosome 12 causes familial diarrhea by increasing GC-C signaling.

Diarrhea is due primarily to alterations of intestinal fluid and electrolyte transport and less to smooth muscle function. Each 24 hours, 8 to 10 L of fluid enters the duodenum. The diet supplies 2 L of this fluid; the remainder comes from salivary, gastric, hepatic, pancreatic, and intestinal secretions. The small intestine normally absorbs 8 to 9 L (80%) of this fluid and presents 1.5 L to the colon for absorption. Of the remaining fluid, the colon absorbs all but approximately 100 mL. Diarrhea can result from increased secretion by the small intestine or the colon if the maximal daily absorptive capacity of the colon (4 L) is exceeded. Alternatively, if the colon is diseased so that it cannot absorb even the 1.5 L normally presented to it by the small intestine, diarrhea results.

Watery diarrheas may be due to osmotic, secretory, or inflammatory mechanisms. With ingestion of a poorly absorbed (e.g., Mg^{2+}) or unabsorbable (polyethylene glycol, lactulose, or, in lactase-deficient individuals, lactose) solute, the osmotic force of the solute pulls water and secondarily sodium and chloride ions into the intestinal lumen. A considerable proportion of the osmolality of stool results from the nonabsorbed solute. This gap between stool osmolality and the sum of the electrolytes in the stool causes osmotic diarrhea.

Active chloride secretion or inhibited sodium absorption, which also creates an osmotic gradient favorable for the movement of fluids from blood to lumen, explains the pathophysiology of the secretory diarrheas. Agents that increase enterocyte cyclic adenosine monophosphate (cAMP) (e.g., cholera toxin, prostaglandins), cyclic guanosine monophosphate (cGMP) (e.g., *Escherichia coli* stable toxin), or intracellular ionized calcium (Ca^{2+}) (e.g., acetylcholine) (see Table 126-1) inhibit non-nutrient Na^+ absorption and stimulate Cl^- secretion (see Table 126-1 and E-Fig. 126-1B and D).

TABLE 126-1 STIMULI OF INTESTINAL SECRETION

AGENT	INTRACELLULAR MEDIATOR	RELATED DIARRHEAL ILLNESS
Cholera, *Escherichia coli* heat labile toxin, *Salmonella, Yersinia*	cAMP	Travelers, endemic
E. coli heat stable toxin	cGMP	Travelers, endemic
Rotatoxin (NSP4)	?	Viral gastroenteritis
Serotonin, PAF	Ca	Inflammatory, allergic
PG, leukotrienes	cAMP, Ca	Invasive enteric bacteria,* inflammatory bowel diseases
PG	cAMP	Villous adenoma
Histamine	Ca	Intestinal allergies, mastocytosis, scombroid poisoning
VIP	cAMP	VIPoma, ganglioneuromas
5-HT, substance P, bradykinin	Ca	Malignant carcinoid
Calcitonin	?	Medullary carcinoma thyroid
Acetylcholine	Ca	Insecticides, nerve gas poisoning, cholinergic drugs
Ricinoleic acid	cAMP, Ca	Laxative abuse†
Caffeine	cAMP	Coffee, sodas, tea

5-HT = 5-hydroxytryptamine; Ca = calcium; cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; PAF = platelet-activating factor; PG = prostaglandin; VIP = vasoactive intestinal peptide.

**Shigella* spp, *Clostridioides difficile,* enteroinvasive, *Escherichia coli, Vibrio parahaemolyticus, Clostridium perfringens.*

†Also phenolphthalein, anthraquinone, bisacodyl, dioctyl sodium sulfosuccinate, and senna.

Inflammatory diarrhea, which may be watery or bloody, are characterized by enterocyte damage, villus atrophy, and crypt hyperplasia. The damaged enterocyte membrane of the small intestine has decreased disaccharidase and peptide hydrolase activity, reduced or absent Na^+-coupled sugar or amino acid transport mechanisms, and reduced or absent sodium chloride absorptive transporters. Conversely, the hyperplastic crypt cells maintain their ability to secrete Cl^- (and perhaps HCO_3^-). If the inflammation is severe, immune-mediated vascular damage or ulceration allows blood, pus, and protein to leak (exudate) from capillaries and lymphatics and contribute to the diarrhea. Activation of lymphocytes, phagocytes, and fibroblasts releases various inflammatory mediators that induce intestinal chloride secretion (see E-Fig. 126-1D). Interleukin-1 (IL-1) and tumor necrosis factor (TNF), which also are released into the blood, cause fever, anorexia, and malaise.

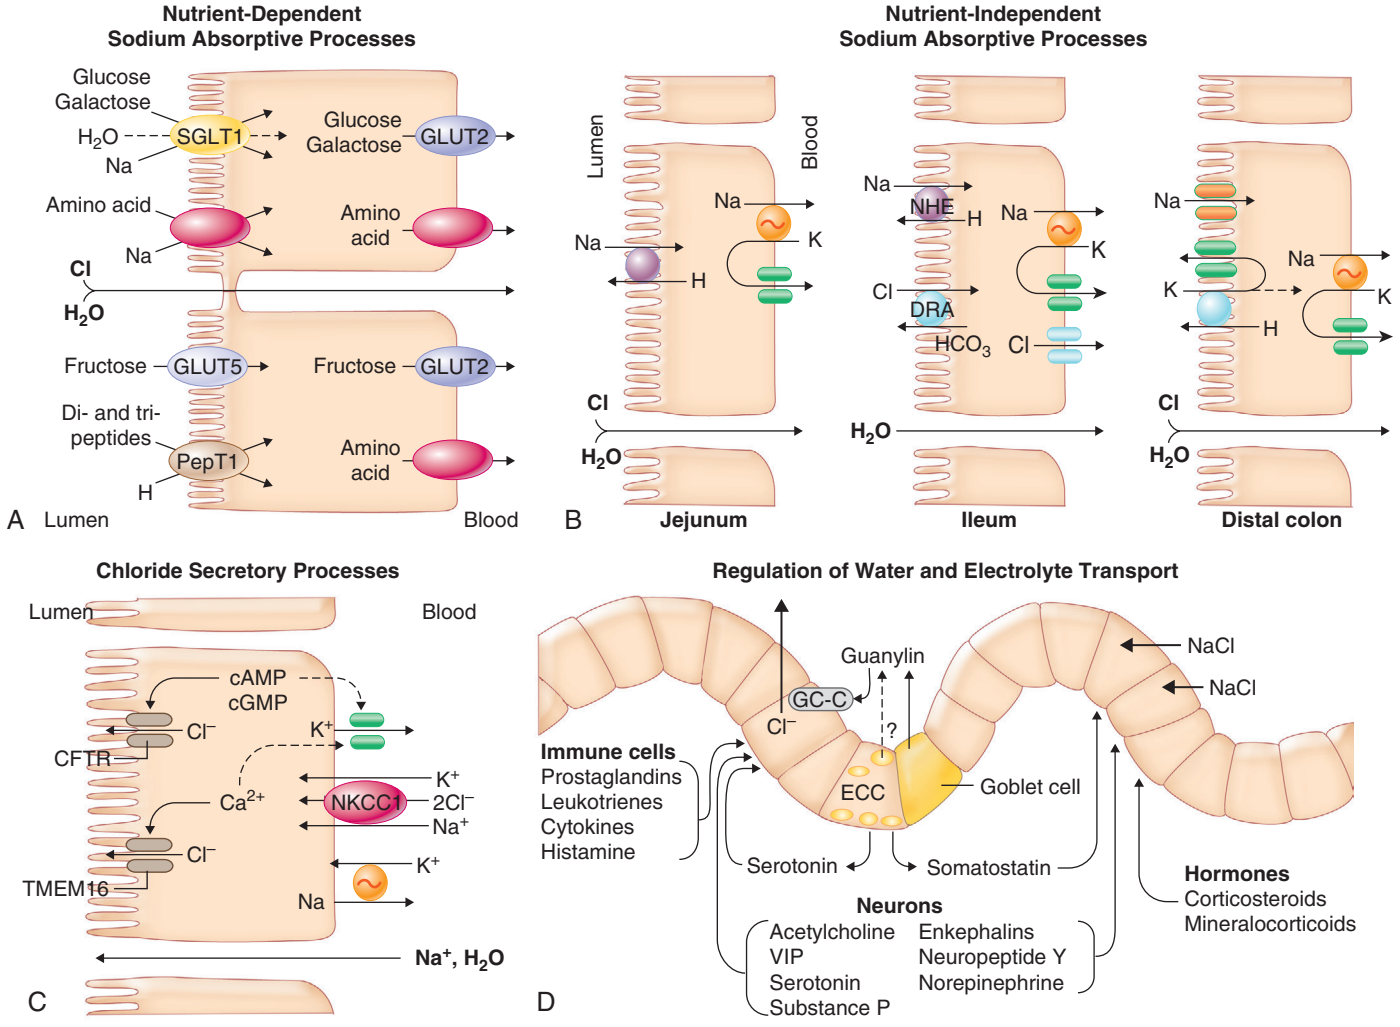
ACUTE DIARRHEA

CLINICAL MANIFESTATIONS

Approximately 80% of acute diarrheas are due to infections with viruses, bacteria, and parasites. The remainder are due to medications that have an osmotic force, stimulate intestinal fluid secretion, damage the intestinal epithelium, or contain poorly absorbable or nonabsorbable sugars (e.g., sorbitol), or less commonly fecal impaction, pelvic inflammation (e.g., acute appendicitis [Chapter 128]), or intestinal ischemia (Chapter 129).

Food-Borne and Water-Borne Infectious Diarrhea

Most infectious diarrheas are acquired through fecal-oral transmission from water, food, or person-to-person contact (Table 126-2). Patients with infectious diarrhea often complain of nausea, vomiting, and abdominal cramps that are associated with watery, malabsorptive, or bloody diarrhea and fever (dysentery). As documented using polymerase chain reaction (PCR) methods of diagnosis, most outbreaks of nonbacterial acute gastroenteritis in the United States and other countries are caused by noroviruses (Norwalk agent; Chapter 350). Rotavirus (Chapter 350) predominantly causes diarrhea in infants, usually in the winter months, but also may cause nonseasonal acute diarrhea in adults, particularly in elderly people.[1] Mechanisms for diarrhea include decreased fluid absorption due to destruction of villus enterocytes and stimulation of fluid secretion by NSP4 rotatoxin and viral activation of the enteric nervous system. Ebola virus *(Filoviridae)* infects endothelial cells, macrophages, and dendritic cells. The mechanism for the massive watery diarrhea is not known.



E-FIGURE 126-1. **Mechanisms of intestinal transport of water and electrolytes. A**, Sodium is absorbed by nutrient-dependent and nutrient-independent transport processes in the small intestine and by a sodium channel (ENaC) in the colon. The Na^+/H^+ (NHE) and Cl^-/HCO_3^- (DRA) exchangers are inhibited by agents that elevate intracellular cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), or calcium. **B**, Chloride secretion by intestinal crypt cells. Chloride can be secreted actively throughout the small intestine and colon. Intracellular mediators of secretion (cAMP, cGMP, Ca^{2+}) open apical Cl^- channels (cystic fibrosis transmembrane conductance regulator [CFTR], calcium-activated chloride channel [TMEM16]) and basolateral K^+ channels. Chloride moves from crypt cells into the intestinal lumen, favoring movement of Cl^- from the blood into cells by the $Na^+/K^+/2Cl^-$ cotransporter (*NKCC1*). Bicarbonate (HCO_3^-) also may be secreted via the CFTR channel. **C**, Intestinal sodium absorption. Sodium is actively absorbed in villus cells of the small intestine and surface cells of the colon. The sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) present on the cell basolateral membrane maintains a low intracellular Na^+ concentration and an electronegative cell interior favoring Na^+ movement across the apical membrane from lumen into cell. In the small intestine, glucose and galactose are taken up with sodium and water at the apical membrane by the sodium-glucose ligand transporter (SGLT1). Several different sodium-dependent amino acid carriers, some with overlapping substrate specificities, transport cationic, anionic, and neutral amino acids into villus cells. Dipeptides and tripeptides are transported by a hydrogen-coupled oligopeptide carrier, *PepT1*, that is driven by luminal hydrogen ions generated by the epithelial Na^+/H^+ exchanger. Fructose is taken up by the facilitative glucose transporter (GLUT5). **D**, Regulation of intestinal water and electrolyte transport. Normally, the intestine is in a net absorptive state under the control of extrinsic adrenergic nerves from the sympathetic nervous system. Guanylin, the natural ligand for the *Escherichia coli* stable-toxin receptor (membrane-bound guanylyl cyclase [GC-C]), may be important in regulating local chloride secretion. The normal tone of the intestine is modified by the enteric nervous system, endocrine and inflammatory cells in the intestinal mucosa, and circulating hormones. The enteric nervous system releases a variety of neurotransmitters, some that stimulate chloride secretion (e.g., vasoactive intestinal peptide [VIP], acetylcholine) and others that promote sodium absorption (e.g., enkephalins, neuropeptide Y). Hormones produced locally from enterochromaffin cells (ECC) in the intestinal epithelium and inflammatory mediators released from immune cells directly affect enterocytes and nearby nerves. Circulating hormones (e.g., aldosterone, glucocorticoids) enhance sodium absorption in the intestine. Glucocorticoids also inhibit release of arachidonic acid and production of prostaglandin by inflammatory cells. DRA (SLC26) = downregulated in adenoma gene; NHE (SLC9) = sodium-hydrogen exchanger.

TABLE 126-2 EPIDEMIOLOGY OF ACUTE INFECTIOUS DIARRHEA AND INFECTIOUS FOOD-BORNE ILLNESS

VEHICLE	CLASSIC PATHOGENS
Water (including foods washed in such water)	*Vibrio cholerae,* norovirus (Norwalk agent), *Giardia, Cryptosporidium*
Food	*Salmonella, Campylobacter, Shigella* spp
Poultry	Enterohemorrhagic *Escherichia coli*
Beef, unpasteurized fruit juice	Tapeworm
Pork	*V. cholerae, Vibrio parahaemolyticus,* and *Vibrio vulnificus; Salmonella* and *Shigella* spp; hepatitis A and B viruses; tapeworm; anisakiasis
Seafood and shellfish (including raw sushi and gefilte fish)	*Listeria* spp
Cheese, milk	*Salmonella* spp
Eggs	Staphylococcal and clostridial food poisonings
Mayonnaise-containing foods and cream pies	*Bacillus cereus*
Fried rice	*Cyclospora* spp
Fresh berries	*Clostridium* spp
Canned vegetables or fruits	Enterohemorrhagic *E. coli, Salmonella* spp
Sprouts	*Salmonella, Campylobacter, Cryptosporidium,* enterohemorrhagic *E. coli,* and *Giardia* spp
Animal-to-person (pets and livestock) contact	All enteric bacteria, viruses, and parasites
Person-to-person (including sexual) contact	*Shigella, Campylobacter, Cryptosporidium,* and *Giardia* spp; viruses; *Clostridioides difficile*
Daycare center	*C. difficile*
Hospitalization, antibiotics, or chemotherapy	*Giardia* and *Cryptosporidium* spp
Swimming pool	*E. coli* of various types; *Salmonella, Shigella, Campylobacter, Giardia,* and *Cryptosporidium* spp; *Entamoeba histolytica*
Foreign travel	

spp = species.
Modified from Powell DW. Approach to the patient with diarrhea. In : Yamada T, Alpers DH, Owyang C, et al, eds. *Textbook of Gastroenterology,* 3rd ed. Philadelphia: Lippincott-Raven; 1999.

The incidence of food-borne bacterial diseases in the United States decreased significantly during the coronavirus disease 2019 (COVID-19) pandemic, in large part because of less international travel but also likely because of increased hand-washing, closure of some child care centers, and decreased restaurant dining.[2] Incidence is highest for *Campylobacter jejuni* (Chapter 279), followed by *Salmonella* (Chapter 284) and *E. coli* O157:H7 (Chapter 280), and less commonly *Shigella* (Chapter 285), *Yersinia, Vibrio* (Chapter 278), *Cyclospora* (Chapter 324), and listeria (Chapter 272). *Vibrio* infection is predominantly due to the consumption of raw shellfish. Outbreaks of *E. coli* O157:H7 have been associated with petting zoos, uncooked ground beef, and green leafy vegetables. These bacteria most often invade the distal small bowel and colon, where they multiply intracellularly and damage the epithelium. Diarrhea is due to the stimulation of intestinal secretion by inflammatory mediators, decreased absorption across the damaged epithelium, and exudation of protein into the lumen. *Shigella* spp and enterohemorrhagic *E. coli* produce a similar toxin, the "Shiga toxin," which is cytotoxic to intestinal epithelial cells and causes inflammation, cell damage, and diarrhea with blood and pus.

Outbreaks of *Cryptosporidium* (Chapter 321) have been reported in water parks. This parasite causes diarrhea by adhering and fusing to the epithelial cell membrane in the small bowel, thereby causing cell damage. Organisms that are specific for seafood include *Vibrio parahaemolyticus* (Chapter 278), which causes either watery or bloody diarrhea, and *Vibrio vulnificus,* which causes watery diarrhea and, especially in patients with liver disease, a fatal septicemia. Ingestion of meat contaminated by anthrax (Chapter 272) causes fever, diffuse abdominal pain, and bloody stool or vomitus. Anthrax invades the intestinal mucosa; the organism, or anthrax toxin, causes inflammation, ulceration, and necrosis.

In addition to enteric infections, certain systemic infections (e.g., viral hepatitis [Chapter 134], listeriosis [Chapter 272], legionellosis [Chapter 290]), mycoplasma, and emerging infections (e.g., Hanta virus [Chapter 351], severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2; Chapter 336], avian influenza [Chapter 332]) may cause or manifest with substantial diarrhea.

Environmental and Food Poisonings

Food poisoning refers to the accumulation of toxin in food owing to the growth of toxin-producing organisms, most commonly *Staphylococcus aureus* (Chapter 267), *Bacillus cereus, Clostridium perfringens* (Chapter 271), and *Clostridium botulinum* (Chapter 271). Diarrhea is usually of rapid onset, as early as 4 hours after ingestion, and is often associated with vomiting. Natural toxins also are responsible for mushroom *(Amanita)* poisoning (Chapter 96), which can also cause acute liver and kidney failure.

Environmental poisonings may be caused by heavy metals (arsenic from rat poison, gold, lead, mercury) that impair cell energy production. Arsenic (Chapter 20) also induces cardiovascular collapse at high doses. Insecticide (organophosphates and carbamates) poisoning occurs most commonly in field workers or from the ingestion of contaminated herbs or teas (Chapter 96); diarrhea, excessive saliva, and pulmonary secretions are caused by acetylcholine-stimulated chloride secretion in intestine and other epithelia. Patients often have associated vomiting and abdominal cramps.

Seafood is a common source of food poisoning, particularly fin fish and bivalve shellfish. Most of these toxins cause varying combinations of gastrointestinal (nausea, vomiting, diarrhea) and neurologic (tingling and burning around the mouth, facial flushing, sweating, headache, palpitations, and dizziness) symptoms within hours of seafood ingestion (Chapter 98). Similar symptoms are reported in patients with scombroid poisoning, which is caused by ingestion of decaying flesh of blood fish (tuna, mahi-mahi, marlin, or mackerel) that release large amounts of histamine (Chapter 98).

Marine dinoflagellates (algae) produce toxins that can cause paralytic shellfish poisoning, diarrhetic shellfish poisoning, and ciguatera (Chapter 98). Sporadic outbreaks of diarrhetic shellfish poisoning "red tides" occur when bivalve mollusks ingest dinoflagellates that produce saxitoxins (voltage-sensitive sodium-channel blocker) and okadaic acid (a lipid-soluble toxin that inhibits serine and threonine protein phosphatases 1 and 2A). Ingestion of contaminated mollusks by humans results in diarrhea and neurologic symptoms. Saxitoxins cause predominantly neurologic symptoms (paralytic, neurotoxic, or amnestic shellfish poisonings) and okadaic acid gastrointestinal symptoms (diarrhetic shellfish poisoning).

Food-chain passage of another dinoflagellate spp *(Gambierdiscus toxicus)* to fin fish (mackerel, amberjack, snapper, grouper, or barracuda) results in the accumulation of ciguatoxin (Chapter 98) that causes a seafood poisoning called ciguatera. Ciguatoxin activates voltage-sensitive sodium channels and causes neurologic and gastrointestinal symptoms. Fish from the Albemarle-Pamlico estuary (eastern United States) ingest toxic dinoflagellates that cause *Pfiesteria piscicida* poisoning. The dinoflagellate toxins cause nausea, vomiting, abdominal pain, diarrhea, and neurologic symptoms such as fatigue, myalgias, pruritus, circumoral paresthesias, reversal of hot and cold sensation, psychiatric abnormalities, and memory loss. The neurologic symptoms may persist for months to years. Puffer fish poisoning by tetrodotoxin, a voltage-sensitive sodium-channel blocker produced by the fish, causes neurologic symptoms, respiratory paralysis, and death.

Traveler's Diarrhea

North American travelers to developing countries and travelers on airplanes and cruise ships are at high risk for acute infectious diarrhea. Common causes of traveler's diarrhea (Chapter 265) include norovirus, enterotoxic or enteroaggregative *E. coli, Shigella,* and giardiasis.[3] *E. coli* heat-stable toxin binds to guanylate cyclase in the enterocyte brush-border membrane, where it results in elevation of intracellular cGMP. *E. coli* heat-labile toxin, similar to cholera toxin, binds to the monosialoganglioside GM_1 in the brush-border membrane,

thereby resulting in the activation of adenylate cyclase and the elevation of intracellular cAMP. cAMP and cGMP stimulate intestinal chloride secretion and inhibit the nutrient-independent absorption of sodium and chloride. Sodium-glucose absorption is not affected, hence the basis for oral rehydration therapy. Cholera toxin permanently binds to adenylate cyclase until the natural turnover of the intestinal epithelium in 5 to 7 days, thereby resulting in persistent secretion and severe diarrhea. DNA sequencing to detect genome sequences of *Vibrio cholerae* isolates suggests human introduction as the cause of recent outbreaks. Of the annual average of six cases of cholera reported in the United States, most are associated with travel.

Antibiotic-Associated Diarrhea

Antibiotics are a common cause of hospital-acquired diarrhea that occurs in approximately 20% of patients receiving broad-spectrum antibiotics, with approximately 30% of cases caused by *Clostridioides difficile* (Chapter 271). Strains that produce increased levels of toxins A and B and a binary toxin have emerged. These strains are associated with an increase in the incidence and severity of *C. difficile* infections, including fulminant *C. difficile* colitis that can lead to colectomy or even death. The A and B toxins produced by *C. difficile* can cause diarrhea. In animal models, IL-8, substance P, and leukotriene B_4 were found to mediate toxin A–stimulated intestinal fluid secretion. *C. difficile* can cause severe diarrhea, pseudomembranous colitis, or toxic megacolon.

Nosocomial Hospital Diarrhea

Diarrhea is the most common nosocomial illness among hospitalized patients and residents in long-term care facilities. Common causes include antibiotic-associated diarrhea, *C. difficile* infection, medications, fecal impaction, tube feeding, and underlying illness. Magnesium-containing laxatives, antacids, and lactulose cause osmotic diarrheas. Bisacodyl laxatives cause secretory diarrhea. Liquid formulations of medications cause diarrhea (elixir diarrhea) because of the high content of sorbitol or other nonabsorbable sugars (e.g., mannitol) used to sweeten the elixir; patients prescribed liquid medications through feeding tubes may receive more than 20 g of sorbitol daily. An important but poorly understood cause of diarrhea is enteral (tube) feeding (Chapter 198), particularly in critically ill patients, who often develop diarrhea. Dysmotility, increased intestinal permeability, and low sodium content in enteral formulas may be contributing factors.

Patients in mental health institutions and nursing homes have a high incidence of nosocomial infectious diarrhea (e.g., *C. difficile* and less commonly *Shigella, Salmonella,* hemorrhagic *E. coli, Giardia, Entamoeba histolytica*). Infectious diarrhea, 50% or more of which is caused by *C. difficile,* is also common in acute care hospitals. Severe *C. difficile* infection also has been reported among peripartum women. If outside foods are not brought to hospitalized patients, the likelihood of a nosocomial infection caused by *Salmonella* or *Shigella* is extremely rare. Immunosuppressed patients are also susceptible to nosocomial viral infections (rotavirus, norovirus, adenovirus, and coxsackievirus).

Cancer Treatment and Medication-Related Diarrhea

Abdominal or whole-body radiation virtually always causes an increased frequency of bowel movements that are often watery. Cancer chemotherapy with amsacrine, azacitidine, cytarabine, dactinomycin, daunorubicin, doxorubicin, floxuridine, 5-fluorouracil, 6-mercaptopurine, methotrexate, plicamycin, IL-2, and resveratrol may cause mild to moderate diarrhea. Irinotecan (CPT-11) or oxaliplatin and the combination of 5-fluorouracil plus leucovorin are frequent causes of severe watery diarrhea.

Immune checkpoint inhibitors of cytotoxic T-lymphocyte antigen (CTLA-4) and programmed death ligand PD-(L) cause diarrhea in up to 40% of patients. Colitis with or without enteritis is the cause. Evaluation of patients with significant diarrhea (>4 stools over baseline) includes exclusion of infection, measurement of fecal calprotectin or lactoferrin, and/or endoscopic biopsies.[4] If unrecognized and untreated, this form of severe colitis can be fatal.

Olmesartan, an angiotensin II receptor antagonist (ARB), causes severe diarrhea as a result of a sprue-like enteropathy. Angiotensin-converting enzyme (ACE) inhibitors may cause abdominal pain and diarrhea resulting from visceral angioedema. Colchicine, neomycin, methotrexate, and *para*-aminosalicylic acid damage the enterocyte membrane. Cholestyramine, colestipol, and colesevelam bind bile salts and can result in malabsorptive diarrhea, especially in patients who have had an ileal resection. Gold therapy causes intestinal inflammation and diarrhea.

Daycare Diarrhea

More than 7 million children in the United States attend daycare, where diarrhea is extremely common, and secondary infection of family members occurs in 10 to 20% of cases. Most outbreaks of diarrhea are due to rotavirus or norovirus; less common causes are *Shigella* (Chapter 285), *Giardia* (Chapter 322), and *Cryptosporidium* (Chapter 321).

Runner's Diarrhea

Diarrhea occurs in 10 to 25% of individuals who exercise vigorously, especially women marathon runners and triathletes. Some athletes have associated abdominal cramps, urgency, nausea, or vomiting. The pathophysiology of runner's diarrhea is unknown. Release of intestinal secretogogues, especially prostaglandins, hormones, or ischemia, may be involved.

DIAGNOSIS

Acute watery diarrhea may be due to infections, food toxins, or medications, or the acute diarrhea may signal the onset of a chronic disease (Fig. 126-1; see Tables 126-1 and 126-2). Multiplex PCR testing on stool is a rapid and sensitive method to detect bacterial, viral, and parasitic pathogens (Chapter 262), but it does not distinguish particles from live organisms or provide antibiotic sensitivity. The diagnostic approach in patients with fever and watery or bloody diarrhea should focus on multiplex PCR testing of stool for pathogens.[5] A positive result requires a culture for antimicrobial sensitivity and contact tracing. A test for *Vibrio* is needed in those who recently traveled to a cholera-endemic area.

Routine stool testing is not indicated when diarrhea occurs after 3 to 5 days of hospitalization, except in patients with neutropenia, human immunodeficiency virus (HIV) infection, or signs of enteric infection. In patients with more than three watery stools daily, particularly patients who have recently used antibiotics, been hospitalized, or are peripartum, a two-test approach is recommended for the diagnosis of *C. difficile* infection (Chapter 271). A positive stool PCR or glutamate dehydrogenase test is followed by an enzyme-based immunoassay for toxins to help distinguish true infection from a carrier state.[6]

Organisms that cause diarrhea but are not routinely cultured by clinical microbiology laboratories include *Yersinia* (Chapter 288), *Plesiomonas,* enterohemorrhagic *E. coli* serotype O157:H7 (Chapter 280), *Aeromonas, Cyclospora,* microsporidia, and noncholera *Vibrio* (Chapter 278). Parasites such as *Giardia* (Chapter 322), *Cryptosporidium* (Chapter 321), and *Strongyloides* (Chapter 327) can be difficult to detect in stool but may be diagnosed by stool antigen testing or intestinal biopsy (Chapter 262).

TREATMENT

Goals for the treatment of diarrhea include fluid replacement, antidiarrheal agents, nutritional support, and antimicrobial therapy when indicated. Because death in patients with acute diarrhea is caused by dehydration, the first task is to assess the degree of dehydration and to replace fluid and electrolyte deficits.

Fluid Replacement

Severely dehydrated patients should be treated with intravenous lactated Ringer solution or saline solution, with additional potassium and bicarbonate as needed. Oral rehydration solutions, which are used extensively to replace diarrheal fluid and electrolyte losses, are effective because they contain sodium, sugars, and, often, amino acids that use nutrient-dependent sodium uptake transporters. In alert patients with mild to moderate dehydration, oral rehydration solution is equally effective as intravenous hydration in repairing fluid and electrolyte losses. Oral rehydration solutions can be given to infants and children in volumes of 50 to 100 mL/kg over 4 to 6 hours; adults may need to drink 1000 mL/hour. Reduced-osmolarity solutions (Na^{2+} 75 mmol/L, osmolarity 245 mmol/L versus Na^{2+} 90 mmol/L, osmolarity 311 mmol/L in standard solutions) are better tolerated and effective in noncholera diarrhea but may cause hyponatremia in patients with high-volume diarrhea, particularly children. Glucose-based solutions, although effective in rehydrating the patient, may worsen the diarrhea. In contrast to glucose-based solutions, polymeric rice-based solutions decrease diarrhea in cholera victims; rice is digested to many glucose monomers that aid in the absorption of intestinal secretions. These solutions may not decrease stool output in acute diarrhea, but they will effectively rehydrate the patient despite continued diarrhea. After rehydration has been accomplished, oral rehydration solutions are given at rates equaling stool loss plus insensible losses until the diarrhea ceases.

Reducing Diarrhea

Bismuth subsalicylate (Pepto-Bismol, 525 mg orally every 30 minutes to 1 hour for five doses, may repeat on day 2) is safe and efficacious in bacterial infectious diarrhea. Opiates and anticholinergic drugs are not recommended for invasive bacterial infectious diarrhea because these drugs paralyze intestinal motility and predispose to increased colonization, invasion, and prolonged excretion of infectious organisms. The opiate loperamide is safe in acute or traveler's diarrhea, provided that it is not given to patients with dysentery (high fever, with blood or pus in the stool), and especially when administered concomitantly with effective antibiotics. A combination of loperamide (2 mg orally four times daily)

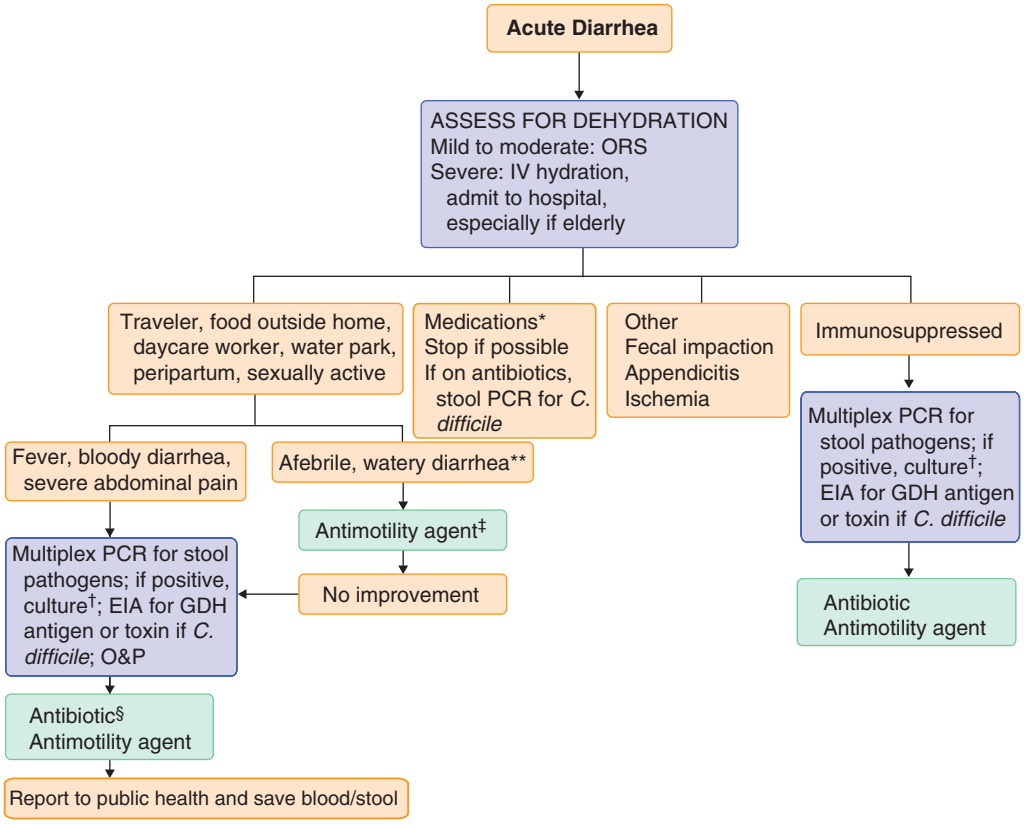


FIGURE 126-1. Approach to the diagnosis of acute diarrhea. *More than 700 medications cause diarrhea, including caffeine, protease inhibitors, immune checkpoint inhibitors, thyroid preparations, metformin, mycophenolate mofetil, sirolimus, cholinergic drugs, colchicine, selective serotonin reuptake inhibitors, proton pump inhibitors, histamine-2 blockers, 5-ASA derivatives, angiotensin-converting enzyme inhibitors and receptor blockers, bisacodyl, senna, aloe, anthraquinones, and magnesium- or phosphorus-containing medications. †Specifically request culture for *Yersinia, Plesiomonas, Vibrio,* enterohemorrhagic *Escherichia coli* serotype O157:H7, and *Aeromonas* if suspected. **_Vibrio_ testing if travel to cholera-endemic area. ‡If high suspicion for *Clostridioides difficile* or invasive bacterial infection, wait for PCR studies before starting. Racecadotril has antisecretory effects without paralyzing intestinal motility and can be used if available. §Not recommended for patients with bloody diarrhea due to *E. coli* O157:H7. EIA = enzyme-based immunoassays; GDH = glutamate dehydrogenase; IV = intravenous; O&P = ova and parasites; ORS = oral rehydration solution; PCR = polymerase chain reaction.

plus simethicone (125 mg orally four times daily) may reduce the abdominal cramps and duration of traveler's diarrhea. Racecadotril (100 mg orally three times daily in adults, 1.5 mg/kg of body weight orally three times daily in children), an intestinal enkephalinase inhibitor that is antisecretory but does not paralyze intestinal motility, is effective in the treatment of acute diarrhea in children and adults. The diarrhea associated with enteral nutrition (Chapter 198) often can be managed with pectin (4 g/kg body weight daily) or, if there are no contraindications, with loperamide (2 mg orally four times daily for 3 to 7 days, maximal dose 16 mg daily), and diarrhea is not a reason to stop tube feeding unless stool volumes exceed 1 L/day.

Anxiolytics (e.g., diazepam 2 mg orally two to four times daily) and antiemetics (e.g., promethazine 12.5 to 25 mg orally once or twice daily) that decrease sensory perception may make symptoms more tolerable and are safe. Some foods or food-derived substances (green bananas, pectins [amylase-resistant starch], zinc) lessen the amount or duration of diarrhea in children. Unabsorbed amylase-resistant starches are metabolized in the colon to short-chain fatty acids that enhance fluid absorption. Zinc supplementation (20 mg of elemental zinc orally once daily) is effective in preventing recurrences of diarrhea in malnourished children; copper deficiency is a potential complication of prolonged zinc therapy. Probiotics are not beneficial in children with acute diarrhea,[A1] but large randomized trials have not been reported in adults.

Antibiotics

While the clinician is awaiting stool culture results to guide specific therapy (Chapter 266), the fluoroquinolones (e.g., ciprofloxacin, 500 mg orally twice daily for 1 to 3 days, or levofloxacin, 500 mg orally daily for 1 to 3 days) are the treatment of choice when antibiotics are indicated (see Fig. 126-1). Trimethoprim-sulfamethoxazole (1 double-strength tablet orally twice daily for 5 days or 2 single-strength tablets orally twice a day for 5 days) is second-line therapy. If the symptom complex suggests *Campylobacter* infection, azithromycin (500 mg/day orally for 3 days) should be added. Regardless of the cause of infectious diarrhea, patients should be treated with antibiotics if they are immunosuppressed; have valvular, vascular, or orthopedic prostheses; have congenital hemolytic anemias (especially if salmonellosis is involved); or are extremely young or old.

Certain infectious diarrheas should be treated with antibiotics, including those associated with shigellosis (Chapter 285), cholera (Chapter 278), pseudomembranous enterocolitis (Chapter 271), parasitic infestations (Chapter 321 to 323), and sexually transmitted diseases (Chapter 264). Treatment of *E. coli* serotype O157:H7 infection is not recommended at present because current antibiotics do not appear to be helpful and the incidence of complications (hemolytic-uremic syndrome) may be greater after antibiotic therapy. Antibiotics are not effective for viral diarrhea or cryptosporidiosis.

For traveler's diarrhea, ciprofloxacin (500 mg orally twice daily for 3 days) is an effective treatment. The nonabsorbable antibiotic rifaximin (200 mg taken orally three times daily or 400 mg twice daily for 3 days) is safe and effective for treatment of traveler's diarrhea in Mexico, but it may not be effective against *Campylobacter* and *Shigella* infections.

Fluoroquinolone-resistant and trimethoprim-sulfamethoxazole–resistant strains of *Shigella, E. coli, Salmonella, Campylobacter*, and *C. difficile* have emerged. Azithromycin (500 mg orally on day 1 and 250 mg/day orally for 4 days) may be an effective alternative treatment for resistant strains of *Shigella* and *Campylobacter* and for traveler's diarrhea acquired in Mexico.

If *C. difficile* is suspected on an epidemiologic basis, fidaxomicin (200 mg orally twice a day for 10 days) is superior to vancomycin (125mg orally four times daily for 10 days)[A2] to prevent of recurrent infection. Other antibiotics and gastric acid suppressants, which are risk factors for recurrent infection, should be discontinued if possible.[7] In patients with recurrent *C. difficile* infection or a high risk for recurrence, immunotherapy with bezlotoxumab (a monoclonal antibody against *C. difficile* toxin B, given as a one-time dose of 10 mg/kg intravenously [IV] infused over 1 hour) decreases recurrence rates.[A3] Fecal microbiota transplantation is more effective than vancomycin for the treatment of recurrences, with resolution rates of 90% compared with 30% for vancomycin.[A4] Non–*C. difficile* antibiotic-induced diarrhea is generally mild and self-limited, and it usually clears spontaneously or in response to cholestyramine therapy (4 g orally four times daily for 2 weeks).

Treatment for chemotherapy-induced and radiation-induced mild to moderate diarrhea includes loperamide (2 mg orally four times daily) and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., naproxen, 250 to 500 mg orally twice daily). Octreotide may be an effective treatment in those with severe diarrhea in doses up to 700 μg/day subcutaneously (SQ). Treatment of diarrhea due to checkpoint inhibitor enterocolitis includes discontinuing the offending agent and starting systemic glucocorticoids (the equivalent of 0.5 to 2 mg/kg prednisone given orally or intravenously), with a 4- to 6-week taper. If no response is seen in 72 hours or the response is incomplete after 1 week, infliximab (5 mg/kg) or vedolizumab (300 mg) should be given intravenously at weeks 0, 2, and 6.

PREVENTION

Rotavirus vaccination (Chapter 350) reduces the risk for infection and death and generally results in milder symptoms among those infected. Travelers to high-risk countries (Central America and parts of Latin America, Africa, Asia, the Middle East) should avoid ingestion of tap water and ice and of raw meat, raw seafood, and raw vegetables (Chapter 265). An oral cholera vaccine against recombinant toxin B subunit and killed whole-cell (rBS-WC) is effective in preventing infection from the O1 El Tor strain and partially effective against enterotoxigenic *E. coli* strains. Cholera vaccination is recommended for relief workers and health professionals who work in endemic countries and for individuals who are immunocompromised or have chronic illnesses or hypochlorhydria. To stop cholera outbreaks in endemic countries, vulnerable communities must be vaccinated and have access to clean drinking water.

Bismuth subsalicylate (525 mg orally four times daily for up to 3 weeks) is effective in preventing traveler's diarrhea when compared to placebo. Rifaximin (200 to 1100 mg/day orally for 2 weeks) is effective for reducing the risk for traveler's diarrhea in Mexico and is recommended for those at high risk for health complications.[A5] The combination of rifaximin plus loperamide is better than either one alone. Loperamide and NSAIDs are taken prophylactically by many runners who are susceptible to runner's diarrhea, but it is not clear whether they are effective. Oral probiotics (e.g., lactobacilli and bifidobacteria) are not effective for preventing antibiotic-associated acute diarrhea.

PERSISTENT ACUTE DIARRHEA

Persistent diarrhea for more than 2 weeks develops in about 3% of individuals who travel to developing countries. Common causes include parasitic infections (e.g., *Giardia* [Chapter 322], *Cryptosporidium* [Chapter 321]) and bacterial infections (e.g., enteroaggregative *E. coli* [Chapter 280], *Shigella* [Chapter 285], and *Salmonella* [Chapter 284]). The evaluation should include culture for bacterial pathogens and methods for detecting bacterial, viral, and protozoal infections (e.g., multiplex PCR) as well as microscopy for protozoal infections. Antimicrobial therapy can be empirically given to patients who have recently returned from the developing world but should preferably be given based on the results of laboratory testing.

CHRONIC DIARRHEA

An estimated 5% of the U.S. population suffers from chronic diarrhea, and approximately 40% of these individuals are older than 60 years of age. The causes of chronic diarrhea include persistent infectious or inflammatory diarrheas, malabsorptive syndromes, and watery diarrheas (Table 126-3).

CLINICAL MANIFESTATIONS

Patients with malabsorption (Table 126-4) can present with a variety of gastrointestinal or extraintestinal manifestations (Table 126-5). Significant malabsorption of fat and carbohydrate usually causes chronic diarrhea, abdominal cramps, gas, bloating, and weight loss. Steatorrhea (fat in the stool) manifests as oily, foul-smelling stools that are difficult to flush down the toilet. Stools may be large and bulky (e.g., pancreatic insufficiency) or watery (e.g., bacterial overgrowth, mucosal diseases). Individuals with malabsorption also can present with manifestations of vitamin and mineral deficiencies. Dyspnea can be caused by anemia from iron, copper, folate, or vitamin B_{12} deficiency. Manifestations of calcium, magnesium, or vitamin D malabsorption include paresthesias and tetany resulting from hypocalcemia or hypomagnesemia and bone pain from osteomalacia or osteoporosis-related fractures. Paresthesias and ataxia are manifestations of cobalamin and vitamin E deficiency. Alternatively, neuropathy may be due to malnutrition or copper deficiency. Dermatitis herpetiformis (Chapter 406) is a blistering, burning, itchy rash on the extensor surfaces and buttocks that is associated with celiac disease.

Inflammatory diarrheas may manifest with fever and abdominal pain or with edema to suggest chronic protein loss. Patients may have multiple, low-volume, bloody stools with tenesmus to suggest proctitis or have severe diarrhea as a result of graft-versus-host disease (GVHD) or celiac disease. Systemic manifestations of inflammatory bowel disease include polymigratory arthritis, sacroiliitis, erythema nodosum, pyoderma gangrenosum, leukocytoclastic angiitis, uveitis, and oral aphthous ulcers.

DIAGNOSIS

A detailed history and physical examination lead to a diagnosis in 25 to 50% of patients with chronic diarrheas (see Table 126-1 and Fig. 126-2). In young adults with chronic diarrhea, the leading causes are irritable bowel syndrome, inflammatory bowel disease, microscopic colitis, bile acid diarrhea, malabsorption, drugs, food additives, thyroid disease, and diabetes mellitus. The addition

TABLE 126-3 CAUSES OF CHRONIC DIARRHEA

- Persistent infectious diarrheas (see Table 126-2)
  - Brainerd diarrhea
- Malabsorptive syndromes (see Tables 126-4 and 126-6)
  - Common causes
    - Celiac disease
    - Infection (*Giardia lamblia,* HIV/AIDS-related)
    - Tropical sprue
    - Crohn disease
    - Radiation enteritis
    - Gastric bypass surgery
    - Dumping syndrome
    - Chronic pancreatitis
    - Intestinal bacterial overgrowth
- Watery diarrhea
    - Osmotic diarrhea
    - Disaccharidase deficiencies (lactase, sucrase)
    - Magnesium, sodium phosphate, sulfate
    - Sorbitol, fructose
  - Alcohol
  - Factitious
  - Functional watery diarrhea (irritable bowel syndrome)
- Pure secretory
  - Hormone-secreting tumors (VIPoma, neuroendocrine, gastrinoma, medullary thyroid cancer)
  - Systemic mastocytosis
  - Villous adenoma
- Idiopathic
- Inflammatory diarrheas
  - Inflammatory bowel disease
  - Eosinophilic gastroenteritis
  - Microscopic colitis (collagenous or lymphocytic)
  - Food allergy

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus; VIP = vasoactive intestinal peptide.

TABLE 126-4 CAUSES OF MALABSORPTION

MECHANISM OF MALABSORPTION	CONDITIONS
Impaired mixing	Partial/total gastrectomy Gastric bypass surgery
Impaired lipolysis	Chronic pancreatitis Pancreatic cancer Congenital lipase or colipase deficiency Gastrinoma
Impaired micelle formation	Severe liver disease Bacterial overgrowth Crohn disease Ileal resection Gastrinoma
Impaired mucosal absorption	Lactase deficiency Abetalipoproteinemia Giardiasis Celiac disease Tropical sprue Agammaglobulinemia Amyloidosis AIDS-related Radiation enteritis Graft-versus-host disease Whipple disease Eosinophilic gastroenteritis Drugs Lymphoma Autoimmune enteritis Short-bowel syndrome
Impaired nutrient delivery	Congenital lymphangiectasia Lymphoma Tuberculosis Constrictive pericarditis Severe congestive heart failure
Unknown	Hypoparathyroidism Adrenal insufficiency Hyperthyroidism Carcinoid syndrome

AIDS = acquired immunodeficiency syndrome.

TABLE 126-5 CLINICAL CONSEQUENCES OF MALABSORPTION OF NUTRIENTS, WATER, AND ELECTROLYTES

NUTRIENT MALABSORBED	CLINICAL MANIFESTATION
Protein	Wasting, edema
Carbohydrate and fat	Diarrhea, abdominal cramps and bloating, weight loss, growth retardation
Fluid and electrolytes	Diarrhea, dehydration
Iron	Anemia, cheilosis, angular stomatitis
Calcium and vitamin D	Bone pain, fractures, tetany
Magnesium	Paresthesias, tetany
Vitamin B_{12} and folate	Anemia, glossitis, cheilosis, paresthesias, ataxia (vitamin B_{12} only)
Vitamin E	Paresthesias, ataxia, retinopathy
Vitamin A	Night blindness, xerophthalmia, hyperkeratosis, diarrhea
Vitamin K	Ecchymoses
Riboflavin	Angular stomatitis, cheilosis
Zinc	Dermatitis, hypogeusia, diarrhea
Selenium	Cardiomyopathy
Essential fatty acids	Dermatitis
Copper	Anemia, mental deterioration, neuropathy

of stool culture and examination for ova and parasites, determination of stool fat, and flexible sigmoidoscopy or colonoscopy with biopsy raises the diagnostic rate to approximately 75%. The remaining 25% of patients with chronic diarrhea may need extensive testing and perhaps hospitalization to make a diagnosis.

A history of 10 to 20 daily bowel movements that do not respond to fasting suggests secretory diarrhea (Fig. 126-3).[8] A history of peptic ulcer should suggest gastrinoma (Chapter 213) or systemic mastocytosis (Chapter 235). Physical examination is helpful only if the thyromegaly of medullary carcinoma (Chapter 207), the cutaneous flushing of the neuroendocrine tumors and systemic mastocytosis, the dermatographism of systemic mastocytosis, or the migratory necrolytic erythema of glucagonoma (Chapter 213) is evident. Autonomic dysfunction (e.g., postural hypotension, impotence, gustatory sweating) is almost invariably present in diabetic diarrhea.

Evaluation for malabsorption begins with a careful elicitation of bowel habits and a description of the stool; weight loss; travel; food or milk tolerance; underlying gastrointestinal, pancreatic, or liver diseases; abdominal surgery; radiation or chemotherapy treatments; family history; and drug and alcohol use.

Blood Tests

Blood measurements (see Fig. 126-2) of iron, folate, vitamin B_{12}, prothrombin time (vitamin K), and other fat-soluble vitamins (A, E, and D) help evaluate malabsorption. Specific antibody tests should be sent when celiac disease is suspected (see later). Peripheral blood findings of leukocytosis, eosinophilia, elevated erythrocyte sedimentation rate or C-reactive protein, hypoalbuminemia, or low total serum protein suggest an inflammatory diarrhea, whose hallmark is the presence of blood, either overt or occult, and leukocytes or calprotectin (a nondegradable leukocyte protein) in the stool.

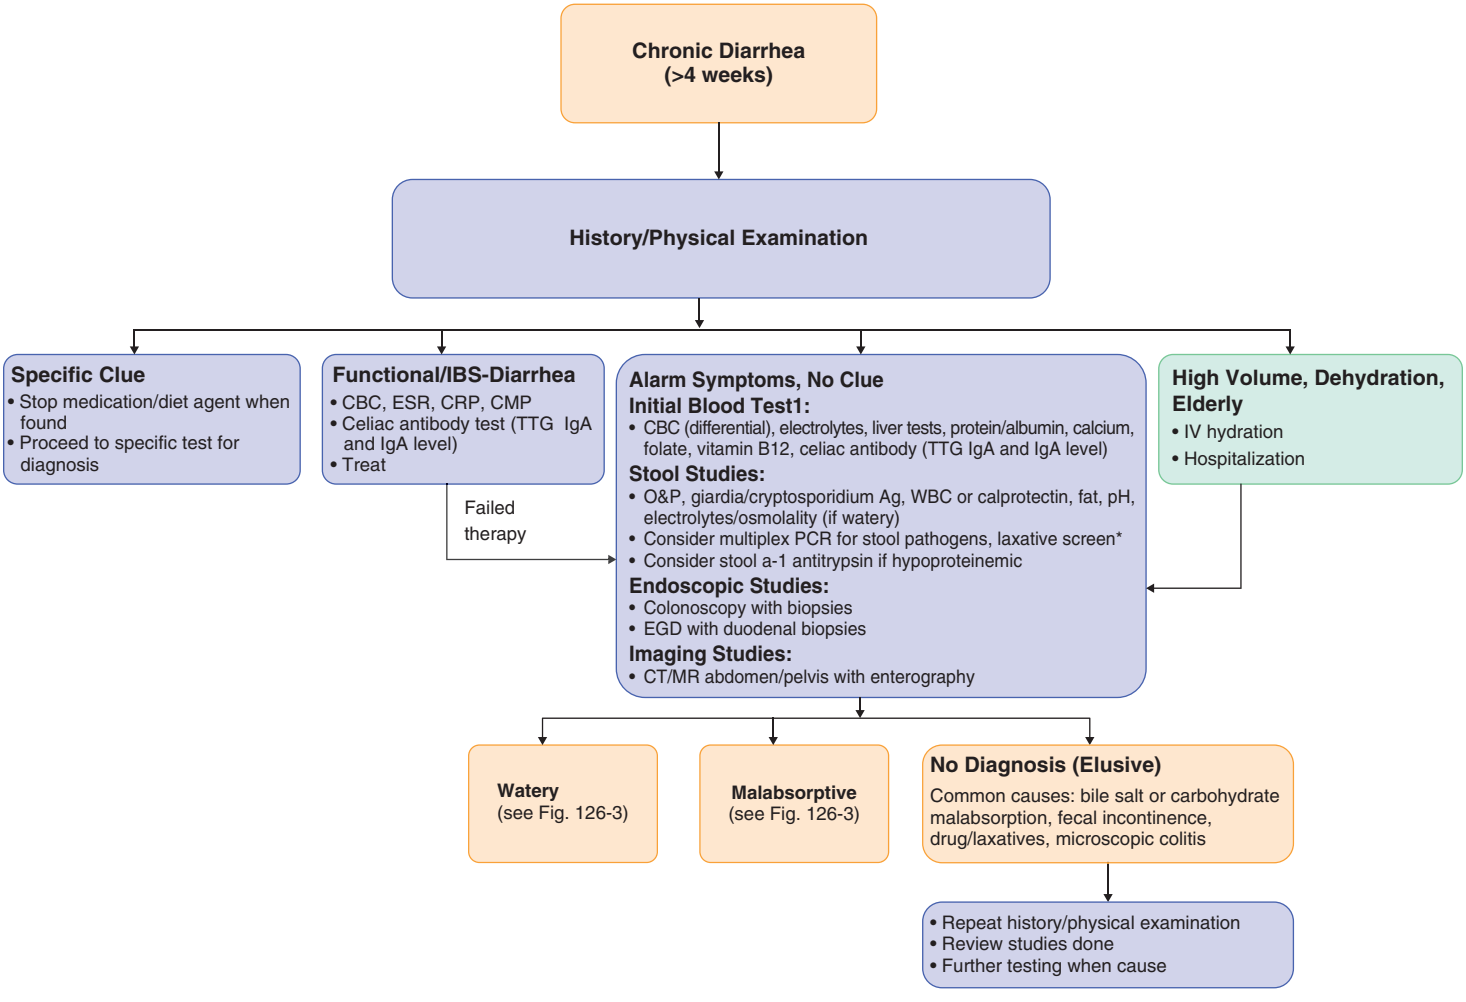

FIGURE 126-2. Initial approach to chronic diarrhea. *Perform multiplex PCR for stool pathogens in those who are immunosuppressed; perform laxative screen if laxative abuse is suspected. Ag = antigen; CBC = complete blood count; CMP = comprehensive metabolic panel; CRP = C-reactive protein; CT = computed tomography; EGD = esophagogastroduodenoscopy; EIA = enzyme-based immunoassay; ESR = erythrocyte sedimentation rate; IgA = immunoglobulin A; IV = intravenous; MR = magnetic resonance; O&P = ova and parasites; PCR = polymerase chain reaction; TTG = tissue transglutaminase; WBC = white blood cells.

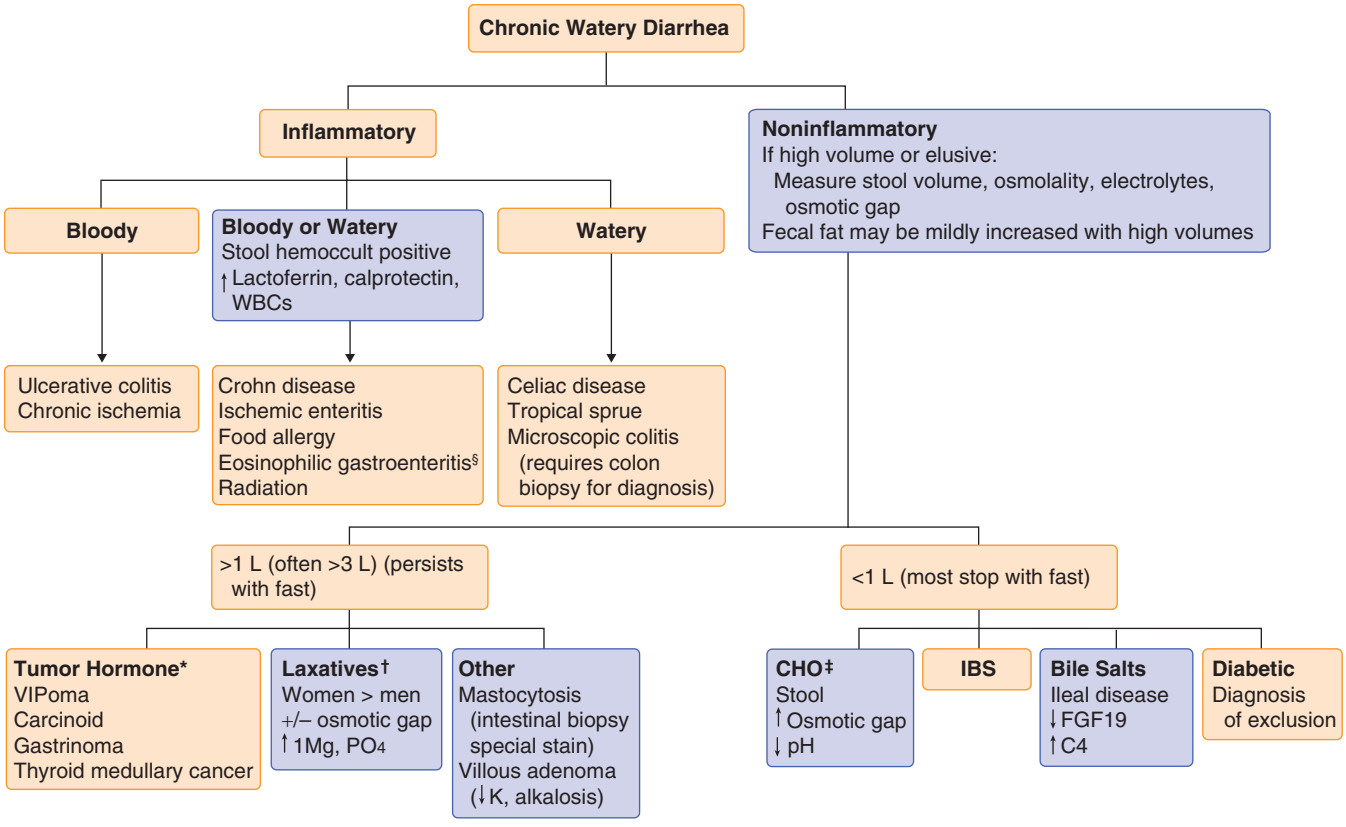

FIGURE 126-3. Approach to the evaluation of watery diarrhea. Many diarrheas have more than one mechanism (i.e., osmotic, secretory, inflammatory). Other causes include medications, postsurgical (vagotomy, Nissan wrap, cholecystectomy), hyperthyroidism, and alcohol. *VIPoma: >3 L output daily "pancreatic cholera," elevated VIP level. Carcinoid: elevated urine 5-hydroxyindole acetic acid, positive OctreoScan. Gastrinoma: elevated gastrin level, positive secretin stimulation test, diarrhea due to high volume of acid secretion. Thyroid medullary cancer: elevated calcitonin level. †Stool volume may be high or low volume depending on dose ingested, may respond to fasting. ‡Carbohydrate malabsorption (CHO) may be due to lactase deficiency, dietary fructose, sorbitol in diabetic candies or liquid medications. §Full-thickness biopsy may be needed for diagnosis. C4 = 7α-hydroxy-4-cholesten-3-one; FGF = fibroblast growth factor; IBS = irritable bowel syndrome; WBCs = white blood cells.

Imaging

Malabsorption may be suggested if a flat plate radiograph of the abdomen shows pancreatic calcification (Chapter 119). Some diseases (e.g., previous gastric surgery, gastrocolic fistulas, blind loops from previous intestinal anastomoses, small intestine strictures, multiple jejunal diverticula, abnormal intestinal motility that could lead to bacterial overgrowth) may be shown by computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen after administration of oral contrast agents or by a traditional upper gastrointestinal and small bowel barium studies. CT or magnetic resonance (MR) enterography, which uses oral neutral contrast to enhance the bowel wall, may show diagnostic evidence of advanced inflammatory bowel disease or changes suggestive of lymphoma, eosinophilic gastroenteritis, or radiation enterocolitis. Somatostatin receptor scintigraphy with gallium-68 or copper-64–labeled dotatate positron emission tomography (PET) scan is useful in localizing neuroendocrine tumors.

Endoscopy and Biopsy

Upper endoscopy with duodenal biopsies should be undertaken if serologic tests for celiac disease are positive or diagnostic clues suggest small bowel mucosal malabsorption (Chapter 120). Some patients with celiac disease may have mild inflammation or patchy mucosal disease and require duodenal bulb biopsies or enteroscopy with jejunal biopsies for diagnosis. Wireless video capsule endoscopy (Chapter 120) and balloon-assisted enteroscopy are used to diagnose refractory celiac disease and other diseases that reside deep in the small bowel. Patients with severe watery or elusive diarrhea should have a colonoscopy to the terminal ileum to assess for villous adenomas, microscopic colitis, mastocytosis, or early inflammatory bowel disease. Colonoscopy also may show brown pigmentation suggestive of melanosis coli due to chronic use of anthracene laxatives. Terminal ileal ulcers may indicate infectious or inflammatory bowel disease.

Other Laboratory Tests

Malabsorption

If chronic diarrhea is the presenting symptom, a stool examination for ova and parasites and a PCR test for *Giardia* or stool antigen-capture enzyme-linked immunosorbent assay (ELISA) should be obtained. A stool test for fat on a high-fat diet (70 to 100 g/day) is the best available screening test for malabsorption (Table 126-6). If the fecal fat test result is negative, selective carbohydrate malabsorption or other causes of watery diarrhea should be considered. If the fecal fat test result is positive, further testing should be based on clinical suspicion for particular diseases. If pancreatic insufficiency is suspected, imaging studies of the pancreas should be performed. If bacterial overgrowth is suspected, culture of an intestinal aspirate or a breath test should be obtained. Small bowel contrast imaging is useful in detecting structural abnormalities that predispose to bacterial overgrowth (Table 126-7). If proximal mucosal damage is suspected, multiple duodenal biopsies should be obtained. If there are no clues, CT or MR enterography may help to detect middle and distal small bowel mucosal diseases. Some individuals with celiac disease present with selective nutrient deficiencies without diarrhea. In these cases, a tissue transglutaminase (tTG) immunoglobulin A (IgA) antibody test and total IgA level should be performed. In patients hospitalized for severe diarrhea or malnutrition, a more streamlined evaluation usually includes a multiplex PCR stool test for pathogens; stool fat test; an abdominal imaging study; and a biopsy of the small intestine and colon.

Watery Diarrhea

Breath tests to measure the respiratory excretion of H_2 and methane after administration of carbohydrates can assess carbohydrate malabsorption or bacterial overgrowth (see Table 126-6).

The diagnosis of rare neuroendocrine tumors, such as carcinoids, gastrinoma, VIPoma, medullary carcinoma of the thyroid, glucagonoma, somatostatinoma, and systemic mastocytosis, is made by showing elevated blood levels of serotonin, chromogranin A, or urinary 5-hydroxyindoleacetic acid and serum levels for gastrin, vasoactive intestinal peptide, calcitonin, glucagon, somatostatin, histamine, or prostaglandins (Chapter 213). Somatostatin receptor scintigraphy and PET dotatate scanning are useful in the diagnosis and evaluation of neurodendocrine tumors (Chapter 213).

TABLE 126-6 TESTS FOR THE EVALUATION OF MALABSORPTION*

TEST	COMMENTS
GENERAL TESTS OF ABSORPTION	
Quantitative stool fat test	Gold standard test of fat malabsorption. Requires ingestion of a high-fat diet (70-100 g) for 2 days before and during the collection. Stool is collected for 2-3 days. Normally, <7 g/24 hr is excreted on a high-fat diet. Borderline abnormalities of 8-14 g/24 hr may be seen in secretory or osmotic diarrheas that are not caused by malabsorption. There are false-negative findings if fat intake is inadequate. False-positive results can occur if the nonabsorbable fat olestra is ingested or mineral oil laxatives or rectal suppositories (e.g., cocoa butter) are given to the patient before stool collection.
Qualitative stool fat test	The nuclear magnetic resonance method determines the percentage of fat in the stool (normal, <20%). The test depends on an adequate fat intake (100 g/day). There is high sensitivity (90%) and specificity (90%) with fat malabsorption of >10 g/24 hr. Sensitivity drops with stool fat in the range of 6-10 g/24 hr.
Hydrogen breath test	Most useful in the diagnosis of lactase deficiency. An oral dose of lactose (25 g) is administered after measurement of basal breath H_2 levels. The sole source of H_2 in the mammal is bacterial fermentation; unabsorbed lactose makes its way to colonic bacteria, resulting in excess breath H_2. A *late peak* within 3-6 hr of >20 ppm of exhaled H_2 after lactose ingestion suggests lactose malabsorption. Absorption of other carbohydrates (e.g., sucrose, glucose, fructose) also can be tested.
SPECIFIC TESTS FOR MALABSORPTION	
Tests for Pancreatic Function	
Secretin stimulation test	The gold standard test of pancreatic function. Requires duodenal intubation with a double-lumen tube and collection of pancreatic juice in response to intravenous secretin. Allows measurement of bicarbonate (HCO_3^-) and pancreatic enzymes. A sensitive test of pancreatic function, but labor intensive and invasive.
Secretin-enhanced MRCP	Noninvasive test for the detection of exocrine dysfunction in early chronic pancreatitis. The signal intensity ratio of pancreas to spleen has a significant positive correlation with the pancreatic fluid bicarbonate level as measured by the ductal secretin test. A ratio of 1 : 2 has a 77% sensitivity and 83% specificity for diagnosing pancreatic exocrine dysfunction, and it also has a strong correlation with histopathology of non-calcific chronic pancreatitis.
Fecal elastase-1 test	Stool test for pancreatic function. Equal sensitivity to the secretin stimulation test for the diagnosis of moderate to severe pancreatic insufficiency. Unreliable with mild insufficiency. False-positive results occur with increased stool volume and intestinal mucosal diseases.
Tests for Bacterial Overgrowth	
Quantitative culture of small intestinal aspirate	Gold standard test for bacterial overgrowth. Greater than 10^3 colony-forming units (CFU)/mL in the jejunum suggests bacterial overgrowth. Requires special anaerobic sample collection, rapid anaerobic and aerobic plating, and care to avoid oropharyngeal contamination. False-negative results occur with focal jejunal diverticula and when overgrowth is distal to the site aspirated.
Hydrogen breath test	The 50-g glucose breath test has a sensitivity of 90% for growth of 10^5 colonic-type bacteria in the small intestine. If bacterial overgrowth is present, increased H_2 is excreted in the breath. An early hydrogen level (<90 min) of >20 ppm suggests bacterial overgrowth. Specificity is increased when performed with simultaneous nuclear scintigraphy to define transit time to the cecum. False-positive results occur in patients with rapid transit. False-negative results occur with non–hydrogen-producing organisms. Concomitant measurement of breath methane improves test sensitivity.
Tests for Mucosal Disease	
Small bowel biopsy	Obtained for a specific diagnosis when there is a high index of suspicion for small intestinal disease. Several biopsy specimens (4-5) must be obtained to maximize the diagnostic yield. Distal duodenal biopsy specimens are usually adequate for diagnosis, but occasionally duodenal bulb biopsies or enteroscopy with jejunal biopsy specimens is necessary. Small intestinal biopsy provides a specific diagnosis in some diseases (e.g., intestinal infection, Whipple disease, abetalipoproteinemia, agammaglobulinemia, lymphangiectasia, lymphoma, amyloidosis). In other conditions, such as celiac disease and tropical sprue, the biopsy specimens show characteristic findings, but the diagnosis is made by positive celiac serology or improvement after specific treatment.
Test of Ileal Function	
^{75}SeHCAT test	This is a test of bile acid absorption. Seven days after ingestion of radiolabeled synthetic selenium–homocholic acid conjugated with taurine (^{75}SeHCAT), whole-body retention is measured by a gamma-counting device. The result is expressed as a fraction of baseline ingestion. Retention values of <10% are abnormal and indicate bile acid malabsorption with a sensitivity of 80-90% and specificity of 70-100%. The radiation dose is equivalent to that of a plain chest x-ray. Liver disease and bacterial overgrowth may give false results. Not approved for use in the United States.

*Not all these tests are readily available. A strong suspicion for any disease warrants forgoing an extensive work-up and obtaining the test with highest diagnostic yield. In some cases, empirical treatment, such as removing lactose from the diet of an otherwise healthy individual with lactose intolerance, is warranted without any testing.
MRCP = magnetic resonance cholangiopancreatography.

Inflammatory Diarrhea

Stool occult blood, white blood cells, and calprotectin are helpful tests for bowel inflammation. Video capsule endoscopy of the small bowel may detect ulcerations deep in the small bowel not reachable by standard upper or lower endoscopy and not detected with conventional radiologic imaging. However, the risk for capsule retention in the small bowel is high in patients with Crohn disease or heavy NSAID use, particularly when there is a history of obstructive symptoms. The most sensitive test for protein-losing enteropathy is measurement of intestinal protein loss by 24-hour stool excretion or clearance of α_1-antitrypsin.

Stool Examination in Elusive Diarrhea

An important adjunct to diagnosing the cause of diarrhea is to examine the stool. The greasy, bulky stool of steatorrhea and the bloody stool of gut inflammation are distinctive. Stool collections (see Table 126-6) can be analyzed for weight, volume, fat, electrolytes (Na^+, K^+, Cl^-), osmolality, pH, and a laxative screen (SO_4^{2-}, PO_4^{2-}, Mg^{2+}). Stool or urine can be analyzed for emetine (a component of ipecac), bisacodyl, castor oil, or anthraquinone.

Carbohydrate malabsorption lowers stool pH because of colonic fermentation of carbohydrate to short-chain fatty acids. Stool pH less than 5.3 usually means pure carbohydrate malabsorption, whereas in the generalized malabsorptive diseases, stool pH is greater than 5.6 and usually greater than 6.0.

The normal stool osmotic gap, which is the difference between stool osmolality (or 290 mOsm) and twice the stool Na^+ and K^+ concentrations, is 50 to 125. In secretory diarrheas, the colon's capacity for adjusting electrolyte concentrations is overwhelmed, the stool osmotic gap is less than 50, and stool electrolytes more nearly resemble plasma electrolytes (Na^+ concentrations are usually >90 mmol/L, K^+ concentrations usually <10 mmol/L), except for higher HCO_3^- concentrations (usually >50 mmol/L). In osmotic diarrhea, the

presence of uncharged solute or unmeasured cation in the colonic lumen draws in water, depresses stool Na^+ (usually <60 mmol/L) and K^+ concentrations, and results in a stool osmotic gap greater than 125. Stools with Na^+ concentrations between 60 and 90 mmol/L and calculated osmotic gaps between 50 and 100 can result from either secretory or malabsorptive abnormalities. Patients with Mg^{2+}-induced diarrhea may be diagnosed by fecal Mg^{2+} values of more than 50 mmol/L. Sodium anion–induced diarrheas (Na_2SO_4, Na_2PO_4) mimic secretory diarrhea because the stool Na^+ content is high (>90 mmol/L) and there is no osmotic gap; this diarrhea may be diagnosed by determining stool Cl^- concentration because these anions displace stool Cl^-, resulting in a depressed stool Cl^- value (usually <20 mmol/L). A low stool osmolality suggests contamination of stool with dilute urine or water in the case of factitious diarrhea.

SPECIFIC CAUSES OF CHRONIC DIARRHEA

PROLONGED, PERSISTENT INFECTIOUS DIARRHEAS

Prolonged infectious diarrheas (>2 weeks) may be due to persistent or recurrent infections. These diarrheas occur most commonly in children exposed to unsafe drinking water in developing countries, patients who have acquired immunodeficiency syndrome (AIDS) or are immunosuppressed for other reasons, and recent travelers. Recurrent or prolonged infectious diarrhea may lead to severe malnutrition and death (mortality rate, 50%). Treatment for children includes nutrition support with supplemental vitamin A (200,000 IU orally twice yearly) and zinc (20 mg elemental orally daily for 14 days). Severe disease may require total parenteral nutrition.

In patients with AIDS, protracted diarrhea may be caused by treatable agents such as *E. histolytica, Giardia*, or *Strongyloides* or by organisms such as *Cryptosporidium, Isospora belli,* and microsporidia that are difficult to treat or untreatable. The most effective treatment is retroviral therapy to improve the immune system (Chapter 357).

In travelers returning from developing countries who have infectious diarrhea that persists for longer than 3 to 4 weeks, stool should be examined for culture and for ova and parasites. In patients with a recent history of antibiotic use, stool also should be sent for *C. difficile* toxin or PCR. Any specific organisms that are identified should be treated. If treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone has been unsuccessful, tetracycline (250 mg orally four times daily for 7 to 10 days), doxycycline (100 mg orally two times a day for 7 to 10 days), or metronidazole (250 mg orally three times daily for 7 to 10 days) can be tried. After documented infectious diarrhea, 25% of patients experience pain, bloating, urgency, a sense of incomplete evacuation, and loose stools for 6 months or longer; some of these patients have celiac disease, so screening (see later) is warranted in this setting. When no other cause is found, these patients are deemed to have postinfectious irritable bowel syndrome.

Sporadic outbreaks of severe, prolonged diarrhea, often greater than 1 year in duration, occasionally have been reported. This form of prolonged diarrhea is called *Brainerd diarrhea*. The organism has yet to be identified. The diarrhea is difficult to treat; cholestyramine (4 g orally three times daily) may be helpful.

MALABSORPTIVE SYNDROMES

Malabsorption is caused by many different diseases, drugs (e.g., the lipase inhibitor orlistat; Chapter 201), and nutritional products (the nonabsorbable fat olestra) that impair intraluminal digestion, mucosal absorption, or delivery of the nutrient to the systemic circulation (E-Fig. 126-2; see Table 126-4). Dietary fat is the nutrient most difficult to absorb. Fatty stools (steatorrhea) are the hallmark of malabsorption; a stool test for fat is the best screening test. Malabsorption does not always cause diarrhea. Clinical signs of vitamin or mineral deficiencies may occur in the absence of diarrhea. A careful focused history is crucial in guiding further testing to confirm the suspicion of malabsorption and to make a specific diagnosis (Fig. 126-4). The goals of treatment are to correct or treat the underlying disease and replenish losses of water, electrolytes, and nutrients.

CONDITIONS THAT IMPAIR INTRALUMINAL DIGESTION

Most digestion and absorption of nutrients occur in the small intestine (see E-Fig. 126-2). Carbohydrates and most dietary proteins are water soluble and readily digested by pancreatic enzymes. Pancreatic proteases (trypsinogen, chymotrypsinogen, procarboxypeptidases) are secreted from acinar cells in inactive forms. The cleavage of trypsinogen to trypsin by the duodenal brush-border peptidase enteropeptidase (enterokinase) allows trypsin to cleave the remaining trypsinogen and other proteases to their active form.

Most dietary lipids (long-chain triglycerides, cholesterol, and fat-soluble vitamins) are water insoluble and must undergo lipolysis and incorporation into mixed micelles before they can be absorbed across the intestinal mucosa. Pancreatic lipase, in the presence of its cofactor, colipase, cleaves long-chain triglycerides into fatty acids and monoglycerides. The products of lipolysis interact with bile salts and phospholipids to form mixed micelles, which also incorporate cholesterol and fat-soluble vitamins (D, A, K, and E) in their hydrophobic centers. Bicarbonate secreted from pancreatic duct cells is physiologically important to neutralize gastric acid because pancreatic enzyme activity and bile salt micelle formation are optimum at a luminal pH of 6 to 8.

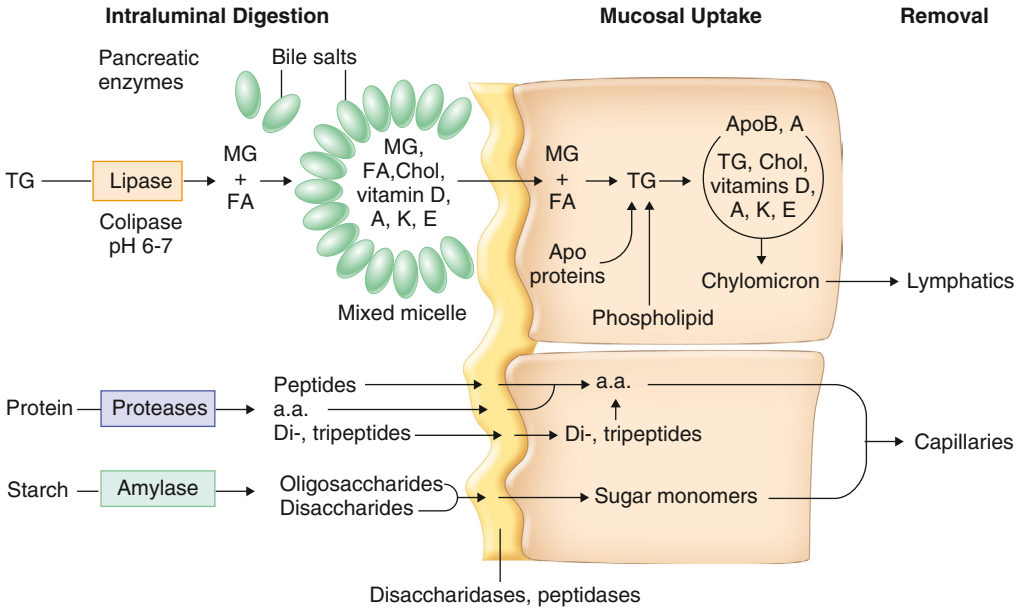
IMPAIRED MIXING

Surgical alterations, such as partial gastrectomy with gastrojejunostomy (Billroth II anastomosis) or gastrointestinal bypass surgeries for obesity, result in the release of biliary and pancreatic secretions into the intestine at a site remote from the site of entry of gastric contents. This imbalance can result in impaired lipolysis and impaired micelle formation, with subsequent fat malabsorption. Bypass of the duodenum also impairs absorption of iron, folate, and calcium. Rapid transit through the jejunum contributes to the malabsorption of nutrients. Individuals with these conditions also have surgical anastomoses that predispose to bacterial overgrowth.

DUMPING SYNDROME

After esophageal (distal esophagectomy, myotomy for achalasia), gastric (gastrectomy, non–pylorus-sparing Whipple surgery, gastrojejunostomy, Nissan wrap, and hiatal hernia repair), and bariatric (Roux-en-Y gastric bypass) surgeries, the unregulated delivery of concentrated sugars and food into the duodenum and jejunum results in altered insulin regulation, maldigestion, osmotic movement of fluid into the intestinal lumen, and rapid transit such that intestinal contact time is insufficient for absorption of nutrients. Glucagon-like peptide-1 (GLP-1) plays a key role in the pathophysiologic response of hyperinsulinemic hypoglycemia following the ingestion of concentrated sweets.[9] Patients may present with severe diarrhea, malabsorption, abdominal cramping, gas, and weight loss. Some patients have associated sweatiness, dizziness, and altered cognition because of postprandial hypoglycemia. Diagnosis is made by characteristic symptoms and a mixed meal tolerance test or continuous glucose monitoring for hypoglycemia.

Treatment is with a diet that is low in concentrated sugars divided into six small meals. Administration of pectin (15 g with each meal) may slow gastric emptying in patients who have a stomach. In patients who are refractory to dietary measures, a short-acting somatostatin analogue (e.g., octreotide, 25



E-FIGURE 126-2. Phases of intestinal digestion and absorption of dietary fat, protein, and carbohydrate. a.a. = amino acids; ApoB, A = apolipoproteins B and A; Chol = cholesterol; FA = fatty acids; MG = monoglycerides; TG = triglycerides.

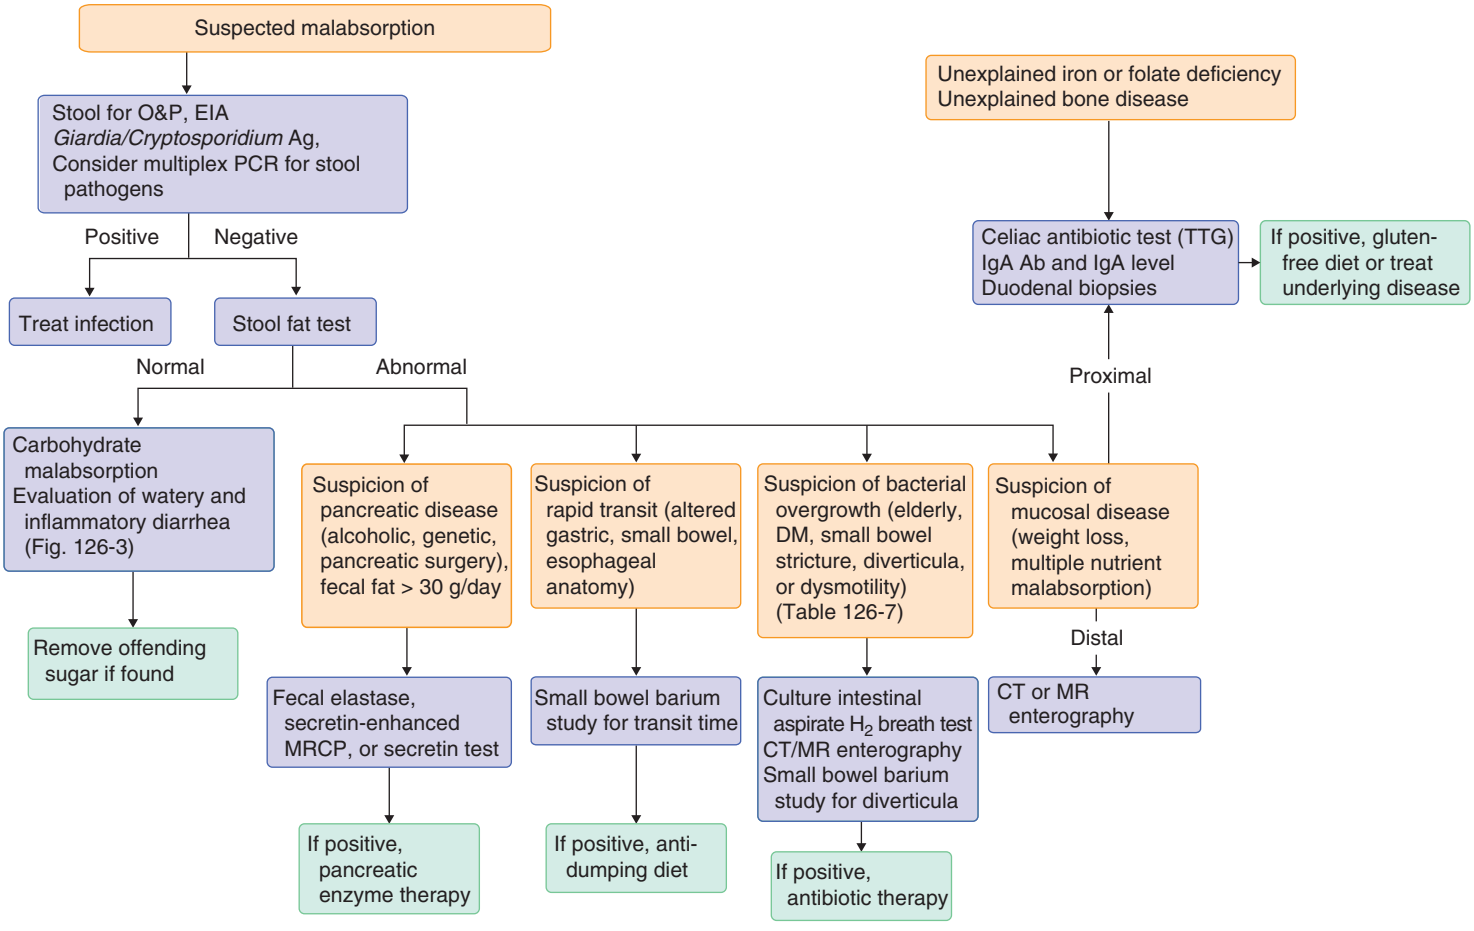


FIGURE 126-4. Approach to the diagnosis of malabsorption. Ab = antibody; Ag = antigen; CT = computed tomography; DM = diabetes mellitus; EIA = enzyme immunoassay; Ig = immunoglobulin; MR = magnetic resonance; MRCP = magnetic resonance cholangiopancreatography; O&P = ova and parasites; PCR = polymerase chain reaction; TTG = tissue transglutaminase.

to 200 μg SQ three times daily) or the better tolerated intramuscular preparation (10 to 20 mg monthly) improves dumping symptoms. In patients with predominant reactive hypoglycemia 1 to 3 hours after a meal (late dumping), an α-glycosidase hydrolase inhibitor (e.g., acarbose, 50 to 100 mg orally three times daily) that blocks carbohydrate absorption in the small bowel may be beneficial. Continuous jejunal tube feeding is also effective. GLP-1 receptor agonists also are a promising therapy for patients with symptomatic hypoglycemia.

IMPAIRED LIPOLYSIS

A deficiency in pancreatic lipase may be caused by the congenital absence of pancreatic lipase or by destruction of the pancreatic gland as a result of alcohol-related pancreatitis, cystic fibrosis, or pancreatic cancer. Pancreatic lipase also can be denatured by excess secretion of gastric acid (e.g., gastrinoma; Chapter 213). In such cases, lipase denaturation can be offset by treatment with a high-dose proton pump inhibitor (e.g., omeprazole 60 mg/day orally) to block acid secretion.

CHRONIC PANCREATITIS

Chronic pancreatitis (Chapter 130) is the most common cause of pancreatic insufficiency and impaired lipolysis. In the United States, chronic pancreatitis most commonly results from alcohol use disorder; in contrast, tropical (nutritional) pancreatitis is most common worldwide. Malabsorption of fat does not occur until more than 90% of the pancreas is destroyed.

CLINICAL MANIFESTATIONS

Individuals with pancreatic causes of malabsorption typically present with bulky, fat-laden stools (usually >30 g of fat daily), abdominal pain, and diabetes, although some present with diabetes in the absence of gastrointestinal symptoms. Stools usually are not watery because undigested triglycerides form large emulsion droplets with little osmotic force and, in contrast to fatty acids, do not stimulate water and electrolyte secretion in the colon. Deficiency of fat-soluble vitamins is seen only rarely, presumably because gastric and residual pancreatic lipase generates enough fatty acids for some micelle formation. In severe disease, subclinical protein malabsorption, manifested by the presence of undigested meat fibers in the stool, and subclinical carbohydrate malabsorption, manifested by gas-filled, floating stools, can occur. Weight loss, when it occurs, is most often caused by decreased oral intake to avoid abdominal pain or diarrhea and less commonly by malabsorption. Pancreatic enzyme replacement and analgesics are the mainstays of treatment for chronic pancreatitis (see Table 130-5 in Chapter 130).

DIAGNOSIS

Between 30 and 40% of individuals with alcohol-related chronic pancreatitis have calcifications on abdominal radiographs. A qualitative or quantitative test for fecal fat is positive in individuals whose pancreas is more than 90% destroyed. Noninvasive tests of pancreatic function are not sensitive enough to detect mild to moderate insufficiency, so secretin-enhanced magnetic resonance cholangiopancreatography (MRCP) or the endoscopic secretin stimulation test is preferred (see Table 126-6) if it can be obtained.

IMPAIRED MICELLE FORMATION

Bile salt concentrations in the intestinal lumen can fall to less than the critical concentration (2 to 3 mmol/L) needed for micelle formation because of decreased bile salt synthesis (severe liver disease), decreased bile salt delivery (cholestasis), or removal of luminal bile salts (bacterial overgrowth, terminal ileal disease or resection, cholestyramine therapy, acid hypersecretion). Fat malabsorption resulting from impaired micelle formation is generally not as severe as malabsorption resulting from pancreatic lipase deficiency, presumably because fatty acids and monoglycerides can form lamellar structures, which to a certain extent can be absorbed. Malabsorption of fat-soluble vitamins (D, A, K, and E) may be marked, however, because micelle formation is required for their absorption.

Decreased Bile Salt Synthesis and Delivery

Malabsorption can occur in individuals with cholestatic liver disease or bile duct obstruction, as well as in occasional patients who have undergone prior cholecystectomy.[10] The clinical consequences of malabsorption are seen most

often in women with primary biliary cirrhosis because of the prolonged nature of the illness. Although these individuals can present with steatorrhea, osteoporosis or, less commonly, osteomalacia is the most common presentation. The cause of bone disease in these patients is poorly understood and often is not related to vitamin D deficiency. Bone disease is treated with calcium supplements (and vitamin D if a deficiency is documented), weight-bearing exercise, and a bisphosphonate (e.g., alendronate, 10 mg/day orally or 70 mg orally once weekly).

Intestinal Bacterial Overgrowth

In health, only small numbers of lactobacilli, enterococci, gram-positive aerobes, or facultative anaerobes can be cultured from the upper small bowel lumen. Motility and acid are the most important factors in keeping the number of bacteria in the upper small bowel low. Any condition that produces local stasis or recirculation of colonic luminal contents allows development of a predominantly "colonic" flora (coliforms and anaerobes, such as *Bacteroides* and *Clostridium*) in the small intestine (see Table 126-7).[11] Anaerobic bacteria cause impaired micelle formation by releasing cholylamidases, which deconjugate bile salts. The unconjugated bile salts, with their higher pK_a, are more likely to be in the protonated form at the normal upper small intestinal pH of 6 to 7 and can be absorbed passively. As a result, the concentration of bile salts decreases in the intestinal lumen and can fall to less than the critical micellar concentration, causing malabsorption of fats and fat-soluble vitamins. Vitamin B_{12} deficiency and carbohydrate malabsorption also can occur with generalized bacterial overgrowth. Anaerobic bacteria ingest vitamin B_{12} and release proteases that degrade brush-border disaccharidases. Although anaerobic bacteria use vitamin B_{12}, they synthesize folate. Individuals with bacterial overgrowth may have low serum vitamin B_{12} levels but normal or high folate levels; this helps distinguish bacterial overgrowth from tropical sprue, in which vitamin B_{12} and folate levels are usually low because of decreased mucosal uptake.

CLINICAL MANIFESTATIONS

Individuals with bacterial overgrowth can present with diarrhea, abdominal cramps, gas and bloating, anorexia, weight loss, and signs and symptoms of vitamin B_{12} and fat-soluble vitamin deficiency. Watery diarrhea occurs because of the osmotic load of unabsorbed carbohydrates and stimulation of colonic secretion by unabsorbed fatty acids.

DIAGNOSIS

The diagnosis of bacterial overgrowth should be considered in elderly people and in individuals with predisposing underlying disorders (see Table 126-7).[12] Bacterial overgrowth may be associated with the irritable bowel syndrome. The identification of greater than 10^3 CFU/mL in a culture of small intestinal aspirate is the gold standard in diagnosis but is not readily available. Noninvasive options, which have a wide range of sensitivities and specificities compared with those of intestinal culture, are the carbohydrate substrate-based glucose hydrogen and methane breath tests (see Table 126-6). In individuals with low vitamin B_{12} levels, a Schilling test before and after antibiotic therapy can be diagnostic if available (Chapter 150).

TREATMENT

The goals of treatment are to correct the structural or motility defect, if possible; to eradicate offending bacteria; and to provide nutritional support.[13] Acid-reducing agents should be stopped, if possible. Treatment with antibiotics should be based on culture results whenever possible; otherwise, empirical treatment is given. Rifaximin (400 mg orally three times daily) is effective,[A6] but less so in individuals with an excluded (blind) intestinal loop. Tetracycline (250 to 500 mg orally four times daily), doxycycline (100 mg orally two times daily), or a broad-spectrum antibiotic against aerobes and enteric anaerobes (ciprofloxacin, 500 mg orally twice daily; amoxicillin-clavulanic acid, 250 to 500 mg orally three times daily; cephalexin, 250 mg orally four times daily with metronidazole, 250 mg orally three times daily) should be given for 14 days. In patients with small bowel dysmotility, prokinetic agents such as prucalopride (2 to 4 mg orally once daily), metoclopramide (10 mg orally four times daily) or erythromycin (250 to 500 mg orally four times daily) can be tried. Octreotide (50 μg subcutaneously every day) may improve motility and reduce bacterial overgrowth in individuals with scleroderma. If the structural abnormality or motility disturbance cannot be corrected, the patient is at risk for malnutrition and deficiencies of vitamin B_{12} and fat-soluble vitamins. Cyclic treatment (1 to 3 weeks of every 4 to 6 weeks) with rotating antibiotics may be required in these patients to prevent recurrent bouts of bacterial overgrowth. If supplemental calories are needed, medium-chain triglycerides should be given because they do not depend on micelle formation for their absorption. Monthly treatment with vitamin B_{12} should be considered, along with supplemental vitamins D, A, K, and E and calcium.

ILEAL DISEASE

Disease of the terminal ileum is most commonly due to Crohn disease, which also may lead to ileal resection, but it also can be caused by radiation enteritis, tropical sprue, tuberculosis, *Yersinia* infection, or idiopathic bile salt malabsorption. These diseases cause bile salt wasting in the colon.

The clinical consequences of bile salt malabsorption are related directly to the length of the diseased or resected terminal ileum. In an adult, if less than 100 cm of ileum is diseased or resected, watery diarrhea results because of stimulation of colonic fluid secretion by unabsorbed bile salts. Bile acid diarrhea responds to cholestyramine (2 to 4 g taken at breakfast, lunch, and dinner).[14] If more than 100 cm of ileum is diseased or resected, bile salt losses (>3 g/day) in the colon exceed the capacity for increased bile salt synthesis in the liver, the bile salt pool shrinks, and micelle formation is impaired. As a result, steatorrhea ensues, and fatty acid–induced intestinal secretion synergizes with the bile acid–induced secretion to cause diarrhea. Treatment is with a low-fat diet, vitamin B_{12} (300 to 1000 μg subcutaneously or intramuscularly once every month), dietary supplements of calcium (500 mg orally two or three times daily, monitor 24-hour urine calcium for adequacy of dose), and a multiple vitamin and mineral supplement. An antimotility agent should be given for diarrhea. Bile salt binders may worsen diarrhea. Screening for fat-soluble vitamin deficiencies (vitamins A and E, 25-OH vitamin D, and prothrombin time) and bone disease (bone densitometry, serum calcium, intact parathyroid hormone, 24-hour urine for calcium) should be done.

Three long-term complications of chronic bile salt wasting and fat malabsorption are renal stones, bone disease (osteoporosis and osteomalacia), and gallstones. Oxalate renal stones occur as a consequence of excess free oxalate absorption in the colon. Free oxalate is generated when unabsorbed fatty acids bind luminal calcium, which is then unavailable for binding oxalate. Renal oxalate stones sometimes can be avoided with a low-fat, low-oxalate diet and calcium supplements. Bone disease is caused by impaired micelle formation with a resulting decrease in absorption of vitamin D; year-round sun exposure reduces this complication. Vitamin D (50,000 U orally one to three times per week) and calcium supplements (500 mg orally two to three times daily) should be given to susceptible individuals, but vitamin D levels and serum and urinary calcium must be monitored for response to treatment because excess vitamin D can be toxic. The mechanism of gallstone formation in these individuals is unclear; pigmented gallstones are most common.

CONDITIONS THAT IMPAIR MUCOSAL ABSORPTION

PATHOBIOLOGY

Nutrients are absorbed along the entire length of the small intestine, with the exception of iron and folate, which are absorbed in the duodenum and proximal jejunum, and bile salts and cobalamin (vitamin B_{12}), which are absorbed in the distal ileum. The efficiency of nutrient uptake at the mucosa is influenced by the number of villus absorptive cells, the presence of functional hydrolases and specific nutrient transport proteins on the brush-border membrane, and transit time. Transit time determines the contact time of luminal contents with the brush-border membrane and influences the efficiency of nutrient uptake across the mucosa.

Mucosal malabsorption can be caused by specific (usually congenital) brush-border enzyme or nutrient transporter deficiencies or by generalized diseases that damage the small intestinal mucosa or result in surgical resection or bypass of the small intestine. The nutrients malabsorbed in these general malabsorptive diseases depend on the site of intestinal injury (proximal, distal, or diffuse) and the severity of damage. The main mechanism of malabsorption in these conditions is a decrease in surface area available for absorption. Some conditions (infection, celiac disease, tropical sprue, food allergies, and GVHD) are characterized by intestinal inflammation and villus flattening; others are characterized by ulceration (ulcerative jejunitis, NSAIDs, Crohn disease), infiltration (amyloidosis), or ischemia (radiation enteritis, mesenteric ischemia).

Long-chain fatty acids are transported across the microvillus membrane of villus epithelial cells by CD36 and the fatty acid transport protein FATP4. The bile salts from mixed micelles remain in the intestinal lumen and are absorbed in the distal ileum by sodium-dependent cotransport. Oligosaccharides and larger oligopeptides (products of pancreatic enzyme digestion), sucrose, and lactose are hydrolyzed further by enzymes present in the brush-border membrane of villus epithelial cells before they are absorbed. Although only

sugar monomers (glucose, galactose, fructose) can be taken up at the apical epithelial cell membrane, dipeptides and tripeptides are readily taken into the cell.

Water-soluble vitamins are readily absorbed throughout the small intestine. Fat-soluble vitamins, minerals, and cobalamin are more difficult to absorb because of the requirement for micelle formation (vitamins D, A, K, and E), a divalent charge (magnesium, calcium, iron), or selected sites of uptake in the intestine (iron, cobalamin). Calcium is absorbed best in the proximal small intestine by a vitamin D–dependent calcium channel (TRPV6). Magnesium is absorbed in the small intestine by members of the transient receptor potential family (TRPM6 and TRPM7). Mutations in TRPM6 have been identified in the rare disorder hereditary hypomagnesemia. Ferrous iron is transported into intestinal epithelial cells by a proton-coupled metal-ion transporter (DMT1 or Nramp2) that has specificity for Fe^{2+} and other divalent cations (Mn^{2+}, Co^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, and Pb^{2+}). The reduced form of copper (Cu^{1+}) is absorbed by the copper transporter 1 (CTR1). Zinc (Zn^{2+}) is predominantly absorbed by the Srt-, Irt-like protein ZIP4. The absorption of calcium and nonheme iron is enhanced by solubilization with hydrochloric acid. Intraluminal compounds such as oxalate, phytate, and long-chain fatty acids bind to calcium and magnesium, decreasing their absorption. Individuals with severe mucosal disease or short-bowel syndrome with high fecal fluid outputs lose magnesium and zinc from endogenous secretions.

Folates (Chapters 150 and 199) are both taken in the diet and produced by bacteria in the colon. Dietary folates are reduced to their monoglutamate form in the lumen of the proximal intestine and absorbed predominantly by a proton-coupled folate transporter. Deficiency can be caused by poor intake or malabsorption secondary to intestinal disease or drugs.

The cobalamins (Chapters 150 and 199) are abundant in foods containing animal proteins (e.g., meat, seafood, eggs, milk). Dietary cobalamin is released from food in the stomach by acid-peptic digestion and binds to haptocorrin at gastric pH. Pancreatic enzymes degrade haptocorrin, thereby freeing cobalamin to bind to gastric intrinsic factor, which that is secreted from parietal cells. The intrinsic factor–cobalamin complex then travels to the distal ileum and binds to the cubam complex (cubulin and amnionless). Once transported into ileal enterocytes, intrinsic factor is degraded; cobalamin binds to transcobalamin II and is transported in the blood stream to target tissues. Various mutations in the factors required for these processes can cause hereditary juvenile cobalamin deficiency. Cobalamin (vitamin B_{12}) deficiency in industrialized countries is rarely due to poor dietary intake but rather reflects the inability to absorb cobalamin. This inability may be caused by a lack of intrinsic factor, consumption of cobalamin by overgrowth of anaerobic bacteria in the small bowel lumen, ileal disease or resection, or defective transcobalamin II. Large amounts of cobalamin are present in the liver (2 to 5 mg), and cobalamin is reabsorbed from bile through the enterohepatic circulation, thereby limiting daily losses to less than 1 µg. It usually takes 10 to 12 years for cobalamin deficiency to develop after it is eliminated from the diet, but deficiency can occur more rapidly (2 to 5 years) with malabsorptive syndromes. If lack of gastric acid causes food-cobalamin malabsorption, treatment with oral cyanocobalamin supplementation (Chapter 150) is curative.

LACTASE DEFICIENCY

EPIDEMIOLOGY

Acquired lactase deficiency is the most common cause of selective carbohydrate malabsorption. Most individuals, except those of northern European descent, begin to lose lactase activity by the age of 2 years. The prevalence of lactase deficiency is highest (85 to 100%) in persons of Asian, African, and Native American descent.

PATHOBIOLOGY

The persistence or nonpersistence of lactase activity is associated with a single nucleotide polymorphism C/T_{-13910} that is found upstream of the lactase gene on chromosome 2q21-22. Hypolactasia is associated with the C/C_{-13910} genotype in diverse ethnic groups. The mechanism by which this variant downregulates the lactase gene is not known, but functional studies suggest genotype-dependent alterations in levels of messenger RNA.

CLINICAL MANIFESTATIONS

Adults with lactase deficiency typically complain of gas, bloating, and diarrhea after the ingestion of milk or dairy products but do not lose weight. Unabsorbed lactose is osmotically active, drawing water followed by ions into the intestinal lumen.[15] On reaching the colon, bacteria metabolize lactose to short-chain fatty acids, carbon dioxide, and hydrogen gas. Short-chain fatty acids are transported with sodium into colonic epithelial cells, facilitating the reabsorption of fluid in the colon. If the colonic capacity for the reabsorption of short-chain fatty acids is exceeded, an osmotic diarrhea results (see later discussion of carbohydrate malabsorption in watery diarrhea).

DIAGNOSIS

The diagnosis of acquired lactase deficiency can be made by empirical treatment with a lactose-free diet, which results in resolution of symptoms; by the hydrogen breath test after oral administration of lactose; or by genetic testing. Many intestinal diseases cause secondary reversible lactase deficiency, including viral gastroenteritis, celiac disease, giardiasis, and bacterial overgrowth.

CELIAC DISEASE

DEFINITION AND EPIDEMIOLOGY

Celiac disease is a chronic inflammatory condition of the small intestine precipitated by the ingestion of wheat, rye, and barley in individuals with certain genetic predispositions.[16] The prevalence in general populations worldwide is approximately 1%. High-risk groups for celiac disease include first-degree relatives and individuals with type 1 diabetes mellitus, autoimmune thyroid disease, autoimmune liver disease, and Down, Turner, or Williams syndromes. Approximately 5% of patients diagnosed with diarrhea-predominant irritable bowel syndrome or with microscopic (lymphocytic) colitis have celiac disease.

PATHOBIOLOGY

Environmental and genetic factors are important in the development of celiac disease, with data suggesting a relationship with prior reovirus infection.[17] Approximately 10% of first-degree relatives of affected individuals are found to have celiac disease. Predisposition has been mapped to the human leukocyte antigen (HLA)-D region on chromosome 6. More than 90% of northern Europeans with celiac disease have the DQ2 heterodimer encoded by alleles DQA1*0501 and DQB1*0201, compared with 20 to 30% of controls. A smaller celiac group carries HLA-DQ8. Many non-HLA alleles identified in genome-wide association studies account for a small portion of genetic risk. Most such genes are involved in adaptive and innate immune responses. Overlap variants have been identified in diabetes, rheumatoid arthritis, and Crohn disease.

The alcohol-soluble protein fraction of wheat gluten, the gliadins, and similar prolamins in rye and barley trigger intestinal inflammation in susceptible individuals. Oat grains, which have prolamins rich in glutamine but not proline, are rarely toxic. Gliadins and similar prolamins with high proline content are relatively resistant to digestion by human proteases. Many gliadin and prolamin peptides have been identified that stimulate HLA-DQ2– and HLA-DQ8–restricted intestinal T-cell clones from individuals with celiac disease. In blood lymphocyte comprehensive screen assays, three immunodominant prolamin peptides have been identified from wheat, barley, and rye in DQ2 celiac individuals; dominant peptides differ in those with DQ8. The DQ2 protein expressed on antigen-presenting cells has positively charged binding pockets; tTG (the autoantigen recognized by endomysial antibody) may enhance intestinal inflammation by deamidation of select glutamine residues in gliadin and similar prolamins to negatively charged glutamic acid. In the deamidated form, most gliadin peptides have a higher binding affinity for DQ2 and are more potent stimulants of gluten-sensitized T cells. Villous atrophy may be caused by inflammation that is triggered by γ-interferon released from DQ2- or DQ8-restricted CD4 T cells in the lamina propria. Intraepithelial lymphocytes also directly kill intestinal epithelial cells under the influence of IL-15 released from stressed enterocytes.

CLINICAL MANIFESTATIONS

Celiac disease usually manifests early in life, at approximately 2 years of age (after wheat has been introduced into the diet), or later in the second to fourth decades of life, but it can occur at any age. It may first manifest clinically after abdominal surgery or an episode of infectious diarrhea.

Adults with celiac disease in the United States often present with anemia or osteoporosis without diarrhea and no or mild other gastrointestinal symptoms. Other extraintestinal manifestations of celiac disease include rash (dermatitis herpetiformis), neurologic disorders (peripheral neuropathy, ataxia, epilepsy), psychiatric disorders (depression, paranoia), reproductive disorders (infertility, spontaneous abortion), short stature, dental enamel hypoplasia, chronic hepatitis, and pancreatitis.

A minority of patients present with severe diarrhea, weight loss or growth retardation, and the clinical manifestations of vitamin and mineral deficiencies.

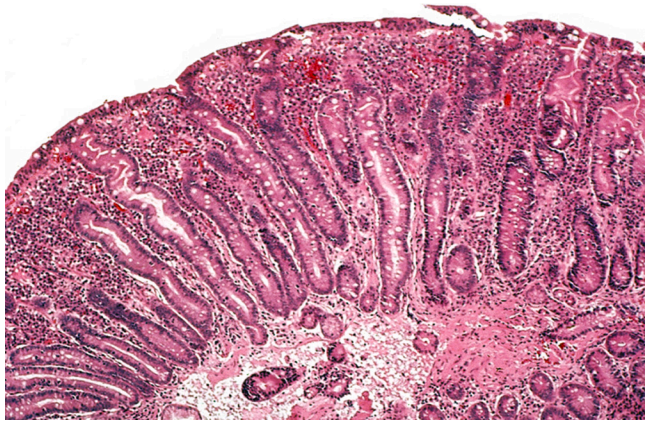

FIGURE 126-5. Intestinal biopsy appearance of flattened villi, hyperplastic crypts, and increased intraepithelial lymphocytes. (Courtesy John Hart, MD.)

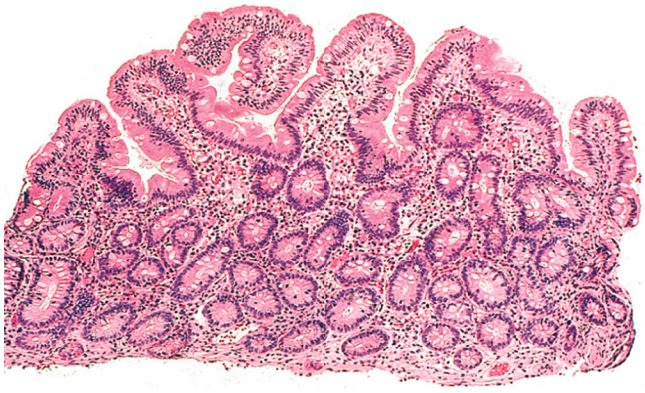

FIGURE 126-6. Regeneration of villi after initiation of a gluten-free diet. (Courtesy of John Hart, MD.)

Cobalamin deficiency is more common (10% of patients) than previously thought and usually corrects itself on a gluten-free diet. Symptomatic individuals require supplementation of vitamin B_{12}. Diarrhea is caused by many mechanisms, including a decreased surface area for water and electrolyte absorption, the osmotic effect of unabsorbed luminal nutrients, an increased surface area for chloride secretion (crypt hyperplasia), and the stimulation of intestinal fluid secretion by inflammatory mediators and unabsorbed fatty acids. Some individuals have impaired pancreatic enzyme secretion caused by decreased mucosal cholecystokinin release or bacterial overgrowth that may contribute to diarrhea. Individuals with nonceliac gluten sensitivity have wheat-related intestinal and extraintestinal symptoms similar to those of celiac disease but lack intestinal inflammation or celiac serologic markers. Fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) and gluten or nongluten wheat proteins (amylase trypsin inhibitors) may be the offending agents.

DIAGNOSIS

Routine screening for celiac disease is not recommended. In individuals who have subtle symptoms or in symptomatic high-risk groups, however, screening with anti-tTG IgA antibody testing is a cost-effective strategy.[18] High titer (>10-fold) of the anti-tTG IgA antibody is virtually diagnostic of celiac disease. EMA IgA antibodies, detected by indirect immunofluorescence, are highly sensitive (90%) and specific (95 to 99%) for active celiac disease in skilled laboratory testing. An ELISA test to detect antibodies against tTG has equal sensitivity to the EMA test but is less specific at lower titers. The anti-deamidated gliadin (a biotinylated synthetic γ-gliadin peptide with glutamic acid substituted for glutamine), antibody immunofluorometric assay has an inferior sensitivity and specificity compared with the anti-tTG IgA antibody.

Patients with mild disease may have negative antibody study results.[19] Anti-tTG, gliadin peptide, and EMA IgA antibodies tests are negative in individuals with selective IgA deficiency (present in up to 3% of individuals with celiac disease). In these patients, the anti-deamidated gliadin IgG antibody, which has a sensitivity and specificity close to that of the tTG IgA antibody, is helpful in diagnosis. In equivocal cases (negative serologic findings and equivocal biopsy result or positive serologic findings and normal biopsy result), HLA genotyping is useful to exclude the diagnosis of celiac disease in persons who lack the *DQ2* or *DQ8* gene.

The diagnosis of celiac disease can be confirmed by characteristic abnormalities seen on duodenal biopsies and improving when a gluten-free diet is instituted (Figs. 126-5 and 126-6). Mucosal flattening may be observed endoscopically as scalloped or reduced duodenal folds. Characteristic features found on intestinal biopsy include blunted or absent villi (villous atrophy), crypt hyperplasia, increased intraepithelial lymphocytes, and infiltration of the lamina propria with plasma cells and lymphocytes. In some individuals, the only abnormal biopsy finding is increased intraepithelial lymphocytes. However, individuals who have a TTG IgA antibody titer greater than 10-fold positive has a high enough predictive value for an abnormal duodenal biopsy characteristic of celiac disease that no biopsy is needed in this subset of individuals.[20,21] The decision to forgo biopsy for diagnosis should be under the guidance of a gastroenterologist.

TREATMENT

Treatment consists of a lifelong gluten-free diet. Wheat, rye, and barley grains should be excluded from the diet. Rice and corn grains are tolerated. Oats (if not contaminated by wheat grain) are tolerated by most. Early referral to a registered dietitian knowledgeable in the gluten-free diet and to a reputable celiac support group or website is crucial in maintaining dietary adherence. Owing to secondary lactase deficiency, a lactose-free diet should be recommended until symptoms improve.

In a preliminary trial, inhibition of transglutaminase-2 attenuated gluten-mediated mucosal damage and tended to improve symptoms[A7] Other therapies under study include exogenous oral enzymes that degrade gluten peptides, tight junction regulators, IL-15 inhibitors, and immune therapies to promote oral gluten tolerance.

Bone densitometry should be performed on individuals diagnosed with celiac disease who are older than 30 years of age because up to 70% have osteopenia or osteoporosis. Patients with diarrhea and weight loss should be screened for vitamin and mineral deficiencies. Documented deficiencies of vitamins and minerals should be replenished (Table 126-8), and women of childbearing age should take folic acid supplements. Bone mass often improves on a gluten-free diet alone. Patients with vitamin D or calcium deficiency should receive supplements (Chapter 199), with the dose monitored by 25-OH vitamin D levels and a 24-hour urine test for calcium. Celiac disease is associated with an increased risk for hospitalization with influenza and pneumococcal infection, so vaccination against both is recommended.

Most patients with seronegative villous atrophy do not have celiac disease. Most such patients have villous atrophy due to another cause or will have spontaneous improvement despite continuing to ingest gluten.

PROGNOSIS

Of patients with celiac disease treated with a gluten-free diet, 90% experience symptomatic improvement within 2 weeks. The most common cause of a poor dietary response is continued ingestion of gluten. Other possibilities include a missed intestinal infection (see later), an alternative diagnosis (e.g., ARB use particularly in elderly patients with a sprue-like enteropathy but negative celiac serologic findings, agammaglobulinemia [diagnosed by hypogammaglobulinemia and lack of plasma cells on small bowel biopsy], autoimmune enteritis [diagnosed by a positive anti-enterocyte antibody and crypt apoptosis or loss of goblet cells on small bowel biopsy]), bacterial overgrowth, pancreatic insufficiency, microscopic colitis, or other food allergies (cow's milk, soy protein). Between 4 and 40% of patients with celiac disease with symptomatic improvement have incomplete histologic recovery on a gluten-free diet; in such patients, a stricter diet may further improve symptoms and histology. A small percentage of patients with severe symptoms and enteropathy do not improve despite a strict gluten-free diet. In such patients, repeat intestinal biopsy with special lymphocyte marker studies is indicated. Some patients will have collagen deposition beneath the surface epithelium (collagenous sprue) or a polyclonal population of intraepithelial lymphocytes (refractory celiac disease type I). Others will have ulcerative jejunitis or a monoclonal population of intraepithelial T cells with an aberrant phenotype or clonal T-cell receptor-γ gene rearrangements (refractory celiac disease type II), which are predictive of enteropathy-associated T-cell lymphoma (Chapter 171) that portends a poor prognosis. Video capsule endoscopy and device-assisted enteroscopy may be helpful in establishing these diagnoses. Patients

TABLE 126-8 VITAMIN AND MINERAL DOSES USED IN THE TREATMENT OF MALABSORPTION

VITAMIN	ORAL DOSE	PARENTERAL DOSE
Vitamin A*	Water-soluble A, 25,000 U/day†	
Vitamin E	Water-soluble E, 400-800 U/day†	
Vitamin D‡	25,000-50,000 U/day	
Vitamin K	5 mg/day	
Folic acid	1 mg/day	
Calcium§	1500-2000 mg elemental calcium/day Calcium citrate, 500 mg calcium/tablet† Calcium carbonate, 500 mg calcium/tablet†	
Magnesium	Liquid magnesium gluconate† 1-3 tbsp (12-36 mEq magnesium) in 1-2 L of ORS or sports drink sipped throughout the day Magnesium chloride hexahydrate† 100-600 mg elemental magnesium/day	2 mL of a 50% solution (8 mEq), total dose, in both buttocks IM
Zinc	Zinc gluconate† 20-50 mg elemental zinc/day‖	
Iron	150-300 mg elemental iron/day Polysaccharide-iron complex† Iron sulfate or gluconate	Iron sucrose¶ Sodium ferric gluconate complex¶ Iron dextran (as calculated for anemia) (IV or IM¶; Chapter 145)
B-complex vitamins	1 megadose tablet/day	
Vitamin B_{12}	2 mg/day	1 mg IM or SQ/mo**
Copper	Copper sulfate 2-3 mg/day	1-2 mg IV/day

*Monitor serum vitamin A level to avoid toxicity, especially in patients with hypertriglyceridemia.
†Form best absorbed or with least side effects.
‡Monitor serum calcium and 25-OH vitamin D levels to avoid toxicity.
§Monitor 24-hr urine calcium to assess adequacy of dose.
‖If intestinal output is high, additional zinc should be given. Monitor for copper deficiency with high doses.
¶Parenteral therapy should be given in a supervised outpatient setting because of the risk for fatal reactions. Decreased risk for fatal reactions when compared with iron dextran.
**For vitamin B_{12} deficiency, 1 mg IM or SQ twice per week for 4 wk, then once per month.
IM = intramuscular; IV = intravenous; ORS = oral rehydration solution; SQ = subcutaneous.

with collagenous sprue, autoimmune enteritis, or refractory celiac disease type I often respond to prednisone (20 to 40 mg/day orally) or budesonide (9 mg opened capsule orally daily).

Patients with celiac disease have a higher likelihood of having other autoimmune conditions, such as type 1 diabetes, thyroiditis, rheumatoid arthritis, inflammatory bowel disease, systemic lupus erythematosus, Sjögren syndrome, primary biliary cirrhosis, autoimmune hepatitis, vitiligo, and pancreatitis. Interestingly, approximately one third of patients with idiopathic sporadic ataxia have transglutaminase-6 antibodies, consistent with gluten-induced disease.

Individuals with celiac disease have a 15 to 35% increased risk of mortality.[22] They also are at increased risk for cancer, particularly T cell lymphoma (Chapter 171) and small bowel carcinoma[23] (Chapter 171), with highest risks in the first year of after diagnosis and in patients over age 60 years. T-cell lymphoma is rare and should be suspected in individuals who have abdominal pain, recurrence of symptoms after initial response to a gluten-free diet, or refractory celiac disease.

TROPICAL SPRUE

Tropical sprue is an inflammatory disease of the small intestine associated with the overgrowth of predominantly coliform bacteria. It occurs in residents or travelers to India, Southeast Asia, Puerto Rico, and parts of the Caribbean. With the expansion of tourism and the global economy, this may be an underrecognized cause of enteropathy or mistaken for celiac disease. Individuals classically present with diarrhea and megaloblastic anemia secondary to vitamin B_{12} and folate deficiency, but some have anemia only. Intestinal biopsy characteristically shows subtotal and patchy villous atrophy in the proximal and distal small intestine, which may be caused by the effect of bacterial toxins on gut structure or by the secondary effects of vitamin B_{12} deficiency on the gut (megaloblastic gut). Diagnosis is based on history, documentation of vitamin B_{12} and/or folate deficiency, and the presence of an abnormal small intestinal biopsy report. Treatment is a prolonged course of tetracycline (250 mg orally four times daily) or doxycycline (100 mg orally two times daily), folic acid (5 mg/day orally), and, with coexistent deficiency, vitamin B_{12} injections (1000 μg weekly) until symptoms resolve. Relapse or reinfection occurs in 20%, mainly in natives of the tropics.

GIARDIA LAMBLIA

Giardia lamblia infection (Chapter 322), the most common protozoal infection in the United States, can cause malabsorption in individuals infected with many trophozoites, especially the immunocompromised or IgA-deficient hosts. Malabsorption occurs when many organisms cover the epithelium and cause mucosal inflammation, which results in villous flattening and a decrease in absorptive surface area. Stool for ova and parasites at this stage of infection is often negative because of the attachment of organisms in the proximal small intestine. Diagnosis can be made by PCR, stool antigen-capture ELISA test, or duodenal biopsy.

HUMAN IMMUNODEFICIENCY VIRUS

Diarrhea, malabsorption, and wasting are common in individuals with AIDS but are seen less frequently with improved antiretroviral therapy (Chapter 359). In patients who are receiving highly active antiretroviral therapy, diarrhea is more likely to be due to protease inhibitors than to enteric infection.

Malabsorption is usually due to infection with cryptosporidia, *Mycobacterium avium-intracellulare* complex, *I. belli,* or microsporidia. *AIDS enteropathy* (a term used if no organism is identified) also can cause malabsorption. Mechanisms of malabsorption and diarrhea include villous atrophy, increased intestinal permeability, rapid small bowel transit (in patients with protozoal infection), and ultrastructural damage of enterocytes (in AIDS enteropathy). Among individuals with AIDS and diarrhea, results of fecal fat absorption are frequently abnormal. Serum albumin, vitamin B_{12}, and zinc levels are often low. Vitamin B_{12} deficiency is caused mainly by ileal disease, but low intrinsic factor and decreased transcobalamin II may be contributing factors. Management of malabsorption should focus on restoring the immune system by treating the underlying HIV infection with antiviral therapy. If possible, the offending organism should be treated with antibiotics. If the organism cannot be eradicated, chronic diarrhea and malabsorption result; treatment in these cases consists of antimotility agents and a lactose-free, low-fat diet. Pancreatic enzyme replacement therapy can be tried in HIV-infected individuals who are taking highly active antiretroviral therapy or nucleoside analogues and who have fat malabsorption of obscure origin. If supplemental calories are needed, liquid oral supplements that are predigested and high in medium-chain triglycerides (semi-elemental) are tolerated best. Vitamin and mineral deficiencies should be screened for and treated.

WHIPPLE DISEASE

Whipple disease (Chapter 305), which is a rare cause of malabsorption, manifests with gastrointestinal complaints in association with systemic symptoms, such as fever, joint pain, or neurologic manifestations.[24] Approximately one third of patients have cardiac involvement, most commonly culture-negative endocarditis. Occasionally, individuals present with ocular or neurologic disease without gastrointestinal symptoms. The gram-positive actinomycete, *Tropheryma whippelii,* can be detected by PCR of duodenal biopsy specimens, gastric juice, saliva, urine,[25] or stool. Small intestinal biopsy shows villous blunting and infiltration of the lamina propria with large macrophages that stain positive with the periodic acid–Schiff method and are filled with the organism. It is important to distinguish these macrophages from macrophages infected with *M. avium-intracellulare* complex (Chapter 300), which stain positive on acid-fast staining and are found in individuals with AIDS. Treatment is with a prolonged course of broad-spectrum antibiotics (e.g., ceftriaxone 2 g/day IV or meropenem 1 g IV three times daily; then trimethoprim 160 mg and sulfamethoxazole 800 mg orally two times daily for 1 year or trimethoprim 160 mg and sulfamethoxazole 800 mg orally two times daily for 1 year). Relapses occur, but initial treatment with parenteral ceftriaxone or meropenem appears to be associated with a low relapse rate.

GRAFT-VERSUS-HOST DISEASE

Diarrhea occurs frequently after allogeneic hematopoietic stem cell transplantation (Chapter 163). Immediately after transplantation, diarrhea is caused by the toxic effects of cytoreductive therapy on the intestinal epithelium. From 20 to 100 days after transplantation, diarrhea is usually due to GVHD or infection. Patients with GVHD present clinically with a skin rash, hepatic cholestasis, buccal mucositis, anorexia, nausea, vomiting, abdominal cramps, and diarrhea. The diagnosis of GVHD in the gastrointestinal tract can be made on biopsy of the stomach, small intestine, or colon. In mild cases, the mucosa appears normal on inspection at endoscopy, but apoptosis of gastric gland or crypt cells can be found on biopsy. In severe cases, denudation of the intestinal epithelium results in diarrhea and malabsorption and often requires parenteral nutritional support. Octreotide (50 to 250 μg SQ three times daily) may be helpful in controlling voluminous diarrhea. Treatment of acute GVHD is with steroids (or antithymocyte globulin or ruxolitinib for steroid-refractory disease) combined with parenteral nutritional support until intestinal function returns.

SHORT-BOWEL SYNDROME

Malabsorption caused by small bowel resection or surgical bypass is called the short-bowel syndrome. The most common causes in the United States are massive resection of the jejunum, owing to strangulated bowel, volvulus, or ischemia (mesenteric or after intra-abdominal surgery), and jejunal exclusion, owing to gastric bypass surgery. Short-bowel syndrome resulting from Crohn disease and radiation enteritis now is less common because of improved medical and radiation therapies. The severity of malabsorption depends on the site and extent of resection; the capacity for adaptive hyperplasia, dilation, and elongation; and the function of the residual bowel. Mechanisms of malabsorption after small bowel resection include a decreased absorptive surface area, decreased luminal bile salt concentration, rapid transit, and bacterial overgrowth. Limited jejunal resection is tolerated best because bile salt and vitamin B_{12} absorption remain normal. Ileal resection is less well tolerated because of the consequences of bile salt wasting and the limited capacity of the jejunum to undergo adaptive hyperplasia. Adaptive hyperplasia in residual small bowel after resection depends on nutrients, endogenous secretions (pancreatic and biliary juice), local factors (trefoil peptides, prostaglandins, polyamines), growth hormone and growth factors (epidermal growth factor [EGF], insulin-like growth factor-1 [IGF1], transforming growth factor-α [TGF-α], IL-11). The glucagon-like peptide-2 (GLP2) produced in L cells in the terminal ileum and colon is a potent stimulant of adaptive hyperplasia in the jejunum in response to a meal. Using intestinal stem cell technology, epithelial organoids have been successfully grown in culture systems, but bowel regeneration has not yet been accomplished.

When less than 100 cm of jejunum remains, the colon takes on an important role in caloric salvage and fluid reabsorption. Malabsorbed carbohydrates are digested by colonic bacteria to short-chain fatty acids, which are absorbed in the colon.

TREATMENT

In patients who have a colon, parenteral nutrition may be avoided using a diet rich in complex carbohydrates, oral rehydration solution, an acid-reducing agent, and an antimotility agent (loperamide 2 to 8 mg orally up to four times a day; diphenoxylate and atropine 1 to 2 tablets orally up to four times a day; codeine 15 to 60 mg orally up to four times a day).[26] In comparison, individuals with fewer than 100 cm of jejunum and no colon have high jejunostomy outputs and often require intravenous fluids or parenteral nutrition to survive. These individuals waste sodium, chloride, bicarbonate, magnesium, zinc, and water in their ostomy effluent. Dietary modifications should include a high-salt, nutrient-rich diet given in small meals. An oral rehydration solution with a sodium concentration 75 to 90 mmol/L is absorbed best. Oral vitamin and mineral doses higher than the usual U.S. recommended daily allowances are required (see Table 126-8). Vitamin B_{12} should be given parenterally (500 to 1000 μg intramuscularly or subcutaneously every month). Magnesium deficiencies are often difficult to replenish with oral magnesium because of its osmotic effect in the intestinal lumen. A liquid magnesium preparation added to an oral rehydration solution and sipped throughout the day may minimize magnesium-induced fluid losses. Potent antimotility agents, such as tincture of opium (0.3 to 1 mL orally four times daily) or liquid morphine 20 mg/mL (1 mL orally four times daily), often are needed to slow transit and maximize contact time for nutrient absorption. High-volume jejunostomy outputs can be lessened by inhibiting endogenous secretions with a proton pump inhibitor (e.g., omeprazole, 40 mg orally one time daily, or lansoprazole, 30 mg orally one time daily) and, in severe cases (>3 L/day output), octreotide (100 to 250 μg subcutaneously three times daily; if effective, convert to an equivalent long-acting monthly dosage). The benefit of octreotide may be offset by its potential to inhibit intestinal adaptation and impair pancreatic enzyme secretion with doses greater than 300 μg/day.

In the most severe cases, supplemental calories must be provided by nocturnal tube feeding or parenteral nutrition. Treatment with growth hormone (0.1 mg/kg/day SQ) with or without glutamine (30 g/day orally) for 4 weeks may reduce parenteral nutrition requirements in patients who have had massive intestinal resections. Teduglutide (0.05 mg/kg/day SQ), a glucagon-like peptide-2 analogue that stimulates adaptive hyperplasia in remnant intestine after resection, improves absorption, and reduces parenteral nutrition requirements. Small bowel transplantation should be considered for individuals who require parenteral nutrition to survive and then develop progressive liver disease or venous access problems. Bioengineering of intestine using organoids and scaffolding systems is a promising future therapy.[27]

PROGNOSIS

Long-term complications include bone disease, renal stones (oxalate stones if the colon is present, urate stones with a jejunostomy), gallstones, bacterial overgrowth, fat-soluble vitamin deficiencies, essential fatty acid deficiency, and D-lactic acidosis.

CONDITIONS THAT IMPAIR NUTRIENT DELIVERY TO THE SYSTEMIC CIRCULATION

Insoluble lipids (present in chylomicrons) are exocytosed across the basolateral membrane of epithelial cells into the intestinal lymphatics. From there, they enter the mesenteric lymphatics and the general circulation through the thoracic duct. Sugar monomers, amino acids, and medium-chain fatty acids are transported across the basolateral membrane of intestinal epithelial cells into capillaries and into the portal circulation. Sugar monomers are transported across the basolateral membrane by the facilitative glucose transporter isoform (GLUT2) and amino acids by facilitative amino acid carriers (see E-Fig. 126-1C).

IMPAIRED LYMPHATIC DRAINAGE

Diseases that cause intestinal lymphatic obstruction, such as primary congenital lymphangiectasia (malunion of intestinal lymphatics), and diseases that result in secondary lymphangiectasia (lymphoma, tuberculosis, Kaposi sarcoma, retroperitoneal fibrosis, constrictive pericarditis, severe heart failure) result in fat malabsorption. The increased pressure in the intestinal lymphatics leads to leakage and sometimes rupture of lymph into the intestinal lumen, with the loss of lipids, γ-globulins, albumin, and lymphocytes. The diagnosis of lymphangiectasia can be made by intestinal biopsy, but the specific cause may be more difficult to identify. Individuals with lymphangiectasia malabsorb fat and fat-soluble vitamins and have protein loss into the intestinal lumen. The most common presentation is hypoproteinemic edema. Nutritional management includes a high protein and low-fat diet and supplementation with medium-chain triglycerides, which are absorbed directly into the portal circulation. Fat-soluble vitamins should be given if deficiencies develop.

CONGENITAL MALABSORPTION AND DIARRHEA

A number of congenital disorders, mostly autosomal recessive, alter nutrient digestion, epithelial cell transport, or villus epithelial architecture. These disorders usually present within the first few weeks of life and may become targets for stem cell therapy.

Mutations in sugar disaccharidases include lactase (rare), sucrose-isomaltase, maltase-glucoamylase, and trehalase (digests trehalose in mushrooms) deficiencies. These disorders are characterized by osmotic diarrhea when the offending sugar is introduced into the diet. Diagnosis is made by a low stool pH (owing to conversion of malabsorbed sugar to short-chain fatty acids by colonic bacteria), reduced enzyme activity on duodenal biopsy, and genetic testing. The treatment is to feed alternative sources of carbohydrates. Congenital enterokinase (enteropeptidase) deficiency due to missense mutations in the gene causes severe protein malabsorption owing to the inability to activate trypsinogen and other pancreatic proteases in the intestinal lumen. Treatment is with supplemental pancreatic enzymes.

Defects in epithelial transport proteins include congenital glucose-galactose malabsorption (mutation in the *SGLT1* gene) that results in severe carbohydrate malabsorption. Congenital chloride and sodium diarrheas are rare autosomal recessive disorders caused by mutations in the epithelial Cl^-/HCO_3^- (SLC26A) and the Na^+/H^+ exchanger (SCL9A3, GUCY2C), respectively. These disorders cause maternal polyhydramnios and fluid-filled bowel loops in utero as well as severe diarrhea at birth. Diagnosis in the newborn is made by high stool chloride levels and metabolic alkalosis in congenital chloride diarrhea, high

stool sodium levels and metabolic acidosis in congenital sodium diarrhea, and genetic testing.

Abetalipoproteinemia is due to defects in chylomicron formation and exocytosis at the basolateral membrane of intestinal epithelial cells that are necessary for the delivery of lipids to the systemic circulation. Mutations in the microsomal triglyceride transfer protein (MTP), apolipoprotein B gene, and SAR1B (triggers coat protein of vesicles in the endoplasmic reticulum) result in chylomicron retention in epithelial cells. Children with this disorder have fat malabsorption and the consequences of vitamin E deficiency (retinopathy and spinocerebellar degeneration). Biochemical tests show low plasma levels of apoprotein B, triglyceride, and cholesterol. Membrane lipid abnormalities result in red blood cell acanthosis (burr cells). Intestinal biopsy, which is diagnostic, is characterized by engorgement of epithelial cells with lipid droplets. Treatment is with a low-fat diet containing medium-chain triglycerides and high doses of fat-soluble vitamins, especially vitamin E.

Homozygous loss-of-function mutations in the gene encoding CD55 (decreased decay-accelerating factor with hyperactivation of complement) cause protein-losing enteropathy, often accompanied by primary intestinal lymphangiectasia, edema due to hypoproteinemia, and malabsorption. Affected individuals often may have recurrent infections and angiopathic thromboembolic disease (CHAPLE syndrome).

Defects in villus epithelial cell structure presents at birth with severe malabsorption. Microvillus inclusion disease is due to defects in intraepithelial cellular protein transport and epithelial polarization. Mutations have been identified in myosin type 5 motor protein *(MYO5B)* and syntaxin-3 *(STX3)* genes. Tufting enteropathy is characterized by disorganized enterocytes at villus tips (tufts). Mutations have been identified in EpCAM and SPINK2 to suggest disorders in tight junction formation. Most infants with these disorders require parenteral nutrition or small bowel transplantation for survival.

WATERY DIARRHEA

Watery diarrhea may be due to osmotic, secretory, inflammatory, or often combined mechanisms (see Fig. 126-3).

INGESTION OF NONABSORBABLE OR POORLY ABSORBABLE SOLUTES

MAGNESIUM AND SODIUM PHOSPHATE AND SULFATE DIARRHEAS

Magnesium, phosphate, and sulfate are poorly absorbed minerals. Individuals who ingest significant amounts of magnesium-based antacids or high-potency multimineral and multivitamin supplements or those who surreptitiously ingest magnesium-containing laxatives or nonabsorbable anion laxatives, such as Na_2PO_4 (neutral phosphate) or Na_2SO_4 (Glauber or Carlsbad salt), may develop osmotically induced, watery diarrhea that may be high volume.

SORBITOL AND FRUCTOSE DIARRHEA

Dietetic food, chewing gum, candies, and medication elixirs that are sweetened with sorbitol, which is an unabsorbable carbohydrate, can cause diarrhea. Excessive consumption of pears, prunes, peaches, and apple juice, which also contain sorbitol and fructose, a poorly absorbable sugar, can result in diarrhea. Most soft drinks are now sweetened with fructose-containing corn syrup and may be a cause of diarrhea when ingested in high concentrations.

RAPID INTESTINAL TRANSIT

A small amount of carbohydrate in the diet is unabsorbed by the normal small intestine. Diets that are high in carbohydrate and low in fat may allow rapid gastric emptying and rapid small intestinal motility, thereby leading to carbohydrate malabsorption and osmotic diarrhea. Rapid transit time also occurs in thyrotoxicosis (Chapter 207). Because of the production of H_2 and carbon dioxide gas by colonic bacteria, abdominal gas and cramping may be the predominant symptoms.

BILE ACID DIARRHEA

Ileal malabsorption of bile salts results in the stimulation of colonic fluid secretion and watery diarrhea. Three types of bile acid malabsorption induce diarrhea. Type 1 results when severe disease (e.g., Crohn disease), resection, or bypass of the distal ileum allows bile salts to escape absorption (see earlier). Type 2 may be congenital: rarely owing to a defect in the intestinal sodium bile acid transporter but more commonly owing to increased bile salt production (associated with decreased levels of fibroblast growth factor 19 [FGF19], an intestinal fibroblast growth factor that normally downregulates bile salt synthesis in the liver, and increased levels of 7-α-hydroxy-4-cholesten-3-one [7αC4], which is a marker of bile acid synthesis, in blood). The result is increased bile salt production that overwhelms reabsorption in the ileum. Type 3 is caused by various conditions, including prior cholecystectomy, celiac disease, pancreatic insufficiency, microscopic colitis, bacterial overgrowth, gastric surgery, or vagotomy. Postulated mechanisms include a bile salt storage problem, increased production, decreased recycling, or saturation of absorption.

Primary (type 2) bile acid diarrhea is now thought to account for up to 30% of cases of functional or irritable bowel syndrome with chronic diarrhea (Chapter 123).[28] The diagnosis is made by selenium homocholic acid taurine (^{75}SeHCAT) testing (see Table 126-6), a 48-hour stool collection for bile acids on a high-fat diet, or fasting blood tests that measure FGF19 and C4 levels.

TREATMENT

Diarrhea due to types 1 and 2 often responds to cholestyramine (2 to 4 g orally two to four times daily), colestipol (5 g orally two or three times daily), or the more potent and better tolerated bile salt binder colesevelam (625-mg tablet orally two to six times daily). Obeticholic acid (25 mg orally daily), a farnesoid X receptor agonist that stimulates FGF19 production, may lessen the frequency of bile acid diarrhea but may cause pruritis.[29] Fat-soluble vitamin deficiency is a potential risk with chronic use of bile salt binders. Although many patients with type 3 respond to cholestyramine or colesevelam, some do not. In these patients, motility-altering drugs such as opiates (e.g., loperamide, 2 to 4 mg orally two to four times daily) and anticholinergics (e.g., hyoscyamine sulfate, 0.125 to 0.250 mg orally two to four times daily) may be of benefit.

TRUE SECRETORY DIARRHEAS

High-volume secretory diarrheas (see Fig. 126-3) can be caused by hormones or cytokines that are secreted by rare endocrine tumors, including carcinoid tumors (Chapter 213), gastrinomas (Chapter 213), VIPomas of the pancreas (Chapter 213), and medullary carcinoma of the thyroid (Chapter 207). Diarrhea is also seen in 60 to 80% of patients with systemic mastocytosis (Chapter 235). Diarrhea resulting from gastrinoma is distinct in that it is caused by high volumes of hydrochloric acid secretion that overwhelm the reabsorptive capacity of the colon and by maldigestion of fat owing to pH inactivation of pancreatic lipase and precipitation of bile salts.

VILLOUS ADENOMAS

Large (4 to 18 cm) villous adenomas, particularly in the rectum or occasionally the sigmoid colon, may cause secretory diarrhea of 500 to 3000 mL/24 hours characterized by hypokalemia, chloride-rich stool, and metabolic alkalosis. Increased numbers of goblet cells and increased prostaglandin E_2 are responsible for the diarrhea. Chloride wasting in the stool and metabolic alkalosis are also found in congenital chloridorrhea, which is caused by a defect in the intestinal Cl^-/HCO_3^- transporter. The metabolic alkalosis distinguishes these two diarrheas from most other diarrheas that cause metabolic acidosis. A villous adenoma is usually diagnosed by colonoscopy. The prostaglandin antagonist indomethacin (25 to 100 mg/day orally) reduces the diarrhea in some patients; resection is curative.

DIABETES MELLITUS–RELATED DIARRHEA

Constipation is more common than diarrhea in patients with diabetes (Chapter 210). High-volume, watery diarrhea, often with nocturnal incontinence, occurs in 20% of patients with poorly controlled type 1 diabetes. These patients usually have concomitant neuropathy, nephropathy, and retinopathy. The diarrhea may be due to several causes, including celiac disease, anal incontinence, bacterial overgrowth related to dysmotility, medications (metformin, acarbose), and autonomic neuropathy. If no specific cause is found, clonidine (initial dose 0.1 mg orally twice daily and titrated slowly to a maximal dose of 0.5 to 0.6 mg orally twice daily) may be helpful. Patients with neuropathy frequently have impaired anal sphincter function, and high-dose loperamide (4 mg orally four times daily) may improve the incontinence.

ALCOHOL-RELATED DIARRHEA

Diarrhea related to alcohol ingestion (Chapter 364) may be due to rapid intestinal transit, decreased bile and pancreatic secretion, nutritional deficiencies such as folate or vitamin B_{12}, or alcohol-related enteric neuropathy. Diarrhea may be acute with binge drinking, or it may be chronic and watery and persist for days or weeks. The diarrhea slowly resolves with abstinence from alcohol, proper nutrition, and the repletion of vitamin deficiencies.

FACTITIOUS DIARRHEA

Approximately 30% of patients referred to tertiary centers have chronic diarrhea from laxative abuse. The diarrhea is usually severe and watery, often with nocturnal symptoms. Some patients may have abdominal pain, weight loss, nausea, vomiting, hypokalemic myopathy, and acidosis. Stool volumes range from 300 to 3000 mL/day depending on the dose of laxative ingested. In the United States, bisacodyl is the most common cause. Other culprits include anthraquinone (senna, cascara, aloe, rhubarb) or osmotic laxatives (neutral phosphate, Epsom salts, and magnesium citrate). Some patients abuse other agents that cause diarrhea, such as the diuretics furosemide and ethacrynic acid.

More than 90% of laxative abusers are women who have underlying eating disorders such as anorexia nervosa or bulimia (Chapter 200) or middle-aged women who have complicated medical histories and who often work in health care. In patients with unexplained diarrhea, laxative screening of stool and urine (see later) should be performed to exclude this syndrome before an extensive medical evaluation is performed for other causes of chronic diarrhea.

CHRONIC IDIOPATHIC SECRETORY DIARRHEA

In a small subset of patients with secretory diarrhea, no cause is found despite an extensive evaluation. These cases are labeled as chronic idiopathic secretory diarrhea. In most patients, the diarrhea resolves within 6 to 24 months, which suggests a possible postinfectious or Brainerd diarrhea. If no diagnosis is found after thorough testing and a search for surreptitious laxative abuse, a therapeutic trial with bile salt–binding drugs (e.g., cholestyramine, 4 g orally before meals three times daily, or the more potent colesevelam, 625-mg tablet two to six times daily) or opiates (e.g., loperamide, 2 mg orally four times daily, maximal dose 16 mg daily) is warranted.

INFLAMMATORY DIARRHEAS

Diarrhea resulting from inflammation is characterized by watery or bloody stools, fecal leukocytes, and loss of protein in the stool (see Fig. 126-3).

INFLAMMATORY BOWEL DISEASE

See Chapter 127.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis is an increasingly recognized condition of unknown etiology characterized by infiltration of eosinophils in the mucosa, muscle, or serosal layers of the gastrointestinal tract.[30] Mast cells play a role in the pathogenesis. Approximately 50% of patients have atopic histories. Infestation with nematodes (Chapter 327) must be excluded before this diagnosis is made. Diarrhea occurs in 30 to 60% of patients with mucosal disease. Patients with involvement of the muscle layer often present with abdominal pain, nausea, and vomiting indicative of gastric outlet or intestinal obstruction. Peripheral eosinophilia is present in about 70% of patients. The disease may involve the entire gastrointestinal tract from esophagus to anus, or it may be isolated to a segment. With diffuse involvement, patients may have steatorrhea, protein-losing enteropathy, and blood loss.

Management includes an elimination diet or an elemental diet. Budesonide (9 mg orally daily) or prednisone (0.5 to 1 mg/kg orally daily) is highly effective, but relapses are common when corticosteroids are tapered. Lirentelimab, a monoclonal antibody against siglec-8 (sialic acid-binding immunoglobulin-like lectin 8 expressed on eosinophils and mast cells) is a promising therapy that significantly decreases tissue eosinophil counts and improves clinical symptoms.[A8]

MICROSCOPIC (COLLAGENOUS AND LYMPHOCYTIC) COLITIS

These two conditions, collectively known as *microscopic colitis,* may or may not be the same disease or variants of the same disease.[31] Lymphocytic colitis is equally prevalent in men and women, whereas collagenous colitis occurs 10 times more often in middle-aged or elderly women. These conditions may be associated with autoimmune disease or with NSAID use. There is an increased prevalence (5%) of microscopic colitis among individuals with celiac disease. These diseases may be categorized as either inflammatory or secretory diarrheas. An epidemiologic relationship to medications such as NSAIDs, proton pump inhibitors, selective serotonin reuptake inhibitors, and smoking has been reported, and increased luminal prostaglandin levels may cause the diarrhea. Enteric infections, food hypersensitivity, and intraluminal bile have been proposed as triggers for prostaglandin release from lymphocytes.

Antidiarrheal agents such as loperamide (2 mg orally four times daily) are the mainstay of therapy for mild diarrhea, which usually has a benign and self-limited course. Budesonide (4.5 to 9 mg orally daily) is the most effective therapy.[A9] In patients who do not tolerate or respond to it, an alternative is bismuth subsalicylate therapy (8 chewable 262-mg tablets orally daily). Patients with refractory disease may require corticosteroids (e.g., prednisone, 40 mg/day orally), a trial of azathioprine, or anti–TNF-α antibodies.

FOOD ALLERGY AND HYPERSENSITIVITY

Food allergies or sensitivities, especially to cow's milk and egg protein, are a well-established cause of enterocolitis in children, with an estimated frequency of 5%. Symptoms of abdominal cramps, diarrhea, and sometimes vomiting occur shortly after ingestion of the allergen (Chapter 233). Food hypersensitivity reactions are reported in 20 to 25% of adults and can lead to anxiety and disordered eating.[32] The role of food allergy in causing diarrhea in adults is less clear owing to the lack of a reliable diagnostic test. Allergy testing correlates poorly with intestinal allergy. The most common food allergens are milk, soy, eggs, seafood, nuts, and wheat. Sequential elimination diets can be diagnostic and therapeutic.

RADIATION ENTERITIS

Patients who receive pelvic radiation for malignancies of the female urogenital tract, gastrointestinal tract, or the male prostate may develop chronic radiation enterocolitis[33] 6 to 24 months after total doses of radiation greater than 40 to 60 Gy (Chapters 18 and 128), but symptoms can develop as late as 20 years after treatment. Early abnormalities include an increase in inflammatory mediators, an increase in cholinergic stimulation of intestinal tissue, and endothelial cell apoptosis that precedes epithelial cell apoptosis. The last finding suggests that vascular injury is the primary event. Diarrhea may be caused by bile acid malabsorption if the ileum is damaged, by bacterial overgrowth if radiation causes small intestinal strictures or bypass, or by radiation-induced chronic inflammation of the small intestine and colon. Rapid transit also may contribute to malabsorption and diarrhea.

TREATMENT

Treatment is often unsatisfactory. Anti-inflammatory drugs (mesalamine, corticosteroids) and antibiotics have been tried with little success. Cholestyramine (4 g orally three times daily) and NSAIDs (e.g., naproxen, 250 to 500 mg orally twice daily) may help, as may opiates (loperamide, 2 mg orally four times daily, or loperamide-*N*-oxide, 3 mg orally two times daily). Hyperbaric oxygen therapy may be useful for refractory disease. Surgery carries a high morbidity.

PROTEIN-LOSING GASTROENTEROPATHY

Severe protein loss through the gastrointestinal tract can be caused by mucosal diseases such as lymphangiectasia, lymphatic obstruction, bacterial or parasitic infection, gastritis (Chapter 125), gastric cancer, collagenous colitis, inflammatory bowel disease (Chapter 127), celiac disease, sarcoidosis (Chapter 83), lymphoma (Chapter 171), tuberculosis (Chapter 299), Ménétrier disease (Chapter 178), eosinophilic gastroenteritis, and food allergies. A variety of extraintestinal diseases, including systemic lupus erythematosus (Chapter 245), heart failure (Chapter 45), and constrictive pericarditis (Chapter 62), also can be causative. Patients with systemic lupus erythematosus (Chapter 245) may present with protein-losing enteropathy as the only manifestation of their disease.

The typical clinical presentation is hypoproteinemia with edema. Diarrhea is a frequent symptom but not always present. Depending on the cause, patients may have lymphocytopenia (from lymphatic obstruction), steatorrhea, and fat-soluble vitamin deficiencies (especially with primary intestinal lymphangiectasia or celiac disease).

Evaluation includes exclusion of renal, liver, heart disease as a cause followed by testing for suspected gastrointestinal mucosal diseases. MRI may play a role in detecting intestinal/mesenteric edema and lymphatic dilation. The α1-antitrypsin clearance test is useful for diagnosis and to evaluate the magnitude of protein loss.[34] Treatment focuses on the underlying disease.

MISCELLANEOUS DISEASES

Although acute mesenteric arterial or venous thrombosis manifests as an acute bloody diarrhea, chronic mesenteric vascular ischemia (Chapter 129) may manifest as watery diarrhea. Gastrointestinal tuberculosis (Chapter 299) and histoplasmosis (Chapter 308) manifest as diarrhea that may be either bloody or watery, as do certain immunologic diseases, such as Behçet syndrome and Churg-Strauss syndrome. All of these diseases may be misdiagnosed as inflammatory bowel disease

(Chapter 127). Neutropenic enterocolitis, an ileocolitis that occurs in patients with neutropenia and leukemia, sometimes is caused by *C. difficile* infection.

TREATMENT

Antidiarrheal agents are of two types: those used for mild to moderate diarrheas and those used for severe secretory diarrheas. A major shortcoming of opiates, the most commonly prescribed antidiarrheal agents, is that they have no antisecretory effect. Rather, they act by decreasing intestinal motility, thereby allowing longer contact time with the mucosa for improved fluid absorption. The exception is racecadotril, an enkephalinase inhibitor, that blocks intestinal fluid secretion without affecting motility.

Bulk-forming agents (psyllium, 7 g in 8 oz water orally up to five times daily and methylcellulose, 3 to 6 tablets twice daily with 300 mL of water) act by binding water and increasing the consistency of stool. Pectin has been shown to have proabsorptive activity. These agents may be useful in patients with fecal incontinence. Bismuth subsalicylates (524 mg orally every hour up to eight doses daily) have mild antisecretory and antimotility effects and are effective and safe in mild diarrheas.

The opiates may be symptomatically useful in mild to moderate diarrhea. Deodorized tincture of opium, codeine, and diphenoxylate with atropine largely have been supplanted by loperamide. Loperamide does not pass the blood-brain barrier and has a high first-pass metabolism in the liver; it has a high therapeutic-to-toxic ratio and is essentially devoid of addiction potential. It is safe in adults, even in total doses of 24 mg/day. The usual dose is 2 to 4 mg two to four times daily. Opiates may be harmful in patients with severe diarrhea because large volumes of fluid may pool in the intestinal lumen (third space), and stool output is no longer a reliable gauge for replacing fluid losses. The antimotility effects are a problem in infectious diarrhea because stasis may enhance bacterial invasion and delay clearance of microorganisms from the bowel. Opiates and anticholinergics also are dangerous in severe inflammatory bowel disease or severe *C. difficile* infection, where they may precipitate megacolon.

Antidiarrheal agents that are used for the treatment of severe secretory and inflammatory diarrheas generally have profiles with more serious side effects. The somatostatin analogue octreotide (initial dose, 100 to 600 μg subcutaneously in two to four divided doses daily; maximal dose, 1500 μg daily) lessens diarrhea in the carcinoid syndrome and in neuroendocrine tumors because it inhibits hormone secretion by the tumor. It is also effective in the treatment of dumping syndrome and chemotherapy-related diarrheas. Long-acting octreotide (20 to 30 mg intramuscularly every month) is available for once-a-month dosing. Octreotide can suppress pancreatic enzyme secretion and make diarrhea worse; it also may be of only limited usefulness in short-bowel syndrome and AIDS diarrhea. Crofelemer (125 mg orally twice daily), a chloride channel inhibitor extracted from the bark latex of the South American tree *Croton lechleri,* improves HIV-related chronic diarrhea. Agents such as phenothiazine and calcium-channel blockers have mild antisecretory effects, but side effects limit their use. Clonidine (initial dose, 0.1 mg orally twice daily, titrated slowly to a maximal dose of 0.5 to 0.6 mg twice daily) is most useful in opiate withdrawal diarrhea and is sometimes useful in diabetic diarrhea; postural hypotension may limit its use, particularly in patients with diabetes. Alosetron (0.5 mg orally twice daily for 4 weeks, maximal dose 1 mg orally twice daily) may be justified for severe diarrhea-predominant irritable bowel syndrome; associations with ischemic colitis and severe constipation have limited its use. Indomethacin (250 to 500 mg orally twice daily), a cyclooxygenase blocker that inhibits prostaglandin production, is useful in the treatment of diarrheas caused by acute radiation, AIDS, or villous adenomas of the rectum or colon; occasionally, it may be useful in neuroendocrine tumors and food allergy. For eosinophilic gastroenteritis, corticosteroids (prednisone, 20 to 40 mg/day orally for 7 to 10 days) are the mainstay of therapy. Lirentelimab, a monoclonal antibody against siglec-8, depletes eosinophils, inhibits mast cell activation, and is a promising new therapy. Food elimination diets are not usually effective. Treatment of inflammatory bowel disease is described in Chapter 127.

127 INFLAMMATORY BOWEL DISEASE

GARY R. LICHTENSTEIN

DEFINITION

Inflammatory bowel disease refers to two chronic idiopathic inflammatory disorders: ulcerative colitis and Crohn disease. Characteristic clinical, endoscopic, and histologic features are critical for the diagnosis of these disorders, but no single individual finding is absolutely diagnostic for one disease or the other. Mucosal ulceration in Crohn disease may be transmural and may occur anywhere in the gastrointestinal tract, most commonly in the distal ileum and proximal colon. The hallmark of ulcerative colitis is continuous ulceration starting in the rectum and limited to the colon. Approximately 10% of patients with inflammatory bowel disease have what is called "inflammatory bowel disease-undetermined," a term used when Crohn colitis cannot be distinguished from ulcerative colitis.

EPIDEMIOLOGY

Inflammatory bowel disease occurs worldwide, but the highest incidence is found in North America, the United Kingdom, and northern Europe. Data suggest an increasing incidence and prevalence over time and in different regions around the world, although ulcerative colitis remains slightly more prevalent than Crohn disease. The incidence of ulcerative colitis in North America is estimated to be about 19 per 100,000 person-years and 24 per 100,000 person-years in Europe, with a prevalence of approximately 280 per 100,000 persons in North America and up to 500 per 100,000 persons in Europe. The incidence of Crohn disease in North America is estimated to be about 20 per 100,000 person-years and 13 per 100,000 person-years in Europe, with a prevalence of approximately 320 per 100,000 person-years in North America and in Europe.[1]

Crohn disease and ulcerative colitis may occur at any age, but both have their peak incidence in the second to fourth decade, with a second peak in the seventh decade. The female-to-male ratio for both ulcerative colitis and Crohn disease suggests no gender preference.

Crohn disease and ulcerative colitis are complex polygenic disorders, for which having a family history of inflammatory bowel disease is a risk factor. Crohn disease and ulcerative colitis occur in all ethnic and socioeconomic groups, but their incidence is highest in White and Jewish people of Eastern European (Ashkenazi) descent. In North America and the United Kingdom, however, the incidence of Crohn disease in African Americans and African Caribbeans appears to be approaching that of Whites. Studies of migrants from certain developing countries in South Asia to the United Kingdom suggest an increased prevalence of inflammatory bowel disease in subsequent generations, presumably because of environmental influences.

Cigarette smoking is associated with a worse prognosis in patients with Crohn disease but an improved course in ulcerative colitis. Nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be associated with new onset of inflammatory bowel disease and with exacerbations of disease. Appendectomy for an inflammatory indication has been suggested as protective against the development of ulcerative colitis. Diet does not clearly affect the course of inflammatory bowel disease.

PATHOBIOLOGY

Although the trigger for inflammatory bowel disease is not known, three major pathways likely activate the disease: a genetic predisposition, immune

(Chapter 127). Neutropenic enterocolitis, an ileocolitis that occurs in patients with neutropenia and leukemia, sometimes is caused by *C. difficile* infection.

TREATMENT

Antidiarrheal agents are of two types: those used for mild to moderate diarrheas and those used for severe secretory diarrheas. A major shortcoming of opiates, the most commonly prescribed antidiarrheal agents, is that they have no antisecretory effect. Rather, they act by decreasing intestinal motility, thereby allowing longer contact time with the mucosa for improved fluid absorption. The exception is racecadotril, an enkephalinase inhibitor, that blocks intestinal fluid secretion without affecting motility.

Bulk-forming agents (psyllium, 7 g in 8 oz water orally up to five times daily and methylcellulose, 3 to 6 tablets twice daily with 300 mL of water) act by binding water and increasing the consistency of stool. Pectin has been shown to have proabsorptive activity. These agents may be useful in patients with fecal incontinence. Bismuth subsalicylates (524 mg orally every hour up to eight doses daily) have mild antisecretory and antimotility effects and are effective and safe in mild diarrheas.

The opiates may be symptomatically useful in mild to moderate diarrhea. Deodorized tincture of opium, codeine, and diphenoxylate with atropine largely have been supplanted by loperamide. Loperamide does not pass the blood-brain barrier and has a high first-pass metabolism in the liver; it has a high therapeutic-to-toxic ratio and is essentially devoid of addiction potential. It is safe in adults, even in total doses of 24 mg/day. The usual dose is 2 to 4 mg two to four times daily. Opiates may be harmful in patients with severe diarrhea because large volumes of fluid may pool in the intestinal lumen (third space), and stool output is no longer a reliable gauge for replacing fluid losses. The antimotility effects are a problem in infectious diarrhea because stasis may enhance bacterial invasion and delay clearance of microorganisms from the bowel. Opiates and anticholinergics also are dangerous in severe inflammatory bowel disease or severe *C. difficile* infection, where they may precipitate megacolon.

Antidiarrheal agents that are used for the treatment of severe secretory and inflammatory diarrheas generally have profiles with more serious side effects. The somatostatin analogue octreotide (initial dose, 100 to 600 μg subcutaneously in two to four divided doses daily; maximal dose, 1500 μg daily) lessens diarrhea in the carcinoid syndrome and in neuroendocrine tumors because it inhibits hormone secretion by the tumor. It is also effective in the treatment of dumping syndrome and chemotherapy-related diarrheas. Long-acting octreotide (20 to 30 mg intramuscularly every month) is available for once-a-month dosing. Octreotide can suppress pancreatic enzyme secretion and make diarrhea worse; it also may be of only limited usefulness in short-bowel syndrome and AIDS diarrhea. Crofelemer (125 mg orally twice daily), a chloride channel inhibitor extracted from the bark latex of the South American tree *Croton lechleri,* improves HIV-related chronic diarrhea. Agents such as phenothiazine and calcium-channel blockers have mild antisecretory effects, but side effects limit their use. Clonidine (initial dose, 0.1 mg orally twice daily, titrated slowly to a maximal dose of 0.5 to 0.6 mg twice daily) is most useful in opiate withdrawal diarrhea and is sometimes useful in diabetic diarrhea; postural hypotension may limit its use, particularly in patients with diabetes. Alosetron (0.5 mg orally twice daily for 4 weeks, maximal dose 1 mg orally twice daily) may be justified for severe diarrhea-predominant irritable bowel syndrome; associations with ischemic colitis and severe constipation have limited its use. Indomethacin (250 to 500 mg orally twice daily), a cyclooxygenase blocker that inhibits prostaglandin production, is useful in the treatment of diarrheas caused by acute radiation, AIDS, or villous adenomas of the rectum or colon; occasionally, it may be useful in neuroendocrine tumors and food allergy. For eosinophilic gastroenteritis, corticosteroids (prednisone, 20 to 40 mg/day orally for 7 to 10 days) are the mainstay of therapy. Lirentelimab, a monoclonal antibody against siglec-8, depletes eosinophils, inhibits mast cell activation, and is a promising new therapy. Food elimination diets are not usually effective. Treatment of inflammatory bowel disease is described in Chapter 127.

127 INFLAMMATORY BOWEL DISEASE

GARY R. LICHTENSTEIN

DEFINITION

Inflammatory bowel disease refers to two chronic idiopathic inflammatory disorders: ulcerative colitis and Crohn disease. Characteristic clinical, endoscopic, and histologic features are critical for the diagnosis of these disorders, but no single individual finding is absolutely diagnostic for one disease or the other. Mucosal ulceration in Crohn disease may be transmural and may occur anywhere in the gastrointestinal tract, most commonly in the distal ileum and proximal colon. The hallmark of ulcerative colitis is continuous ulceration starting in the rectum and limited to the colon. Approximately 10% of patients with inflammatory bowel disease have what is called "inflammatory bowel disease-undetermined," a term used when Crohn colitis cannot be distinguished from ulcerative colitis.

EPIDEMIOLOGY

Inflammatory bowel disease occurs worldwide, but the highest incidence is found in North America, the United Kingdom, and northern Europe. Data suggest an increasing incidence and prevalence over time and in different regions around the world, although ulcerative colitis remains slightly more prevalent than Crohn disease. The incidence of ulcerative colitis in North America is estimated to be about 19 per 100,000 person-years and 24 per 100,000 person-years in Europe, with a prevalence of approximately 280 per 100,000 persons in North America and up to 500 per 100,000 persons in Europe. The incidence of Crohn disease in North America is estimated to be about 20 per 100,000 person-years and 13 per 100,000 person-years in Europe, with a prevalence of approximately 320 per 100,000 person-years in North America and in Europe.[1]

Crohn disease and ulcerative colitis may occur at any age, but both have their peak incidence in the second to fourth decade, with a second peak in the seventh decade. The female-to-male ratio for both ulcerative colitis and Crohn disease suggests no gender preference.

Crohn disease and ulcerative colitis are complex polygenic disorders, for which having a family history of inflammatory bowel disease is a risk factor. Crohn disease and ulcerative colitis occur in all ethnic and socioeconomic groups, but their incidence is highest in White and Jewish people of Eastern European (Ashkenazi) descent. In North America and the United Kingdom, however, the incidence of Crohn disease in African Americans and African Caribbeans appears to be approaching that of Whites. Studies of migrants from certain developing countries in South Asia to the United Kingdom suggest an increased prevalence of inflammatory bowel disease in subsequent generations, presumably because of environmental influences.

Cigarette smoking is associated with a worse prognosis in patients with Crohn disease but an improved course in ulcerative colitis. Nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be associated with new onset of inflammatory bowel disease and with exacerbations of disease. Appendectomy for an inflammatory indication has been suggested as protective against the development of ulcerative colitis. Diet does not clearly affect the course of inflammatory bowel disease.

PATHOBIOLOGY

Although the trigger for inflammatory bowel disease is not known, three major pathways likely activate the disease: a genetic predisposition, immune

ABSTRACT

Inflammatory bowel disease represents idiopathic inflammatory disorders comprised primarily of ulcerative colitis and Crohn disease, both of which are chronic disorders that are increasing in prevalence and occur worldwide. Better understanding of pathogenesis, including the roles of genetics and the intestinal microbiome, has led to transformational changes in medical treatments, fewer extraintestinal manifestations, lower rates of surgery, and improved quality of life.

colitis

dysregulation, and an environmental trigger.[2] A possible explanation is that the inability of the innate immune system to clear microbial antigens, combined with increased intestinal epithelial permeability to antigens, eventually leads to an overactive adaptive immune response.[3]

Genetics

Of patients with inflammatory bowel disease, 5 to 20% have another family member with inflammatory bowel disease. First-degree relatives have a 10- to 15-fold increased risk for developing inflammatory bowel disease. The concordance rate of developing Crohn disease in identical twins, siblings, and first-degree relatives is 50%, 0 to 3%, and 5 to 10%, respectively. Ulcerative colitis follows similar genetic patterns but with slightly lower risk rates. Twenty percent of patients with a positive family history of inflammatory bowel disease will have discordant disease type: one family member with Crohn disease and another with ulcerative colitis.

More than 200 gene susceptibility loci have been linked to inflammatory bowel disease, with at least 30 specific for Crohn disease and more than 20 specific for ulcerative colitis.[4] *NOD2/CARD15*, which is located on chromosome 16 (16q12) and expressed in intestinal epithelial Paneth cells, macrophages, and dendritic cells, is involved in the expression of an intracellular receptor that senses muramyl dipeptide, which is a peptidoglycan component of gram-positive bacteria. Activation of *NOD2* leads to activation of nuclear factor κ-B (NF-κB), which mediates transcription of numerous proinflammatory cytokines. A mutation in the leucine-rich domain of the NOD2 protein, which interacts with bacterial lipopolysaccharide, leads to failure in activation of NF-κB and is associated with the development of Crohn disease.

The *ATG16L1* gene on chromosome 2 and the *IRGM* gene on chromosome 5 also have been associated with increased susceptibility to Crohn disease. Both are members of a family of genes involved in autophagy, an autonomous process that involves the maintenance of cellular homeostasis and organelle turnover, as well as the processing of intracellular pathogens, the subsequent presentation of antigens, and the regulation of cell signaling. Toll-like receptor-4 gene polymorphisms are associated with both Crohn disease and ulcerative colitis. Polymorphisms of the interleukin-23 (IL-23) receptor gene are associated with ulcerative colitis and a varied risk for Crohn disease. The presence of an adenylate cyclase 7 (*ADCY7*) missense mutation leads to an excessive inflammatory response that predisposes to ulcerative colitis. Human leukocyte antigen (HLA) class II polymorphisms, especially in HLA-DR molecules, may confer increased risk for ulcerative colitis and possibly Crohn as well. The *OCTN1* gene (located on chromosome 5q31) and the *DLG5* gene (located on chromosome 10) are associated with Crohn disease. *DLG5* encodes a scaffolding protein that is important for maintaining epithelial integrity in various organs, whereas *OCTN1* encodes for an ion channel that regulates cell-to-cell signaling in the intestinal epithelium.

Inflammatory bowel disease also has been associated with Turner syndrome (Chapter 214), glycogen storage type Ib (Chapter 191), and the Hermansky-Pudlak syndrome (triad of albinism, platelet aggregation defect, and accumulation of ceroid-like pigment in tissue) (Chapter 159). Inflammatory bowel disease also is associated with various diseases that have known genetic predisposition, including ankylosing spondylitis (Chapter 244), psoriasis (Chapter 405), atopy (Chapter 230), eczema (Chapter 405), celiac sprue (Chapter 126), cystic fibrosis (Chapter 77), primary sclerosing cholangitis (Chapter 141), multiple sclerosis (Chapter 380), autoimmune thyroid disease (Chapter 207), autoimmune hemolytic anemia (Chapter 146), primary biliary cirrhosis (Chapter 141), myasthenia gravis (Chapter 390), and Cogan syndrome (Chapter 249).

PATHOPHYSIOLOGY

Microbes likely play a part in the development of inflammatory bowel disease. In several animal models of colitis, colitis does not develop in a sterile environment but can be induced after the introduction of commensal bacteria. For instance, helminth infection protects mice with *Nod2* mutations, which otherwise make them susceptible to Crohn disease, by inhibiting colonization by an inflammatory *Bacteroides* species. *Debaryomyces hansenii* (also known as *Candida famata*) has recently been implicated as a fungus that is found in Crohn disease tissue and can lead to dysregulated healing.[5]

Diverting the fecal stream away from active mucosal inflammation, such as in an ileostomy, also helps alleviate inflammation in Crohn disease. Crohn disease and ulcerative colitis preferentially occur in the terminal ileum and colon, which contain the highest concentration of bacteria, on the order of approximately 10^{12} organisms per gram of luminal contents. Antibiotics, particularly antibiotics with broad-spectrum anaerobic coverage, are helpful in the treatment of Crohn disease. More recently, several genetic polymorphisms associated with sensing the intestinal microbial environment and triggering an immune response have been linked to inflammatory bowel disease.

Both Crohn disease and ulcerative colitis are products of a dysregulated innate immune system that triggers T cells and a humoral response. T_H17 cells, which are activated in Crohn disease and ulcerative colitis, are stimulated by IL-23, which is produced by antigen-presenting cells.

Western-type diets (which are typically high in protein, fat, salt, sugar, other additives, and preservatives but low in fruit, vegetables, and fiber) are associated with almost a two-fold increased risk of developing inflammatory bowel disease.[6] Such foods and additives may disrupt the gut microbiota and propagate of immune activation.

Pathology

Crohn Disease

As a result of a dysregulated immune system, patients with Crohn disease develop aphthous ulcers, which are superficial mucosal ulcers. As the disease progresses, the ulceration becomes deeper, transmural, and discrete; it may form a serpiginous pattern and may occur anywhere from the mouth to the anus in a noncontinuous pattern. The most common location for ulceration is the ileocecal region. In some patients, chronic disease leads to the formation of fibrotic strictures, and approximately 30% of patients may develop fistulas in the course of their disease.

In early Crohn disease, the histopathologic findings are characterized by an acute inflammatory infiltrate in the lamina propria, with cryptitis, and crypt abscesses. Later in the disease process, the crypt architecture becomes distorted, with a lymphocytic infiltrate and a resulting branching and shortening of the crypts. Noncaseating granulomas, which may be found in up to 15% of endoscopic biopsy specimens and up to 70% of surgical specimens, are not unique to Crohn disease but help confirm the diagnosis when other classic features are present.

Surgical specimens also may show transmural intestinal wall inflammation and fat creeping on the serosal surface.

Ulcerative Colitis

In mild ulcerative colitis, the mucosa is granular, hyperemic, and edematous in appearance. As the disease becomes more severe, the mucosa ulcerates, and the ulcers may extend into the lamina propria. Ulcerative colitis starts in the rectum and may extend proximally in a continuous pattern, but it affects only the colon. Pseudopolyps may form owing to epithelial regeneration after recurrent acute attacks. With chronic disease, the colonic mucosa may lose the normal fold pattern, the colon may shorten, and the colon may appear narrowed.

In early ulcerative colitis, the histopathologic findings are characterized by epithelial necrosis, an acute inflammatory infiltrate in the lamina propria, with cryptitis and crypt abscesses. In chronic disease, a predominant lymphocytic infiltrate and distortion of crypt architecture are seen.

CLINICAL MANIFESTATIONS

Symptoms of inflammatory bowel disease are varied and may be a consequence of the location of the disease, the duration of disease, and any anatomic complications of the disease, such as strictures and fistulas in Crohn disease (Table 127-1).

TABLE 127-1 CLINICAL CHARACTERISTICS OF CROHN DISEASE AND ULCERATIVE COLITIS

CHARACTERISTICS	CROHN DISEASE	ULCERATIVE COLITIS
Peak age of onset (years of age)	15-30, 2nd peak in the 7th decade	20-40, 2nd smaller peak beyond the 7th decade
Sex distribution (F/M)	1.2/1	1/1
Potential sites of gastrointestinal involvement	Esophagus to anus	Colon
Skipped areas of involvement	+	–
Transmural inflammation	+	–
Type of ulceration	Usually discrete	Continuous
Fistula	+	–
Stricture	+	–
Perianal disease (fissure, skin tags)	+	–

Symptoms

Crohn Disease

The terminal ileum is affected in about 70% of patients with Crohn disease. Primary ileal disease occurs in 30% of patients, whereas ileocolonic disease occurs in 40%. Symptoms may include abdominal pain, typically in the right lower quadrant, diarrhea, hematochezia, and fatigue. With more severe disease, fever and weight loss may be present. Some patients may present with obstructive symptoms, such as abdominal pain, abdominal distention, and nausea.[7]

Only approximately 5% of patients develop Crohn disease in the upper gastrointestinal tract, and esophageal Crohn disease occurs in fewer than 2% of patients. Subjects with upper gastrointestinal Crohn disease may present with dysphagia, odynophagia, chest pain, or heartburn. Gastroduodenal disease occurs in 0.5 to 4% of patients and commonly occurs along with distal disease. Symptoms may include upper abdominal pain. Isolated jejunal disease is rare; if the jejunum is involved, there is also distal small bowel involvement. Up to 30% of patients have perianal disease (Chapter 131) that may include the development of fistulas, abscesses, fissures, and skin tags. Symptoms of perianal disease include pain and discharge. Fever may be present if there is an abscess.

Fistulae, which are internal tracts that connect one organ to another (e.g. rectovaginal, enterovesicular, perianal) or to the skin surface (e.g., anus to skin), can occur anywhere in the gastrointestinal tract and develop in 20 to 40% of Crohn patients. Penetrating Crohn disease also may cause intra-abdominal and perianal abscesses owing to a fistula with a blind end or intestinal perforation. External fistulas, which present with symptoms of fluid discharge from the cutaneous opening, can be enterocutaneous or perianal. Internal fistulas can be enteroenteric, rectovaginal, or enterocolonic. Patients may present with persistent abdominal pain and fever with an abscess in this location.

Ulcerative Colitis

As with Crohn disease, symptoms and signs of ulcerative colitis depend on the extent and severity of disease. At the time of diagnosis, 14 to 37% of patients have pancolitis, 36 to 41% have disease extending beyond the rectum, and 44 to 49% have proctosigmoiditis. Symptoms include hematochezia, diarrhea, tenesmus, production of excessive mucus, urgency to defecate, and abdominal pain. In the setting of proctitis or proctosigmoiditis, patients may have constipation with difficulty defecating. With more extensive and severe colonic involvement, patients also may have weight loss and fever. They also may have nausea and vomiting because of abdominal pain, fatigue because of anemia, and peripheral edema as a consequence of hypoalbuminemia.

Physical Examination

Signs on physical examination are representative of the type of disease as well as its location and severity. Oral ulcers may be present in Crohn disease. The location of abdominal tenderness usually reflects the location of intestinal involvement. In Crohn disease, abdominal tenderness is classically in the right lower quadrant and may include fullness or a mass depending on the severity of inflammation. Peritoneal signs may occur when penetrating Crohn disease causes intestinal perforation. Rectal examination may reveal skin tags, hemorrhoids, fissure, and fistulae. Additionally, the finding of a rectal stricture maybe a sign of current or past Crohn involvement.

Extraintestinal Manifestations

Arthropathy, the most common extraintestinal manifestation (Table 127-2), affects up to 10 to 20% of subjects. Peripheral arthralgias, arthritis, ankylosing spondylitis (Chapter 244), and sacroiliitis may exacerbate with gastrointestinal symptoms. Dermatologic disorders, such as erythema nodosum (in 10 to 15% of patients; see Fig. 407-24) and pyoderma gangrenosum (in 1 to 2% of patients; Chapter 240), develop in up to 15% of patients. Ocular disorders, especially uveitis and episcleritis (Chapter 391), may occur in 5 to 15% of patients with irritable bowel disease. Patients with inflammatory bowel disease also have up to a 10% risk for renal calculi, especially calcium oxalate stones (Chapter 111), in the setting of fat malabsorption with Crohn disease in the small bowel. Uric acid stones can occur in the setting of severe volume depletion. Patients with inflammatory bowel disease, especially patients with ulcerative colitis, are at increased risk for primary sclerosing cholangitis—2 to 7.5% of patients develop this disorder, and 70 to 80% of patients with this disorder have underlying inflammatory bowel disease (Chapter 141).

Extraintestinal Complications

Patients with inflammatory bowel disease are susceptible to extraintestinal complications from the disease itself or medications used to treat disease.

TABLE 127-2 EXTRAINTESTINAL COMPLICATIONS OF INFLAMMATORY BOWEL DISEASE

COMPLICATIONS	CROHN DISEASE	ULCERATIVE COLITIS
Ocular disorders (uveitis, episcleritis)	+	+
Arthropathy	+	+
Oral ulcers	+	–
Skin disorders (pyoderma gangrenosum, erythema nodosum)	+	+
Nephrolithiasis	+	+
Primary sclerosing cholangitis	+	+
Bone disorders (osteoporosis, osteomalacia)	+	–
Thromboembolic disease	+	+
B_{12} deficiency	+	–

These complications include osteoporosis, osteomalacia, arthritic complications, thromboembolic events, pulmonary disease,[7] and renal, dermatologic, and neurologic complications. Osteoporosis occurs in approximately 15% of patients, and steroid therapy (Chapter 28) is the major risk factor; avascular necrosis of the hip and septic arthritis are unusual complications of steroids or other immunosuppressive therapies. Cheilitis may be a result of iron deficiency anemia (Chapter 145). Patients with inflammatory bowel disease are at an increased risk for thromboembolic disease, especially in the setting of active intestinal disease, even when compared with other autoimmune diseases such as rheumatoid arthritis and celiac disease. Secondary amyloidosis with renal involvement can be a consequence of chronic inflammation. Asthma is the most common pulmonary disorder observed in association with Crohn disease. Patients also are at risk for optic neuritis and multiple sclerosis (Chapter 380), as well as for peripheral neuropathy (Chapter 388) from vitamin B_{12} deficiency, which may occur as a result of poor absorption owing to active small bowel disease, surgical resection, or small intestinal bacterial overgrowth.

DIAGNOSIS

When diarrhea (Chapter 126) is the predominant symptom, the initial evaluation should include a thorough medical history, testing for infectious colitis (Chapter 126), and screening for endocrine-metabolic disorders such as hyperthyroidism (Chapter 207) and hypocalcemia (Chapter 227). Infections with organisms such as *Salmonella* (Chapter 284), *Shigella* (Chapter 285), *Amoeba* (Chapter 323), *Giardia* (Chapter 322), *Escherichia coli* O157:H7 (Chapter 280), and *Campylobacter* (Chapter 279) can be accompanied by bloody diarrhea, abdominal cramps, and an endoscopic mucosal appearance identical to that of ulcerative colitis. Stool studies are needed to diagnose or exclude these infections. If hematochezia and abdominal pain are the predominant symptoms, the differential diagnosis is broad (Table 127-3).

Diagnostic Evaluation

Endoscopic Evaluation

In a patient with symptoms suggestive of inflammatory bowel disease and no evidence for an infection to explain the symptoms, endoscopic evaluation is essential. Colonoscopy is the initial endoscopic test for patients who present with lower gastrointestinal symptoms such as diarrhea and hematochezia, except in the presence of acute severe peritoneal symptoms. Colonoscopy up to and including the terminal ileum is important if there is a potential diagnosis of inflammatory bowel disease. Small bowel imaging (such as small bowel follow-through or computed tomography [CT] enterography, or magnetic resonance imaging [MRI] enterography) also may be needed to determine whether there is small bowel disease or to determine the distribution of disease. Capsule endoscopy is useful if all other endoscopic and radiologic testing is nondiagnostic, but Crohn disease of the small bowel is still suspected. Findings on capsule endoscopy should be followed by endoscopy to obtain biopsies. Capsule endoscopy should not be performed if Crohn disease is complicated by a known small bowel stricture. If it is uncertain whether a stricture is present, a patency capsule can be used initially to discern if it passes.

TABLE 127-3 DIFFERENTIAL DIAGNOSIS OF ILEITIS AND COLITIS

FIGURE 127-1. Endoscopic appearance of Crohn disease with cobblestoning.

Crohn Disease

Early endoscopic findings in Crohn disease include superficial small mucosal ulcers, also called aphthous ulcers. As the severity of Crohn disease progresses, the ulcerations become deeper and may become round, linear, or serpiginous. Intersecting longitudinal and transverse ulcers cause a cobblestone mucosal appearance, with "stone" areas representing normal mucosa (Fig. 127-1). Areas of ulceration, which are typically interspersed with normal "skip" areas, may occur anywhere from the esophagus to anus but are most common in the ileocecal region. Isolated colonic disease occurs in 25% of patients, and 60% will have rectal involvement, thereby making it at times difficult to differentiate from ulcerative colitis.

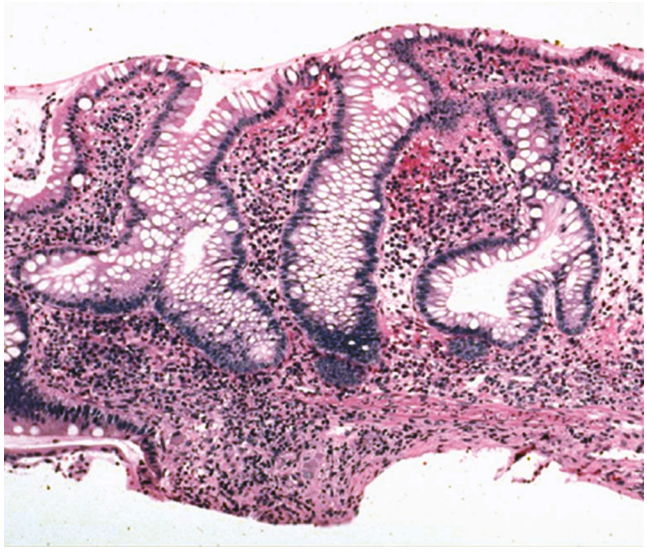

FIGURE 127-2. In ulcerative colitis, histopathology from colonic biopsies reveals features of crypt distortion and lymphocytic infiltration in the mucosa. (Modified from AGA Institute Slides 2010.)

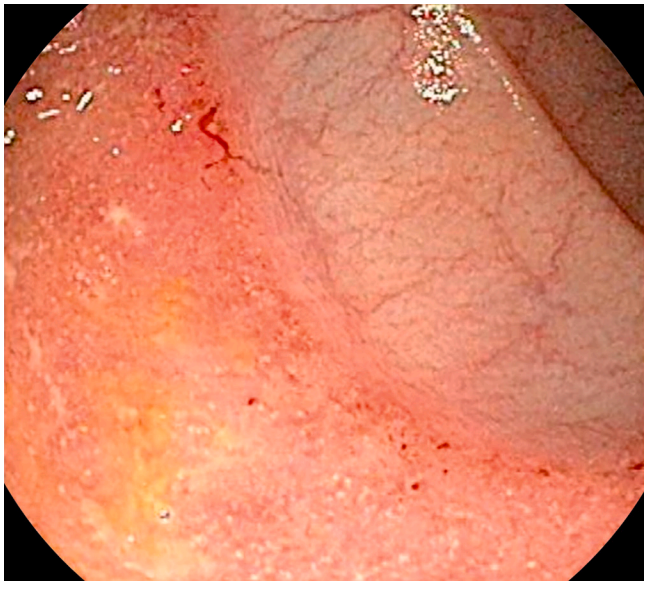

FIGURE 127-3. Endoscopic appearance of ulcerative colitis.

The diagnosis of inflammatory bowel disease is contingent upon accurate histopathologic results, so biopsy of the affected area(s) is key. Findings of an inflammatory infiltrate in the lamina propria and distortion of the crypt architecture support the diagnosis (Fig. 127-2). The diagnosis of Crohn disease may be made by histopathologic examination alone if noncaseating granulomas are seen, but granulomas are rarely found on endoscopic biopsies. The diagnosis of Crohn disease is usually based on a combination of information gleaned from histopathologic findings, colonoscopy, and small bowel imaging. A skip pattern of ulceration, ulceration in the small bowel or upper gastrointestinal tract, or the presence of fistulas support the diagnosis of Crohn disease. Colonic and small bowel ulceration occur in several other disorders, including infections that may not be detected by routine stool studies (such as enterohemorrhagic *E. coli*), vascular disorders, immune-related enterocolitis, neoplasia, diverticulitis, radiation, and medications such as NSAIDs (see Table 127-3).

Ulcerative Colitis

The diagnosis of ulcerative colitis is based on endoscopic findings (Video 127-1) and histopathology.[8] Early in the disease process, patients develop diffuse mucosal erythema with loss of the normal mucosal vascular pattern. In mild disease, the mucosa may have a granular and edematous appearance. As the disease becomes more severe, the mucosa becomes more friable, bleeds easily when the mucosa is touched, and may eventually ulcerate (Fig. 127-3). Endoscopic findings, which start in the rectum and may extend proximally

in a continuous pattern, affect only the colon. The term "backwash ileitis" describes a spillover effect from ulcerative colitis and should not be construed as actual involvement of the terminal ileum by ulcerative colitis. Pseudopolyps may form owing to epithelial regeneration after recurrent attacks in patients with long-standing disease. The presence of pseudopolyps is thought to be a marker of more severe disease. With chronic disease, the colonic mucosa may lose its normal fold pattern, and the colon may shorten and appear narrowed. Careful endoscopic observation—including the observed vascular pattern, bleeding, and ulceration—can assess the severity of ulcerative colitis and monitor its response to treatment.

Features such as crypt distortion, continuous mucosal inflammation starting from the rectum, absence of granulomas, and absence of small bowel disease are consistent with ulcerative colitis. Early in the disease process, chronic inflammatory findings, such as crypt distortion, may not be present, and the diagnosis may be more difficult to establish.

Radiology

Radiologic imaging is vital and almost always should be obtained when inflammatory bowel disease, particularly Crohn disease, is suspected. CT enterography and magnetic resonance imaging (MRI) enterography have supplanted barium studies (such as an upper gastrointestinal series, small bowel follow-through, and barium enema) to diagnose the extent, severity, and type of disease (strictures and fistulas) of Crohn disease. CT and MRI enterography are also useful for the detection of abdominal abscesses and perineal abscesses.

Laboratory Findings

Anemia may result from chronic disease, blood loss, or nutritional deficiencies of iron, folate, or vitamin B_{12}. A modestly elevated leukocyte count is indicative of active disease, but a marked elevation suggests an abscess or another suppurative complication. The erythrocyte sedimentation rate and C-reactive protein are nonspecific serum inflammatory markers that are commonly used to monitor the activity of disease. Fecal calprotectin levels tend to be elevated in active disease and lower when patients are in remission.[9] Hypoalbuminemia is an indication of malnutrition and is common with active disease. Ileal disease or resection of more than 100 cm of distal ileum results in a diminished serum vitamin B_{12} level because of malabsorption.

Serologic Markers

Serologic markers are supportive but may not be used independently to diagnose inflammatory bowel disease. Anti–*Saccharomyces cerevisiae* antibodies (ASCA), which are antibodies to yeast, are present in 40 to 70% of patients with Crohn disease and in less than 15% of patients with ulcerative colitis. The combination of elevated ASCA immunoglobulin A (IgA) and IgG titers is highly specific for Crohn disease, ranging from 89 to 100%. Perinuclear antineutrophil cytoplasmic antibodies (pANCA) are present in 20% of Crohn patients, primarily in colon-predominant disease, and in 55% of patients with ulcerative colitis. ASCA-positive and pANCA-negative disease are associated with a sensitivity of 55% and specificity of 93% for Crohn disease. The antimicrobial antibodies anti-I2 (Crohn disease–related protein from *Pseudomonas fluorescens*), anti-Cbir1 (flagellin-like antigen), and anti-OmpC (*E. coli* outer membrane porin C) are also associated with Crohn disease.

TREATMENT

The aim of medical therapy is to reduce inflammation and subsequently induce and maintain clinical remission while simultaneously healing the mucosa. Medications used to treat inflammatory bowel disease include the categories of 5-aminosalicylate (5-ASA), antibiotics, corticosteroids, immunomodulators (azathioprine, mercaptopurine, methotrexate, and ozanimod), and biologics (infliximab, adalimumab, certolizumab pegol, golimumab, vedolizumab, natalizumab, and ustekinumab; Table 127-4). The specific medical therapy selected[10] is based on the location, extent (nonpenetrating and nonstricturing, stricturing, and penetrating and fistulizing disease), severity of disease, and future prognosis. Patients with high-risk disease (high potential for future surgery or complications such as fistula and abscess) or high disease activity are considered candidates for biologic therapy.[11] Supportive medical therapy, such as antidiarrheal and antispasmodic medications, also may be used. In patients over age 60 years, who represent about 15% of newly diagnosed cases, the risk-benefit ratio of more aggressive therapies may be less favorable.[12]

Categories of Medical Therapy

5-Aminosalicylate

5-ASA, which acts as a topical anti-inflammatory within the lumen of the intestine, is used to treat mild to moderate ulcerative colitis and as maintenance therapy for patients in remission.[A1,A2] Sulfasalazine is the combination of a sulfapyridine with 5-ASA; 5-ASA is responsible for the anti-inflammatory property of this drug, whereas sulfapyridine is the carrier that allows 5-ASA to be delivered to the colon. Other oral formulations of 5-ASA allow it to be delivered to the intestine by different mechanisms. Mesalamine is released in the intestine based on a pH delivery model, whereas sulfasalazine, olsalazine, and balsalazide are released in the intestine by bacterial cleavage of a covalent bond between 5-ASA and a prodrug. For rectal and sigmoid disease, 5-ASA suppository and enema preparations are also effective for induction and maintenance of remission in patients with ulcerative colitis. Adverse events associated with 5-ASAs are uncommon but may include nausea, dyspepsia, hair loss, headache, pancreatitis, worsening diarrhea, and hypersensitivity reactions.

Corticosteroids

Corticosteroids are primarily used to treat flares of ulcerative colitis and Crohn disease. Oral formulations may be used for mild to moderate disease, whereas systemic corticosteroids are used for moderate to severe disease.

Enteric-coated budesonide, a pH-dependent ileal release formulation, is an oral corticosteroid with high topical activity and low systemic bioavailability (10%). Enteric-coated budesonide is indicated for treatment of active mild to moderate ileocecal Crohn disease. Budesonide MMX is released in the colon and is available for treatment of mild to moderately active ulcerative colitis. Budesonide foam is administered rectally with an applicator in the colon for mild to moderately active ulcerative colitis limited to the rectum and sigmoid colon. Oral corticosteroids such as prednisone and methylprednisolone are used for moderate to severe disease, starting at doses ranging from 40 to 60 mg/day for 1 to 2 weeks, then typically tapered over a period of 8 to 12 weeks. Intravenous methylprednisolone is used for severe disease, with dosing ranging from 40 to 60 mg/day. When symptoms are controlled, systemic corticosteroids are not recommended because of their substantial side effects and their lack of efficacy for maintaining remission (Chapter 28).

Immunomodulation

In patients who remain symptomatic despite 5-ASA therapy or who have moderate to severe Crohn disease[A3] or ulcerative colitis,[A4] immunomodulators can provide substantial benefit.[13]

Janus-Kinase Inhibition

Tofacitinib (an oral, nonselective inhibitor of the Janus kinase family) has a more rapid onset of activity for moderate to severe ulcerative colitis[A5] at 10 mg orally twice daily for at least 8 weeks, then 5 or 10 mg twice daily with the medication discontinued if an adequate therapeutic benefit is not achieved by 16 weeks. Side effects include activation of nonsystemic herpes zoster, an abnormal lipid profile, thrombosis, and the potential risk of lymphoma.

Upadacitinib (an oral, selective inhibitor of the Janus kinase family) has a rapid onset of activity and is approved for the treatment of moderate to severely active ulcerative colitis.[A6] The induction dose (45 mg once daily for 8 weeks) should be followed by a maintenance dose (usually 15 mg once daily, but 30 mg once daily can be considered for patients who have refractory, severe, or extensive disease), but dosing should be at the lowest effective dose in the individual patient. Upadacitinib should be discontinued if adequate therapeutic response is not achieved with the 30 mg dosage.

Anti–Tumor Necrosis Factor-α Agents

Monoclonal antibody therapy directed against tumor necrosis factor-α (anti–TNF-α) include infliximab (which is a chimeric mouse-human IgG1 monoclonal antibody that is infused intravenously), adalimumab and golimumab (which are fully human IgG1 antibodies that are self-administered subcutaneously), and certolizumab pegol (which is a chimeric pegylated Fab fragment IgG-4 to TNF-α administered subcutaneously). Infliximab is effective against moderate to severe Crohn disease, fistulizing Crohn disease, and moderate to severe ulcerative colitis that has failed to respond to conventional therapy, as well as in patients who have ulcerative colitis with high-risk prognostic indicators. Adalimumab and certolizumab pegol are effective for moderate to severe Crohn disease that has failed to respond to conventional therapy, and adalimumab and golimumab are useful for moderate to severe ulcerative colitis that has failed to respond to conventional therapy or have high active disease with high-risk prognostic indicators.

In patients with early Crohn disease, timely use and escalation of anti–TNF-α treatment based on symptoms and biomarkers (e.g., a fecal calprotectin ≥250 μg/g of stool, a C-reactive protein level ≥5 mg/L, a Crohn Disease Activity Index ≥150 [E-Table 127-1], or prednisone use in the previous week) results in better clinical and endoscopic outcomes than does symptom-driven decisions alone. Before anti-TNF therapy is considered, however, risk versus benefit needs to be assessed in each individual patient, given the potential risks, including infection and malignancy.

Other Biologics

Natalizumab (a humanized IgG4 monoclonal antibody, against the α_4 subunit of $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins expressed on all leukocytes except neutrophils) is useful for treatment of moderate to severe Crohn disease that is refractory to other therapies, but strict guidelines must be followed because of its associated risk for progressive multifocal leukoencephalopathy (Chapter 341). Another small adhesion molecule, vedolizumab (see Table 127-4) is used in patients who have

E-TABLE 127-1 CROHN DISEASE ACTIVITY INDEX

CLINICAL OR LABORATORY VARIABLE	WEIGHTING FACTOR
Number of liquid or soft stools each day × 7 days	× 2
Abdominal pain (graded from 0-3 on severity) each day × 7 days	× 5
General well-being, subjectively assessed from 0 (well) to 4 (terrible) each day × 7 days	× 7
Presence of complications (see below)	× 20
Taking diphenoxylate-atropine or opiates for diarrhea	× 30

TABLE 127-4 MEDICAL THERAPIES FOR INFLAMMATORY BOWEL DISEASE

DRUG	DOSE	RELEASE SITE
5-AMINOSALICYLATES		
Sulfasalazine (Azulfidine)	2-6 g PO/day	Colon
Mesalamine (Asacol, Lialda, Apriso)	2.4-4.8 g PO/day	Distal ileum, colon
Olsalazine (Dipentum)	1-3 g PO/day	Colon
Balsalazide (Colazal)	6.25 g PO/day	Colon
Mesalamine (Pentasa)	2-4 g PO/day	Duodenum, jejunum, ileum, colon
Mesalamine (Rowasa), enema, suppository	4 g/day (enema) 1 g/day (suppository)	Rectum/sigmoid Rectum
Mesalamine (Canasa), suppository	1 g/day (suppository)	Rectum
CORTICOSTEROIDS		
Budesonide (Entocort EC)	Induction: 9 mg PO daily Maintenance: 6 mg PO daily	Small intestine
Budesonide (MMX, UCERIS)	Induction 9 mg PO daily	Colon
Budesonide (UCERIS foam)	2 mg budesonide per metered dose 1 metered dose administered twice daily for 2 weeks followed by 1 metered dose administered once daily for 4 weeks	Colon
Prednisone	0.25-0.75 mg/kg PO daily	Systemic
Methylprednisolone	40-60 mg IV daily	Systemic
IMMUNOMODULATORS		
Upadacitinib	45 mg PO once daily for 8 weeks then 15 mg PO a day further for at least 8 weeks. A maintenance dose of 30 mg PO once daily can be considered for patients who have refractory, severe, or extensive disease. Upadacitinib should be discontinued if an adequate therapeutic response is not achieved with the 30 mg dose	
Tofacitinib	10 mg PO twice daily for 8 weeks then 5 to 10 mg PO twice daily for 8 weeks further then 10 mg twice daily for at least 8 weeks; followed by 5 or 10 mg twice daily, depending on therapeutic response	Systemic
6-Mercaptopurine	1.5 mg PO/kg/day	Systemic
Azathioprine	2.5 mg PO/kg/day	Systemic
Methotrexate	Induction: 25 mg SQ weekly for 4 months Maintenance: 15-25 mg SQ weekly	Systemic
Cyclosporine	2-4 mg/kg/day IV	Systemic
Ozanimod	1 mg PO daily	Systemic
BIOLOGICS		
Infliximab	Induction: 5 mg/kg IV weeks 0, 2, 6 Maintenance: 5-10 mg/kg IV every 8 weeks	Systemic
Adalimumab	Induction: 160 mg SQ week 0, 80 mg week 2 Maintenance: 40 mg SQ every other week	Systemic
Golimumab	Induction: 200 mg SQ week 0 and 100 mg week 2 Maintenance: 100 mg SQ every 4 weeks	Systemic
Certolizumab pegol	Induction: 400 mg SQ weeks 0, 2, 4 Maintenance: 400 mg SQ every 4 weeks	Systemic
Natalizumab	300 mg IV every 4 weeks	Systemic
Vedolizumab	Induction: 300 mg IV at 0, 2, and 6 weeks Maintenance: 300 mg IV every 8 weeks	Systemic
Ustekinumab	Induction: intravenous: Up to 55 kg: 260 mg; greater than 55 kg to 85 kg: 390 mg; greater than 85 kg: 520 mg Maintenance: 90 mg SQ every 8 weeks	
Risankizumab	Induction: 600 mg IV at 0, 4, and 8 weeks Maintenance: 180 mg or 360 mg SQ at week 12 and every 8 weeks thereafter	

IV = intravenously; PO = orally; SQ = subcutaneously.

moderate to severe ulcerative colitis and adult patients with moderate to severe Crohn disease when one or more standard therapies (corticosteroids, immunomodulators, or TNF blocker medications) have not provided an adequate response. Ustekinumab (a monoclonal antibody to the p40 subunit of interleukin-12 and interleukin-23), used as intravenous induction therapy followed by subcutaneous maintenance therapy, can induce and maintain clinical remission in patients with moderately to severely active ulcerative colitis.[A7] Risankizumab (a monoclonal antibody to the p19 subunit of interleukin-23) given as an intravenous induction followed by subcutaneous maintenance therapy (see Table 127-4) can induce and maintain clinical remission in patients with moderately to severely active Crohn disease.[A8,A9] Ozanimod (an oral sphingosine phosphate agonist that reduces lymphocytes at 1 mg orally daily) has rapid onset of action and can induce and maintain remission in patients with moderate to severe ulcerative colitis.[A10]

Other Immunomodulators

The use of azathioprine, 6-mercaptopurine, and methotrexate has fallen out of favor as primary therapy for patients with ulcerative colitis and Crohn disease, because of the superior efficacies and safety profiles of biologic and other agents. These immunomodulators have a slow onset of action, often requiring

several months of administration before their benefits are achieved, so they are used principally for maintenance of remission.

Azathioprine, the prodrug of 6-mercaptopurine, typically is prescribed at a dose of 2 to 3 mg/kg/day; the equivalent dose of 6-mercaptopurine is 1.5 mg/kg/day. Side effects include allergic reactions, pancreatitis, myelosuppression, nausea, infections, hepatotoxicity, and malignancy, especially lymphoma. The white blood cell count and liver chemistries must be monitored routinely. Methotrexate, which is a folic acid antagonist, is given as 25 mg intramuscularly or subcutaneously once per week for 16 weeks for active Crohn disease and 15 mg to 25 mg intramuscularly or subcutaneously once per week for maintaining remission. In addition to its use as primary therapy for Crohn disease, methotrexate has been used in conjunction with other biologic agents to reduce immunogenicity.

Antibiotics

The exact mechanism for the beneficial effect of broad-spectrum antibiotics in the treatment of inflammatory bowel disease is not known. Potential mechanisms include eliminating small intestinal bacterial overgrowth, eradicating a bacterially mediated antigenic trigger by altering the intestinal microbiome, and potential immunosuppressive properties (e.g., metronidazole). The primary role of antibiotics is in Crohn disease, where metronidazole (10 to 20 mg/kg/day for 4 to 8 weeks), ciprofloxacin (500 mg orally [PO] twice daily for 4 to 8 weeks), or both are primary inductive therapies for perianal fistulae. Antibiotics are not used as primary therapy for ulcerative colitis or luminal Crohn disease because they do not induce mucosal healing.

Crohn Disease Medical Therapy

Mild to Moderate Crohn Disease

Sulfasalazine (3 to 6 g/day) is superior to placebo for treating active symptoms of ileocolonic and colonic Crohn disease, with response rates ranging from 45 to 55% for mild to moderate disease.[14] However, sulfasalazine is not clearly effective for small bowel disease alone (Fig. 127-4) and has not been demonstrated to heal the colonic or ileal mucosa. For mild to moderate Crohn disease involving the distal small intestine or proximal colon, enteric-coated budesonide (9 mg/day) provides approximately a 70% response rate after 8 weeks and is significantly more effective than mesalamine (4 g/day) for distal ileal and right colonic disease. Early combined immunosuppression with an anti–TNF-α antagonist and an antimetabolite is more effective than conventional management and more effective than either agent as monotherapy.

Upper gastrointestinal Crohn disease (jejunal, duodenal, gastric, and esophageal) is uncommon, and few clinical trials are available to assess therapies for this location. Because local therapies such as 5-ASAs and budesonide are not released in these locations, systemic immunosuppressants (azathioprine, mercaptopurine, methotrexate, infliximab, adalimumab, and certolizumab pegol, natalizumab, vedolizumab, risankizumab, and ustekinumab; see Table 127-4 for doses) are the mainstays of therapy.[15] In the absence of comparative trials, initial therapy might include the use of anti-TNF therapy alone on in combination with an antimetabolite (6-mercaptopurine, azathioprine, or methotrexate), ustekinumab, risankizumab, or vedolizumab.

Moderate to Severe Crohn Disease

Patients with moderate to severe disease are often initially treated with systemic corticosteroids, but corticosteroids should not be used as maintenance therapy. Biologics can be used initially as therapy for patients with high-risk disease or severe disease activity.[16,17] A meta-analysis suggests that either adalimumab, infliximab plus azathioprine, or ustekinumab are the three most effective therapies for induction and maintenance of remission of Crohn disease.[A1.1] For example, infliximab (5 mg/kg at 0, 2, and 6 weeks and then every 8 weeks) alone or infliximab plus azathioprine (2.5 mg/kg/day) is more effective than azathioprine alone, and initial combined therapy (corticosteroids, daily azathioprine, and infliximab) is preferable to reserving it only for patients who do not respond to corticosteroids plus azathioprine or who have aggressive disease. However, the benefit of using these medications as combination therapy versus individual monotherapy must be assessed in the context of the potential risk of long-term use.

Of patients with Crohn disease who are treated for at least 1 year with infliximab and azathioprine, approximately 50% will experience a relapse within 1 year after discontinuation of infliximab. Given the significant escalated risk for lymphoma in patients under the age 35 years, especially in men, methotrexate is often used in place of azathioprine or 6-mercaptopurin in this patient population. Patients who do not respond to conventional therapy, including an anti-TNF agent (e.g., adalimumab or certolizumab pegol), may be considered for vedolizumab, ustekinumab, or natalizumab (see Table 127-4 for dosing).

For severe Crohn disease, patients should be hospitalized, given nothing by mouth, rehydrated with intravenous fluids, and administered parenteral corticosteroids. Patients who respond to parenteral corticosteroids should be switched to high-dose oral corticosteroids (prednisone, 40 to 60 mg/day), with the dose of prednisone gradually reduced. Patients who have severe Crohn disease and who do not respond to parenteral corticosteroids within 3 to 5 days should be considered for either infliximab or surgery. A course of total parenteral nutrition (Chapter 198) may be useful as adjunctive therapy.

Fistulizing Crohn Disease

Fistulas (Chapter 131) occur in one third of patients with Crohn disease, and perianal fistulas represent the most common location. Asymptomatic internal fistulas rarely require therapy. A concomitant abscess, which may occur in the setting of a fistula, must be excluded before initiating immunosuppressive therapy. Surgery may be required. Medical treatment depends on the location and associated complications.

High-output enterocutaneous fistulas in the setting of proximal small bowel involvement can lead to outputs of more than 500 mL/day and can cause severe volume depletion. Initial management requires volume repletion. In the postoperative setting, a fistulous opening is usually in the area of a wound, and it is imperative to protect the healing skin from infection caused by the drainage

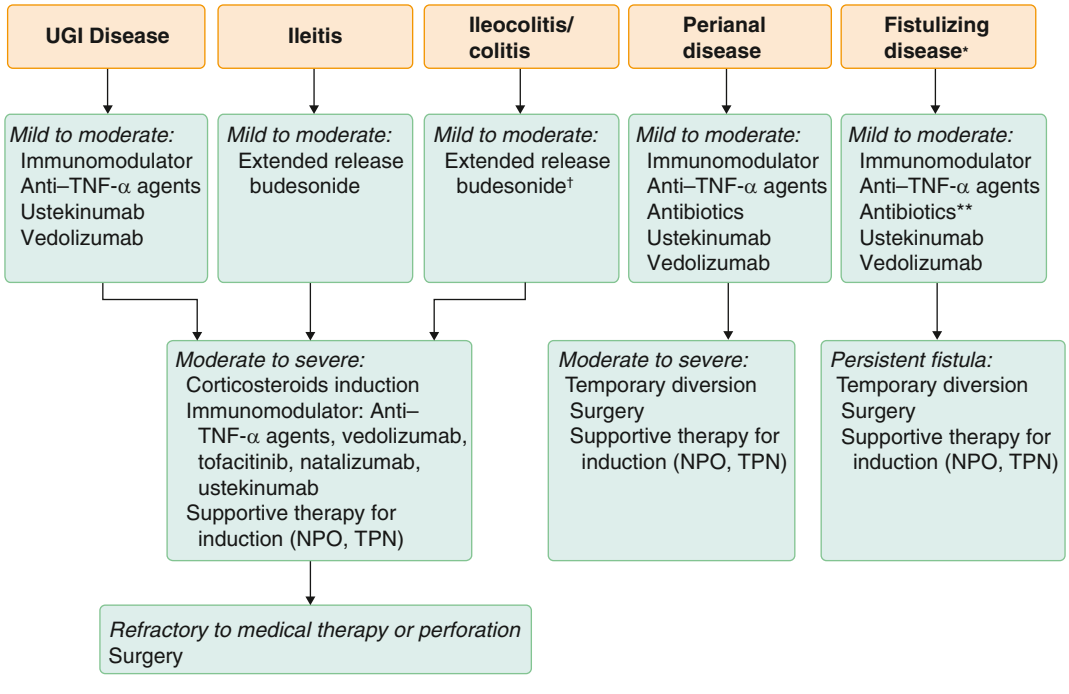

FIGURE 127-4. Crohn disease treatment algorithm. *Abscess should be excluded before initiating medical therapy. †Proximal colon disease involvement. **Perianal location. NPO = nothing by mouth; TNF-α = tumor necrosis factor-α; TPN = total parenteral nutrition; UGI = upper gastrointestinal.

from either an ostomy bag or a catheter used for a high-output fistula. High-output fistulas will rarely close spontaneously and typically will require surgical closure. Low-output fistulas are usually treated initially with anti–TNF-α therapy (e.g., infliximab, adalimumab, or certolizumab; see Table 127-4 for dosing).

Perianal fistulas are classified into simple and complex (Chapter 131). A simple fistula is located below the dentate line (i.e., most of the anal sphincter) and has one track. A complex fistula passes through the intersphincteric (high location), transsphincteric, or suprasphincteric region and may have multiple tracks. Simple fistulas respond well to medical therapy, initially with metronidazole (10 to 20 mg/kg/day PO for 4 to 8 weeks) and/or ciprofloxacin (500 mg PO twice daily for 4 to 8 weeks), but patients will also require additional treatment of the fistula and of any coexisting mucosal disease under expert supervision. Anti–TNF-α agents, ustekinumab, and vedolizumab (see Table 127-4 for dosing) are the first-line medical therapy. Patients with fistulas without rectal mucosal Crohn disease may respond well to fistulotomy, whereas patients with mucosal involvement may benefit from seton placement rather than fistulotomy. Complex fistulas usually require a combination of surgical and medical therapy. In the setting of intractable disease, colonic or ileal diversion may allow for rectal and perianal healing; in severe cases, proctocolectomy may be necessary.

For Crohn disease–related rectovaginal fistulas, medical therapy with anti–TNF-α agents (see Table 127-4 for dosing) or even azathioprine or 6-mercaptopurine is usually considered before surgery. Surgical therapy, such as fistulotomy and mucosal advancement flap surgery, may be considered.

Enterovesicular or colovesicular fistulas may be treated with antimetabolite therapy or anti–TNF-α agents, or both, but recurrent urinary tract infection is an indication for surgery. Surgery usually involves resection of involved bowel and closure of the bladder defect.

Asymptomatic internal fistulas, such as enteroenteric fistulas, do not require surgical intervention, but treatment with an anti-TNF agent (see Table 127-4 for dosing) or perhaps azathioprine or 6-mercaptopurine and/or a biologic agent may be considered. Internal fistulas, such as cologastric and coloduodenal, may cause substantial symptoms because of bypass of part of the intestine. If medical management fails or if an abscess forms, surgery is recommended.

Medical Management of Ulcerative Colitis

The decision guiding which therapy is appropriate for a specific patient with ulcerative colitis is dependent upon several factors, including anatomic distribution of disease; severity of disease activity; and risk (prognosis) of disease (Figure 127-5).[18] When focusing on anatomic distribution of ulcerative colitis as a guide to therapies, several options exist, including suppositories, retention enemas, topical foam, oral therapy, and parenteral therapy. Suppositories are effective to treat proctitis in the distal 20 cm of the colon. Topical foam and enemas are effective for distal and left-sided colitis. Oral therapy and parenteral therapy are effective for all locations of disease.[19]

Proctitis

For active ulcerative proctitis, topical 5-ASA (enema and suppository) in combination with oral treatment is superior to oral treatment alone.[20] Topical 5-ASA is superior to topical corticosteroids for treatment of active ulcerative proctitis; rectal 5-ASA therapy produces a faster response when given with oral 5-ASA. Corticosteroid enemas, suppositories, or foam[A12] also can be used if 5-ASA fails. 5-ASA or corticosteroid retention enemas can be used for active disease up to the splenic flexure (i.e., the rectum, sigmoid colon, and descending colon). Another approach to proctitis or distal colitis is an oral aminosalicylate, although a response may not be evident for 3 to 4 weeks. Additionally, once-a-day extended-release budesonide (budesonide MMX) and topical budesonide foam[A13] are effective for mild to moderately active ulcerative proctosigmoiditis, with fewer steroid-related side effects than conventional corticosteroids.

Extensive Colitis, Mild to Moderate

In patients with mild to moderate activity ulcerative colitis extending proximal to the splenic flexure, the initial drug of choice is an oral 5-ASA; efficacy increases with increasing doses. Even with more extensive disease, supplementation of oral 5-ASA with 5-ASA enemas or suppositories may help reduce the symptoms of fecal urgency that result from rectal involvement, and budesonide MMX provides incremental benefit. In patients with more than five or six bowel movements per day, in patients in whom a more rapid response is desired, or in patients who have not responded to 3 to 4 weeks of 5-ASA, the treatment of choice is oral corticosteroids. Patients with severe diarrhea, systemic symptoms, or significant amounts of blood in their stool should be started on prednisone 40 mg/day; most patients respond to oral corticosteroids within a few days. After the symptoms are controlled, prednisone can be tapered gradually by 5 mg every 1 to 2 weeks. Patients who respond to oral prednisone and can be fully withdrawn from it should be maintained on 5-ASA.

Severe Colitis

If patients with severe ulcerative colitis do not begin to respond to corticosteroids at the equivalent dose of methylprednisolone 60 mg IV within 3 to 5 days or do not completely respond within 7 to 10 days, options include colectomy, infliximab, or cyclosporine[21] (see Table 127-4 for dosing). Tofacitinib (10 mg twice daily) also can improve symptoms and maintain remission in patients with moderate to severe active ulcerative colitis.[22] Ozanimod (1 mg orally daily) also is effective in this situation for inducing and maintaining remission.

For patients whose disease flares whenever the corticosteroids are withdrawn or their corticosteroid dose is lowered, temptation to continue high-dose corticosteroid must be avoided. If the patient requires a substantial dose (>15 mg/day of prednisone) for more than 4 months, a trial of a biologic agent (infliximab, adalimumab, golimumab, vedolizumab, or ustekinumab) or an immunomodulator (azathioprine, mercaptopurine, ozanimod, tofacitinib, or upadacitinib) should be considered for maintenance of remission.[A14–A16] All those agents are efficacious, but vedolizumab may be the most efficacious and safe option.[A17] The choice among these agents requires expert guidance and consideration of the presence or absence of extraintestinal manifestations, the severity of the disease, the presence or absence of other comorbid conditions, the patient's preferences, and insurance coverage. Attempts should be made to reduce the steroid dose, and the goal of treatment is complete steroid withdrawal.

Fecal microbial transplantation is an experimental approach to the treatment of ulcerative colitis. Data so far are promising but inconclusive.[23]

Acute Flare

The most common indication for hospitalization in patients with ulcerative colitis is intractable diarrhea, although blood loss is also common. Patients with severely active ulcerative colitis should be evaluated for toxic megacolon by abdominal radiography or CT. Antidiarrheal medications and anticholinergic medications are contraindicated in patients with severe ulcerative colitis because of the risk for precipitating toxic megacolon. The mainstays of

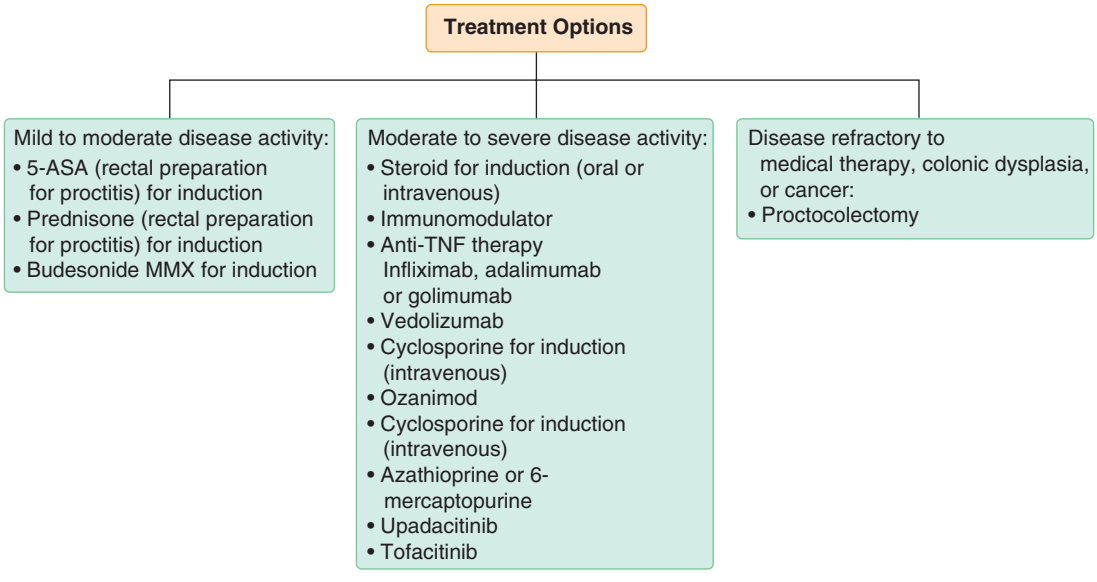

FIGURE 127-5. Ulcerative colitis treatment algorithm. 5-ASA = 5-aminosalicylic acid; MMX = multi-matrix system; TNF = tumor necrosis factor.

therapy for severe ulcerative colitis are rehydration with intravenous fluids and intravenous corticosteroids (hydrocortisone, 300 mg/day; prednisolone, 60 to 80 mg/day; or methylprednisolone, 40 to 60 mg/day). Total parenteral nutrition (Chapter 198) may be necessary in patients with malnutrition. Patients with peritoneal signs or signs of systemic infection should be treated with parenteral antibiotics (Chapter 128). Patients who do not respond in 3 to 5 days should be considered for either colectomy, a trial of intravenous cyclosporines, or a trial of infliximab (see Table 127-4 for dosing).

Maintenance Therapy

Aminosalicylates reduce recurrent disease in patients with ulcerative colitis, and essentially all patients should receive maintenance therapy with a 5-ASA preparation. However, the utility of 5-ASA preparations in patients who are using biologic agents is less well established, and data suggest that once a patient initiates a biologic, aminosalicylates do not add clinical benefit and can be discontinued. Corticosteroids are not effective as maintenance therapy and should not be used in this way. Azathioprine, 6-mercaptopurine, tofacitinib, upadacitinib, ozanimod, infliximab, adalimumab (160 mg at week 0, 80 mg at week 2, and then 40 mg every other week), ustekinumab, and golimumab (see Table 127-4 for dosing) are effective for maintenance therapy in patients whose ulcerative colitis is not controlled by 5-ASA.

Surgical Therapy

Crohn Disease

Since surgical resection does not cure Crohn disease and recurrences are likely after resection, the approach should be conservative in terms of the amount of bowel resected. Failure of medical management is a common cause for resection in patients with Crohn disease, but complications (e.g., obstruction, fistula, and abscess) are often the indications for resection. Overall, the overall 1-, 5-, and 10-year risks of surgery in patients with Crohn disease are about 12%, 18%, and 26%.

For Crohn disease of the small bowel, the most common surgical procedure is segmental resection for obstruction or fistula; the incidence of a recurrence severe enough to require repeat surgery after ileal or ileocolic resection is approximately 25% after 10 years and 35% after 15 years in the absence of biologic therapies. For patients with extensive colonic disease that includes the rectum, the procedure of choice is total proctocolectomy with a Brooke (end) ileostomy. Total colectomy with ileal pouch anal anastomosis is not appropriate in Crohn colitis because recurrent disease in the ileal segment of the new pouch would require a repeat operation and loss of a long segment of ileum. Anti-TNF monotherapy (e.g., infliximab, adalimumab, or certolizumab; see Table 127-4 for dosing) appears to be the most effective strategy for postoperative prophylaxis for Crohn disease,[A18] but ustekinumab and vedolizumab (see Table 127-4 for dosing) also may be effective.

Ulcerative Colitis

For ulcerative colitis, colectomy is a curative procedure. Emergency colectomy may be required in patients with toxic megacolon or a severe fulminant attack without toxic megacolon. Fortunately better medical therapy has substantially reduced the need for colectomy for refractory disease to about 3% at one year, 7% after 5 years, at 10% after 10 years.[24] The decision for or against colectomy and among types of surgery requires expert consultation. The standard operation for ulcerative colitis is proctocolectomy and a Brooke ileostomy, but creating a pouch from the terminal 30 cm of ileum and pulling the distal end of the pouch through the anal canal can preserve anal function and avoid an ileostomy. Ileoanal anastomosis is sometimes complicated by inflammation in the ileal pouch (termed *pouchitis*), which can be treated with antibiotics (typically, metronidazole, 500 mg three times daily or 20 mg/kg/day, or ciprofloxacin, 500 mg twice daily for 2 weeks). The risk for malignancy (see later) also can be an indication for colectomy.

Complications

Crohn Disease

Abscesses

Abscesses, which are common complications in Crohn disease, result from extension of a mucosal fissure or ulcer through the intestinal wall and into extraintestinal tissue. Leakage of intestinal contents through a fissure into the peritoneal cavity results in an abscess. Abscesses occur in 15 to 20% of patients with Crohn disease, especially in the terminal ileum. The typical clinical manifestation of an intra-abdominal abscess is fever, abdominal pain, abdominal tenderness, and leukocytosis. A CT scan is the preferred modality to diagnose intra-abdominal abscess. Broad-spectrum antibiotic therapy, including anaerobic coverage, is indicated. Percutaneous drainage of abscesses in patients with Crohn disease may improve the clinical picture but does not provide adequate therapy because of persistent communication between the abscess cavity and the intestinal lumen. Resection of the involved intestine is usually required for definitive therapy.

Obstruction

Obstruction is a common complication of Crohn disease, particularly in the small intestine, and is a leading indication for surgery. In Crohn disease, mucosal thickening from acute inflammation, muscular hyperplasia and scarring as a result of previous inflammation, or adhesions may cause small bowel obstruction. Obstruction also may occur because of impaction of a bolus of fibrous food in a stable, long-standing stricture. Cramping abdominal pain and diarrhea, which worsen after meals and resolve with fasting, suggest obstruction. Strictures may be evaluated by CT enterography, MRI enterography, oral contrast studies, barium enema, or colonoscopy, depending on the anatomic location. Corticosteroids (e.g., methylprednisolone, 40 to 60 mg/day IV, or hydrocortisone, 200 to 300 mg/day IV for 5 to 14 days) are useful if acute inflammation is an important component of the obstructive process, but not if the obstruction is caused by fibrosis. A common error in the management of Crohn disease is inappropriate treatment with long courses of corticosteroids in patients who have obstructive symptoms from fixed anatomic lesions. If the obstruction does not resolve with nasogastric suction and corticosteroids, surgery is necessary.[25]

Perianal Disease

Perianal disease is a potentially disabling complication of Crohn disease. Ulcerations in the anal canal may coalesce and result in fistula formation (Chapter 131). The fistulous openings are most commonly found in the perianal skin but can occur in the groin, vulva, or scrotum. Fistulas are accompanied by drainage of serous or purulent material. If the fistula does not drain freely, there is local accumulation of pus (perianal abscess) with redness, pain, and induration. The pain of a perianal abscess is exacerbated by local pressure that may result from defecation, sitting, or walking. The typical physical manifestation of an abscess is redness with tenderness on digital examination; fluctuance also may be present. Persistent severe perianal Crohn disease can result in destruction of the anal sphincter and subsequent fecal incontinence. Adequate evaluation of perianal disease generally requires endoscopic examination under anesthesia. Cross-sectional CT or MRI can define the presence and extent of perianal abscesses. The goals of therapy for perianal disease are relief of local symptoms and preservation of the sphincter. Limited disease can be approached with sitz baths and metronidazole, but most cases also require adequate external drainage. Infliximab, adalimumab, certolizumab pegol, ustekinumab, vedolizumab, azathioprine, or 6-mercaptopurine (see Table 127-4 for dosing) may be useful in healing perianal disease, but the disease may reactivate when the drug is stopped. Allogeneic, expanded, adipose-derived stem cells are an experimental treatment for complex perianal fistulas in patients whose Crohn disease does not respond to conventional or biologic treatments or both.

Ulcerative Colitis

One of the most significant complications of ulcerative colitis is toxic megacolon, which is dilation of the colon to a diameter greater than 6 cm associated with worsening of the patient's clinical condition and the development of fever, tachycardia, and leukocytosis. Physical examination may reveal postural hypotension, abdominal tenderness over the distribution of the colon, and absent or hypoactive bowel sounds. Agents that reduce gastrointestinal motility, such as antispasmodics and antidiarrheal agents, have the potential to initiate or exacerbate toxic megacolon. Medical therapy is designed to reduce the likelihood of perforation and return the colon to normal motor activity as rapidly as possible. The patient is given nothing by mouth, and nasogastric suction is begun. Intravenous fluids should be administered to replete water and electrolyte abnormalities, broad-spectrum antibiotics (e.g., ampicillin-sulbactam, given as 1 g ampicillin plus 0.5 g sulbactam, 1.5 to 3 g every 6 hours for 5 to 14 days; levofloxacin, 500 mg/day IV, plus metronidazole, 500 mg IV or PO twice daily; cefazolin, 500 mg IV three times daily, plus metronidazole, 500 mg IV or PO twice daily; or trimethoprim-sulfamethoxazole, 8 to 10 mg/kg/day IV or PO in two to four divided doses, plus metronidazole, 500 mg IV or PO twice daily for approximately 7 days or until symptomatic improvement) are given in anticipation of possible peritonitis as a result of perforation, and parenteral corticosteroids are administered at a dose equivalent to more than 40 to 60 mg of prednisone per day. Signs of improvement include a decrease in abdominal girth and the return of bowel sounds. Deterioration is marked by the development of rebound tenderness, increasing abdominal girth, and cardiovascular collapse. If the patient does not begin to show signs of clinical improvement during the first 24 to 48 hours of medical therapy, the risk for perforation increases markedly, and surgical colectomy is indicated.

Follow-Up

Colon Cancer, Dysplasia, and Colonoscopic Surveillance

The risk for colorectal cancer (Chapter 179) is increased beginning after 8 years of disease and continues to increase in subsequent years.[26] The incidence of colorectal adenocarcinoma is 60 to 100% higher in persons with inflammatory bowel disease than in the general population but has been decreasing over time, likely at least in part because of advances in modern therapies. Patients with extensive ulcerative colitis have a markedly increased risk for colon cancer, patients with left-sided disease have an intermediate risk, and patients with long-standing ulcerative colitis are at risk for colorectal cancer even if their symptoms have been relatively mild or even quiescent for 10 to 15 years.

Colon cancers may be submucosal and may be missed at colonoscopy. Colon cancer in patients with ulcerative colitis is most commonly associated with dysplastic changes in the mucosa, often at multiple sites in the colon. Although

recent data have demonstrated that most dysplasia is visible, not all dysplasia can be identified by visual inspection, so microscopic examination of biopsy specimens is required.

In patients with long-standing ulcerative colitis, current practice guidelines recommend colonoscopy with surveillance using chromoendoscopy or narrow band imaging, with biopsies of abnormal lesions or random colon biopsies, beginning 8 years after the onset of disease and repeated every 1 to 2 years.[27] If the specimens show dysplasia and if a discrete polypoid lesion with well-defined borders cannot be identified, colectomy is recommended.[28]

The risk for colon cancer in patients with Crohn colitis is similar to the risk in patients with a similar extent of ulcerative colitis. Surveillance colonoscopy is also recommended in patients with Crohn colitis.

Pregnancy

Fertility in women with inflammatory bowel disease usually is normal or only minimally impaired, and the incidence of prematurity, stillbirth, and developmental defects in the offspring of women with inflammatory bowel disease, except fetal complications may be somewhat more likely when the mother's disease is clinically active, regardless of drug therapy. Previous proctocolectomy or the presence of an ileostomy is not an impediment to successful completion of a pregnancy, but women who have had ileal pouch anal anastomosis surgery with a total proctocolectomy have markedly reduced fertility.

If a woman's disease is inactive at the time of conception, it is likely that it will remain inactive during the course of the pregnancy. Ulcerative colitis that is active at the time of conception tends to worsen. In patients with active Crohn disease at the time of conception, the degree of activity remains the same in two thirds of women; of the other one third, some improve clinically and others deteriorate.

Sulfasalazine does not harm the fetus, but pregnant women have an increased requirement for folic acid and sulfasalazine interferes with folate absorption by competitively inhibiting the jejunal enzyme folate conjugase. Therefore, women who are taking sulfasalazine and who are pregnant or considering pregnancy should receive folate supplementation (1 mg twice daily) to ensure that the fetus receives adequate amounts for normal development. The use of corticosteroids by pregnant women with inflammatory bowel disease is associated with an increased rate of premature rupture of the membranes and a higher rate of cleft lip. In general, it appears that the risk to the pregnancy of treatment with sulfasalazine or corticosteroids is less than the risk in allowing disease activity to go untreated.

Most of the data on the teratogenicity of azathioprine and 6-mercaptopurine in pregnancy are derived from the transplant literature and involve higher doses than are commonly used for inflammatory bowel disease. Reported fetal effects in the transplant population include congenital malformations, immunosuppression, prematurity, and growth retardation. The risks of these medications in the inflammatory bowel disease population are not completely known, given that only a small number of such patients have been formally studied.

Infliximab, adalimumab, golimumab, certolizumab pegol, vedolizumab, and ustekinumab are considered to be safe during pregnancy, but the risks of these agents are not completely known, because only a relatively small number of patients have been formally studied. To date, data are inadequate to assess fetal risk and guide therapy with ozanimod upadacitinib, and tofacitinib during pregnancy.

PROGNOSIS

Ulcerative Colitis

Recurrent flares and remissions characterize typical ulcerative colitis. A rapidly progressive initial attack results in serious complications in approximately 10% of patients. Complete recovery after a single attack may occur in another 10% of patients. Some patients may actually have had an acute undetected infection rather than true ulcerative colitis. The probability that a patient with clinically inactive disease will remain in remission the following year is 80 to 90%. By comparison, patients with clinically active disease have a 70% probability of relapse during the following year.

Patients who present with ulcerative proctitis have the best overall prognosis, and only approximately 5% of patients with proctitis will require colectomy over a lifetime. Severe complications are very uncommon, but the disease will extend more proximally in the colon in up to 50% of patients. Ulcerative colitis–related mortality has decreased substantially since the introduction of corticosteroids, and recent studies suggest that long-term survival rates for patients with ulcerative colitis are similar to those of the general population.

Crohn Disease

The manifestations of Crohn disease can wax and wane. A patient with clinically active Crohn disease has a 70 to 80% chance of having active disease in the subsequent year, whereas 80% of patients in remission will remain so over the following year. Over the course of a 4-year period, approximately 25% of patients will have persistently active disease after diagnosis, 25% will remain in remission, and 50% will have a fluctuating course with years of remission and years with clinically active disease. Approximately 75 to 80% of all patients with luminal and fistulizing Crohn disease will require surgical intervention for their disease, with approximately 50% of them requiring surgery within 6 months of diagnosis. The rate for a second surgery for luminal Crohn disease ranges from 25 to 38% within 5 years, and 40 to 70% will need reoperation by 15 years.

Patients with Crohn disease have an increased mortality rate, approximately 1.3 to 1.5 times higher than the general population, unrelated to whether they have small intestine or large intestine involvement, or both. This excess mortality, which is most notable in the first few years after diagnosis, is most commonly related to complications of Crohn disease (e.g., colorectal cancer, shock, volume depletion, protein-calorie malnutrition, and anemia). Whether aggressive use of immunomodulators and biologic therapy will alter the natural course of disease is unknown.

128 INFLAMMATORY AND ANATOMIC DISEASES OF THE INTESTINE, PERITONEUM, MESENTERY, AND OMENTUM

JOHN F. KUEMMERLE

CONGENITAL STRUCTURAL ABNORMALITIES

MECKEL DIVERTICULUM

Meckel diverticulum, which is the most common congenital anomaly of the gastrointestinal (GI) tract, is present in 2 to 3% of the population and is more common in men. Meckel diverticulum occurs when the omphalomesenteric or vitelline duct connecting the fetal yolk sac to the primordial gut fails to close during development. Located on the antimesenteric border, the Meckel diverticulum is commonly found within about 100 cm of the ileocecal valve and typically is 1 to 10 cm in size. Heterotopic tissue is found in about 50% of Meckel diverticula, most commonly gastric or pancreatic tissue but usually not both. The presence of heterotopic tissue correlates with the development of symptomatic complications, with a lifetime risk of about 6%.

CLINICAL MANIFESTATIONS

The complications from a Meckel diverticulum include lower GI bleeding, obstruction, diverticulitis, and perforation.[1] Bleeding can occur when the production of acid from heterotopic gastric mucosa causes ileal ulcerations. Obstruction can result from volvulus around the diverticulum, intussusception of the diverticulum into the intestine, or herniation of the diverticulum and adjacent intestine. Inguinal, femoral, and umbilical hernias all can occur. Repeated and chronic inflammation at the neck of the diverticulum and nearby ileum also can lead to intestinal fibrosis and bowel obstruction. The most common complications are intestinal bleeding in children and obstruction in adults.

DIAGNOSIS

The diagnosis of a Meckel diverticulum can be challenging. Radionuclide imaging with sodium pertechnetate (^{99m}Tn) can be used in cases of bleeding because both normal and heterotopic gastric mucosa take up the tracer (Fig. 128-1). This test has high sensitivity and specificity in children but higher rates of false-positive and false-negative tests in adults. Crohn disease (Chapter 127) and other ileal inflammatory diseases can yield false-positive results. Radiographic imaging with a barium small bowel follow-through typically is not helpful because the diverticulum does not fill with barium contrast. Enteroclysis increases the yield of barium imaging by increasing the pressure and filling of the diverticulum. Angiography can visualize the vestigial vitelline artery that arises from the superior mesenteric artery or a superior mesenteric artery branch that directly feeds the diverticulum or adjacent ileum. Both small bowel capsule endoscopy (Chapter 120) and double-balloon enteroscopy can identify a Meckel diverticulum during the evaluation of obscure bleeding.

TREATMENT AND PROGNOSIS

The management of bleeding, obstruction, or perforation that occurs in association with a Meckel diverticulum is open or laparoscopic surgical resection of the diverticulum and possibly of adjacent ulcerated and bleeding ileum. The surgical resection of a Meckel diverticulum incidentally identified at the time of surgery for another condition is controversial given the low lifetime risk of complications but can be considered in young men, patients with large diverticula, or patients with suspected heterotopic tissue. After identification and treatment, the prognosis is excellent because the Meckel diverticulum is removed, and the risk of complications is eliminated.

INTESTINAL ATRESIA AND STENOSIS, MALROTATION, GASTROSCHISIS, AND OMPHALOCELE

The congenital disorders of intestinal atresia and stenosis, malrotation, gastroschisis, and omphalocele disorders usually present early in infancy and childhood, but sometimes the diagnosis of stenosis or malrotation may be made in adulthood. With the exception of pyloric stenosis, significant long-term morbidity and mortality are associated with these anomalies even after surgical correction. Patients with malrotation or gastroschisis typically present with complications of their surgery, including adhesions, bowel obstruction, or abdominal wall hernias. Patients with intestinal atresia and resulting short gut syndrome also have significant morbidity and mortality related to intestinal failure and the need for long-term total parenteral nutrition.

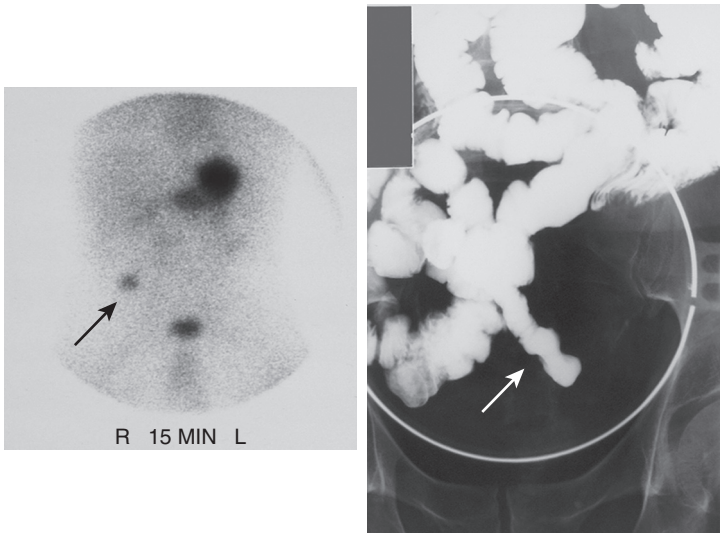

FIGURE 128-1. Meckel diverticulum. Nuclear medicine imaging with ^{99m}Tn pertechnetate scan shows tracer uptake in a Meckel diverticulum (*arrow* in left panel) and in the stomach and bladder. Barium radiography in the same patient also shows the Meckel diverticulum (*arrow* in right panel).

ACQUIRED STRUCTURAL DISORDERS

VOLVULUS

Intestinal volvulus, which is pathologic twisting of the intestine around the mesentery, can result in obstruction of the proximal bowel. Because the mesentery is involved, possible complications include vascular compromise, bowel necrosis, bowel perforation, and peritonitis. The most susceptible regions for volvulus are the sigmoid colon, cecum, and occasionally the transverse colon, with an estimated annual incidence of two to six cases per 100,000. Sigmoid volvulus is most common in men, with a peak age in the 80s, whereas cecal volvulus is more common in women, who typically present in their 60s. Elderly institutionalized individuals are at the highest risk. Small bowel volvulus is uncommonly observed in U.S. adults but can result from preexisting anomalies such as malrotation or congenital bands of Ladd.

CLINICAL MANIFESTATIONS

Volvulus can present with symptoms and signs of acute bowel obstruction, including pain that may be out of proportion to physical findings. Nausea and vomiting are usually present. The presentation also can be more insidious or intermittent with constipation, laxative use, and a previously recognized dilated colon. Physical findings include abdominal distention, tympanic percussion, rebound, guarding, and rigidity. Escalating pain and tenderness can indicate colonic ischemia and perforation.

DIAGNOSIS

The diagnosis of colonic volvulus can be made using abdominal radiographs, which demonstrate a distended colon, loss of haustrations, and a typical "bent inner tube" sign with the apex in the right upper quadrant of the abdomen (Fig. 128-2A) or the "omega" sign (Fig. 128-2B). In cases of a cecal volvulus, the dilated cecum is observed in the epigastrium or in the left upper quadrant. A water-soluble contrast-enhanced radiograph can identify the point of obstruction due to volvulus.

TREATMENT AND PROGNOSIS

Patients with colonic volvulus should have nothing per oral cavity (NPO) with nasogastric (NG) tube decompression and receive appropriate fluid volume resuscitation. In the absence of complete obstruction or signs of ischemia or perforation, patients with a sigmoid volvulus can undergo emergent colonoscopy

ABSTRACT

This chapter reviews the presentation, diagnosis, and treatment of common inflammatory and anatomic diseases of the abdominal organs. Structural disorders include volvulus, hernias, and intussusception. Diverticulitis and appendicitis are common inflammatory disorders of the colon. Rarer disorders of the mesentery and omentum are discussed also.

KEYWORDS

volvulus
diverticulitis
appendicitis
abdominal hernias
peritonitis

and attempted reduction, which is successful in up to 75% of cases.[2] Surgical intervention is indicated for volvulus involving the cecum, transverse colon, or small intestine, as well as after colonoscopic reduction of a sigmoid volvulus because of the risk of recurrence. The mortality rate is about 9% for sigmoid volvulus, 7% for cecal volvulus, and about 17% for combined sigmoid and cecal volvulus or transverse colon volvulus.

INTUSSUSCEPTION

Intestinal intussusception occurs when a segment of bowel invaginates into the adjacent distal intestine and results in bowel obstruction and ischemia. Intussusception usually involves just the small intestine, but it can also present as small intestinal intussusception into the colon. Although intussusception is a common cause of small bowel obstruction in pediatric patients, especially after rotavirus vaccination (Chapter 350), it is rare in adults and accounts for only about 5% of small bowel obstruction. The cause of intussusception is infrequently identified in children, but a cause can be identified in about 90% of adult cases. Typical precipitating causes in adults include small intestinal polyps, benign tumors (including leiomyomas and neurofibromas), malignant tumors, inflammatory bowel disease (Chapter 127), postoperative adhesions, Meckel diverticulum, and feeding tubes.[3]

CLINICAL MANIFESTATIONS

Most patients present with symptoms of partial bowel obstruction, including pain, nausea, and vomiting, and some patients have diarrhea with occult or overt bleeding. The clinical picture can be confusing when the patient has intermittent symptoms from a spontaneously resolved event. A mass may be palpable on examination. Passage of "currant jelly" stools is characteristic of intussusception, especially in children.

DIAGNOSIS

The diagnosis of intussusception is usually made using computed tomography (CT), which reveals a characteristic alternating high- and low-attenuation target-like or sausage-shaped lesion that represents the invaginated intestinal segments. However, because of the confusing presentation of intussusception in adults, a combination of plain radiographs, upper GI series, and barium enema frequently is required for an adequate evaluation.

TREATMENT AND PROGNOSIS

Colonic intussusceptions are treated surgically in adults because of the high likelihood that a colonic malignancy is the causative lesion. For small intestinal intussusception, a randomized trial showed that hydrostatic reduction is superior to pneumatic reduction in children.[A1] This approach has been tried in adults in whom no other significant causative lesion is present. However, adults with small intestinal intussusception frequently have an underlying pathologic cause, so their treatment consists primarily of surgical intervention and bowel resection, which not only resolves the obstruction but also provides a diagnosis of the causative lesion. If the predisposing cause can be diagnosed and corrected, the prognosis is good, and recurrence rates are low. If the underlying cause is not fully correctable such as with neurofibromatosis (Chapter 385) or adhesions, intussusceptions may recur.

HERNIAS

Anatomically, hernias comprise a herniated viscus, the hernial sac (internal wall of the hernia lined by peritoneum), and the hernial ring. Whereas an external hernia occurs when the viscus lies outside the abdomen, an internal hernia occurs when the viscus lies in an abnormal location within the abdominal cavity. Secondary hernias can occur at previous sites of incision or injury. Incisional, inguinal, and umbilical hernias comprise 90% of all hernias. Hernias are common and occur in about 5% of the population within their lifetimes. For inguinal hernias alone, the lifetime cumulative incidence is estimated to be 43% in men and 6% in women. By comparison, femoral, umbilical, and incisional hernias occur twice as often in women.

CLINICAL MANIFESTATIONS, DIAGNOSIS, AND TREATMENT OF SPECIFIC HERNIAS

Epigastric hernias

Epigastric hernias occur at sites of congenital weakness in the midline between the xiphoid and umbilicus along the linea alba. Small epigastric hernias may be asymptomatic or difficult to identify. Larger epigastric hernias can present as nodules, sometimes with tenderness. Multiple hernias may be present. Diagnosis is made by physical examination complemented by ultrasound or CT imaging. They can be repaired surgically if symptomatic or if complications are present.

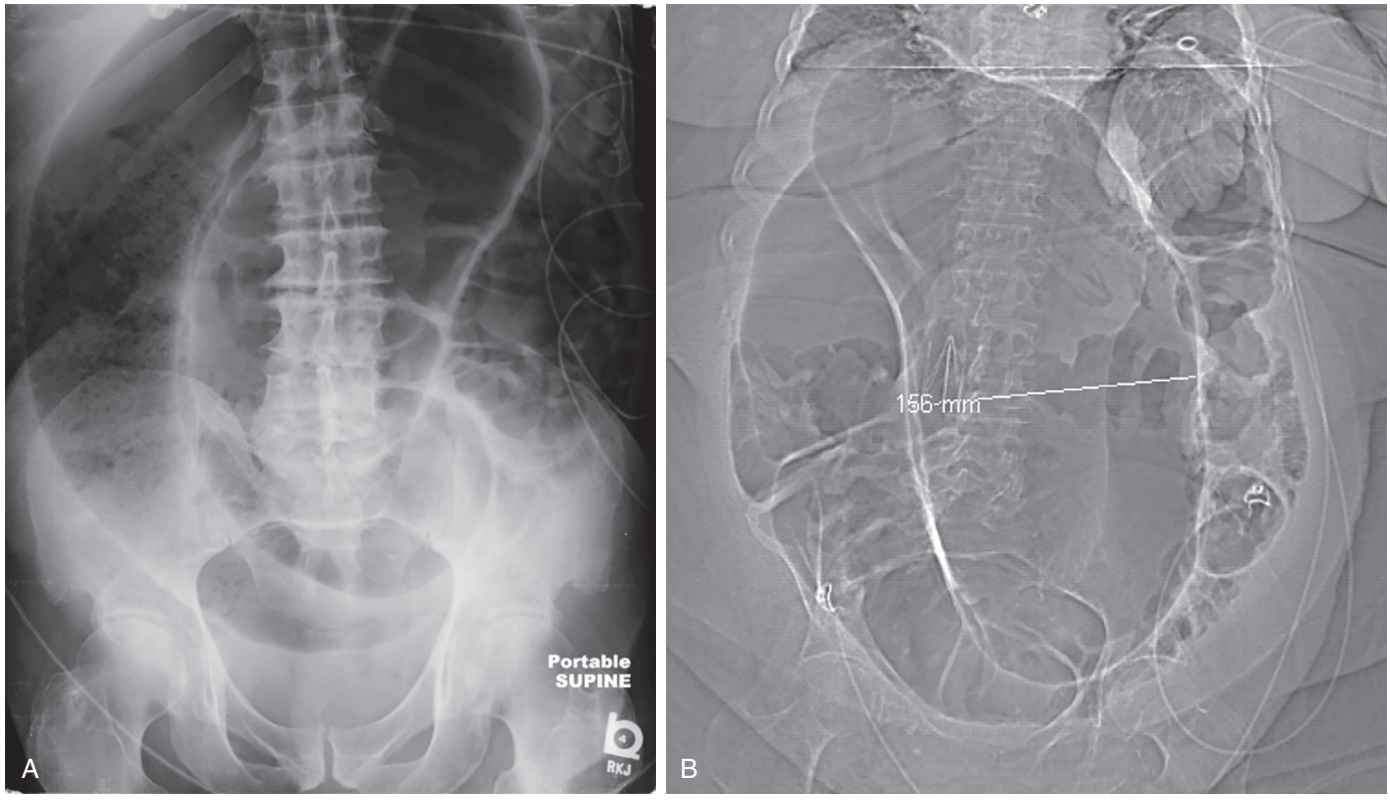

FIGURE 128-2. Sigmoid volvulus. Plain abdominal radiograph shows the presence of a sigmoid volvulus. **A,** "Bent inner tube" sign. **B,** "Omega" or "coffee bean" sign.

Umbilical hernias

Umbilical hernias occur in association with obesity, in multiparous women, and in patients with ascites. They present as a protuberant mass palpable at the umbilicus. Incarceration of small bowel or omentum is common, and strangulation occurs in about one third of umbilical hernias. Umbilical hernias can be repaired surgically, with mesh repair preferable to suture repair,[A2] if they are symptomatic or associated with complications, but ascites should be controlled for the hernia repair to succeed.

Groin hernias

Groin hernias present with bulging in this region, particularly with Valsalva maneuvers. Whereas direct inguinal hernias occur at the site of weakness at the base of the Hesselbach triangle, indirect inguinal hernias occur lateral to the Hesselbach triangle. Both direct and indirect inguinal hernias are above the inguinal ligament. Femoral hernias occur below the inguinal ligament in the femoral canal. Pain is typically mild, but more severe pain or colicky abdominal pain suggests incarceration or strangulation. Palpation can reveal the presence of a groin hernia that increases in size with standing or increased intra-abdominal pressure, such as a Valsalva maneuver, but palpation may be difficult in obese patients. In unclear cases, CT imaging can be helpful. The differential diagnosis of an inguinal bulge also includes adenopathy, lipoma or other tumors, testicular torsion of an undescended testicle, and abscess. Femoral hernias should be repaired when first diagnosed because of their risk for strangulation. Because the presence of strangulation can reliably be made only at surgery, more severe symptoms warrant early surgical intervention.

Watchful waiting is an acceptable option for men with minimally symptomatic inguinal hernias, although the majority of men will ultimately be referred for surgery, primarily because of pain, within 10 years.[4] The treatment of symptomatic groin hernias is surgical, now usually by open mesh-based techniques or laparoscopic repair, with mesh techniques probably providing slightly better long-term results.[A3] Open repair can be performed under local anesthesia, whereas laparoscopic repair, which generally results in less postoperative pain and an earlier return to normal activities, requires general anesthesia and carries a small risk of major intra-abdominal injury.[5]

Pelvic hernias

Pelvic hernias occur through a weakened pelvic floor and are six-fold more common in women, especially with advancing age. The most common form is an obturator hernia, but less common forms include a sciatic hernia through the sciatic foramen or perineal hernias through the pelvic floor musculature. Most obturator hernias present with acute bowel obstruction. A tender mass may be palpable near the obturator canal on rectal or vaginal examination. Inner thigh pain on internal rotation of the hip may be present in 50% of patients. Diagnosis can be aided using CT imaging. The treatment is surgical.

Incisional hernias

Incisional hernias can develop after 1 to 4% of laparotomy incisions. Incisional hernias may cause chronic abdominal discomfort, especially with maneuvers that increase intra-abdominal pressure. Repair is usually performed with prosthetic mesh, which appears to provide better outcomes than suture repair[6] and is also useful for prophylaxis against a future incisional hernia at the time of a midline laparotomy.[A4]

More rare hernias include lumbar hernias (which are more common in men and after surgery for trauma), Spigelian hernias occurring through the linea semilunaris in elderly patients, and internal hernias that occur when an intraperitoneal organ protrudes into a separate compartment within the abdomen. Some hernias occur in surgically created defects or because of congenital defects (e.g., paraduodenal, pericecal, or foramen of Winslow). Up to 15% of internal hernias occur through mesenteric or omental defects. Most patients present with intermittent symptoms of pain and bowel obstruction or strangulation. Radiologic studies can be of variable assistance. The differential diagnosis should include volvulus, adhesions, and tumors. The diagnosis can be made using barium studies and CT imaging. Surgery is needed to reduce the herniated viscus and close any defect.

INFLAMMATION OF THE INTESTINE AND COLON

APPENDICITIS

Appendicitis, which is the most common intra-abdominal pathology that requires emergency surgery, affects about 1 per 1000 adults annually worldwide.[7] The lifetime prevalence of appendicitis is 8.7% in men and 6.9% in woman. Lifetime rates of appendectomy are higher, 12% in men and 23% in women, because the diagnosis may be difficult to confirm noninvasively and because of the practice of operating on patients in whom the condition is highly suspected.[8] About one third of patients have luminal obstruction of the vermiform appendix, most commonly caused by an appendicolith but also occasionally by lymphoid hyperplasia or tumors, including carcinoid tumors (Chapter 213). Gangrenous appendicitis is almost always associated with luminal obstruction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The differential diagnosis of appendicitis is extensive (Table 128-1). Current guidelines for diagnosis include characteristic history and physical findings of abdominal pain; localized tenderness; or other signs of acute appendicitis, including increased right lower quadrant pain with cough, pain with flexion and internal rotation of the hip, pain with passive extension of the right hip, and increased right lower quadrant pain during palpation of the left lower quadrant. Laboratory evidence of inflammation includes leukocytosis, greater than 10,000/μL but usually less than 18,000/μL unless perforation has occurred, with left shift, and elevated markers such as the C-reactive protein or procalcitonin level. The use of a standardized approach, the Adult Appendicitis Score (Table 128-2),[9] can reduce unnecessary imaging and hospital admissions.[A5] However, none of these tests are accurate enough to make or exclude the diagnosis of appendicitis in patients with an intermediate probability score. The preferred diagnostic test is multidetector CT, preferably using a low-dose, 2 mSv CT, which has a sensitivity and specificity of at least 94%[A6] and perhaps higher and can also detect perforation (Figs. 128-3 and 128-4). Nonenhanced CT is nearly as good as contrast-enhanced CT for diagnosing acute appendicitis,[10] while limiting exposure to iodinated contrast and its potential adverse effects in patients for whom it is a concern. A point-of-care ultrasound is helpful if positive, but a negative test does not exclude the diagnosis. Even expert ultrasonography is less sensitive and specific, 83% and 93%, respectively than CT, but it is useful when CT is contraindicated, such as in pregnant women or a suspected ectopic pregnancy. Magnetic resonance imaging is no better than CT but is an accurate option for pregnant women.[11]

TREATMENT AND PROGNOSIS

When acute appendicitis is suspected, emergent surgical consultation and appendectomy are indicated. Laparoscopic appendectomy is preferred over open appendectomy because of lower rates of postoperative complications and a more rapid return to normal eating and activity, except open appendectomy is preferred in patients with evidence of perforation.[A7] Preoperative antibiotics (e.g., cefotetan, 2 g intravenously, or cefoxitin, 2 g intravenously followed by three postoperative doses or ticarcillin–clavulanic acid) reduce infectious complications in otherwise uncomplicated appendicitis. Because perforation of the appendix increases the risk of mortality from 0.0002% to 3% and increases the morbidity rate from 3% to 47%, the traditional approach is that a negative laparotomy is an acceptable trade-off to missing true appendicitis.

A nonoperative approach using antibiotics to treat uncomplicated appendicitis[12] can reduce routine surgical morbidity but at the expense of more than

From Sammalkorpi HE, Mentula P, Leppäniemi A. A new adult appendicitis score improves diagnostic accuracy of acute appendicitis—a prospective study. *BMC Gastroenterol.* 2014;14:114.

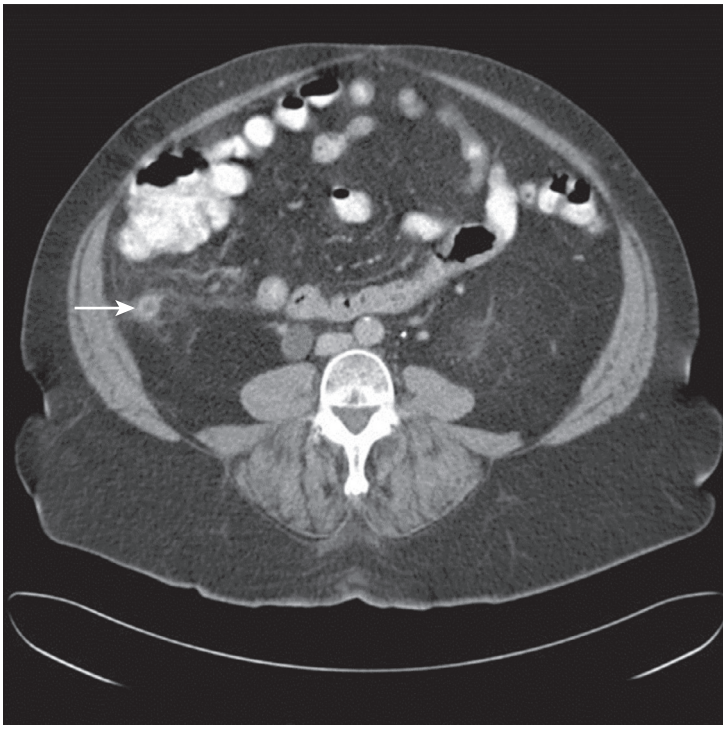

FIGURE 128-3. Appendicitis. A computed tomography scan shows an inflamed appendix with a diameter greater than 1 cm (*arrow*) consistent with acute, uncomplicated appendicitis.

a two-fold increase in complications, including about a 2% risk of rupture, a 1% risk of gangrenous appendicitis, and a 25 to 30% need for readmission or surgery within 3 to 12 months.[A8,A9] If antibiotics are chosen for uncomplicated appendicitis, 2 days of intravenous ertapenem (1 g daily) followed by 5 days of oral levofloxacin (500 mg daily) and metronidazole (500 mg three times daily) is slightly better than 7 days of oral moxifloxacin (400 mg daily).[A10]

The benefits of surgery are most notable in patients with an appendicolith. In the United States, the professional consensus tends to favor surgical appendectomy, except in patients who have had prior surgical complications, but informed decision making is recommended because many patients may prefer a nonoperative approach.[12]

For a perforated appendix with abscess formation, immediate appendectomy yields similar results to a strategy of percutaneous ultrasound- or CT-guided drainage, intravenous (IV) antibiotics, and laparoscopic appendectomy about 10 weeks later. In the setting of perforation, once-daily dosing with ceftriaxone and metronidazole for 7 to 10 days is as good as triple-dose therapy.

Complications develop in more than 15% of patients, with an overall mortality rate of about 3% in patients with perforated appendicitis. Complications are uncommon in surgically treated nonperforated appendicitis. Patients who have appendectomies for suspected but not confirmed appendicitis have a prognosis that depends on whether they had an underlying disease, such as Crohn disease (Chapter 127) or carcinoid tumor (Chapter 213). In adults over age 40 years, the risk of developing a right-sided colon cancer may be increased by as much as 10-fold,[13] so careful follow-up is warranted.

DIVERTICULITIS OF THE COLON

Colonic diverticula are technically pseudodiverticula. They form when the colonic mucosa and submucosa herniate through the muscularis propria of the colon. A spectrum of problems can result from diverticulosis, including diverticulitis, which is an infected diverticulum, or diverticular bleeding, which is manifested as acute lower GI bleeding (Chapter 121).[14] Diverticular disease (Fig. 128-5 and E-Fig. 128-1) affects about 10% of middle-aged adults and increases in prevalence up to about 80% in elderly adults. Acute diverticulitis is now more common than acute appendicitis in the emergency departments of developed countries.[14]

Colonic diverticula form at the site where the nutrient artery, the vasa recta, penetrates the muscularis propria. Diverticulosis in Western populations is most common in the left colon and has been thought to be associated with the low-fiber content of the typical Western diet, although recent epidemiologic studies cast doubt on this hypothesis. Diverticulosis can occur anywhere in the colon, however, and it is more commonly observed in the right colon in Asian populations.

The lifetime risk of diverticulitis is up to 25%. Diverticulitis is thought to occur when impacted material in the diverticulum compresses the blood supply, thereby resulting in a microperforation. Diverticulitis can be complicated further by free perforation, abscess, or fistula formation.

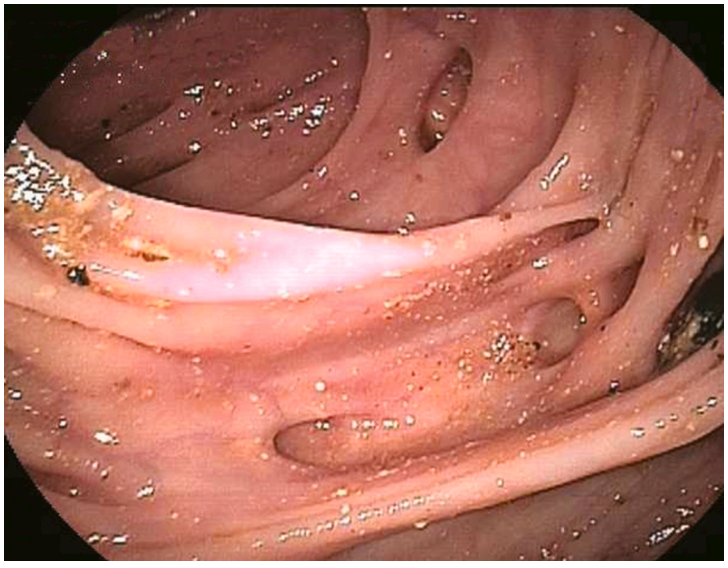

FIGURE 128-5. Sigmoid diverticulosis. The colonoscopic appearance of sigmoid diverticulosis coli.

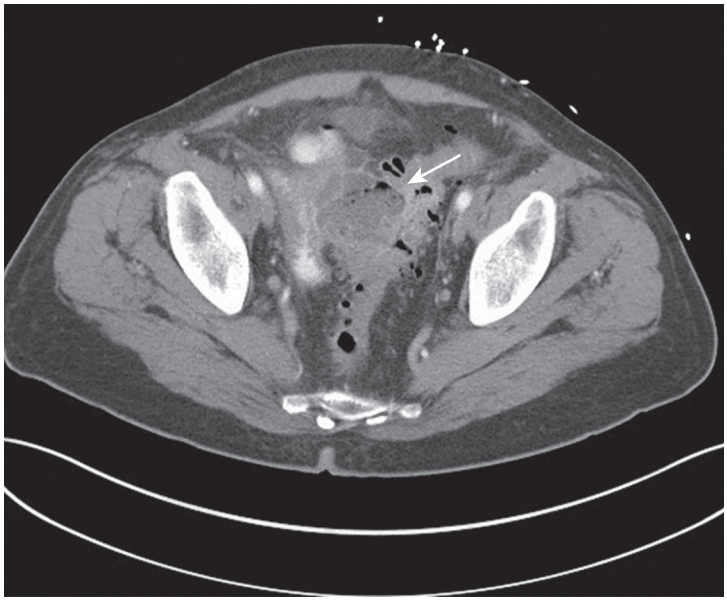

FIGURE 128-6. Diverticulitis. A computed tomography scan shows acute diverticulitis with perforation. An abscess (*arrow*) is seen presenting as a fluid and air-filled collection.

CLINICAL MANIFESTATIONS

The majority of patients with colonic diverticulosis are asymptomatic. Patients with diverticulitis commonly present with localized pain, fever, and anorexia. The pain may radiate to the back, flank, or suprapubic region. Nausea and vomiting, constipation or diarrhea, or urinary symptoms may be variably present. Physical examination typically reveals left lower quadrant tenderness, sometimes with localized guarding or a palpable mass. Rebound tenderness or peritoneal signs should suggest the presence of free perforation. Visible diverticular bleeding is rare in the setting of acute diverticulitis. Leukocytosis is present. When the acutely inflamed diverticulum is adjacent to the bladder, sterile pyuria may be found.

DIAGNOSIS

The clinical suspicion of acute diverticulitis is correct in only about 40 to 56% of cases, so the diagnosis must be confirmed in the appropriate setting by leukocytosis plus an ultrasound examination or a CT scan showing diverticulosis coli with localized inflammation of the colonic wall and pericolic fat at the site of acute diverticulitis.[15,16] A CT scan also can demonstrate free perforation, abscess, or fistula formation (Fig. 128-6). Because of the increased risk of perforation, invasive testing such as barium enema or colonoscopy is contraindicated when a diagnosis of acute diverticulitis is being entertained. The differential diagnosis of acute diverticulitis includes inflammatory bowel disease (Chapter 127), gastroenteritis, appendicitis, and colon cancer (Chapter 179) with perforation.

TREATMENT

Perforated diverticulitis with rupture of fecal material into the full peritoneum is a life-threatening surgical emergency. For diverticulitis with purulent but non-fecal peritonitis, randomized trials comparing laparoscopic peritoneal lavage with surgical resection have shown essentially no difference in outcomes.[A11] For diverticulitis with focal abscess formation, treatment is percutaneous CT-guided drainage and subsequent surgery, usually laparoscopic, typically after 6 weeks.[17]

Uncomplicated acute diverticulitis is usually treated with antibiotics, but antibiotics have limited benefit.[A12] A 7- to 10-day course of oral antibiotics (e.g., amoxicillin–clavulanate[18] [500 mg/125 mg] alone or ciprofloxacin [750 mg twice daily] plus metronidazole [500 mg four times daily]), perhaps after a single IV dose of antibiotics, is as effective and safe as hospitalization for IV antibiotics.[19] Patients who can tolerate clear liquids can be treated in the outpatient setting with gradual advancement of their diet. Patients who are unable to tolerate eating should be admitted to the hospital for IV fluids and antibiotics (e.g., levofloxacin 750 mg daily and metronidazole 500 mg every 6 hours or piperacillin–tazobactam 3.375 g every 6 hours). For diverticular and other intra-abdominal infections that have had adequate surgical treatment, fixed-duration antibiotic therapy of approximately 4 days provides similar outcomes to longer courses until after the resolution of physiologic abnormalities (about 8 days).

Although the risks associated with one episode of uncomplicated diverticulitis are low, with a mortality rate that is less than 1%, complicated diverticulitis, defined as diverticulitis with abscess, fistula formation, free perforation, or obstruction, is associated with increased inpatient morbidity in up to 25% of cases and has a mortality rate as high as 5%. Furthermore, these risks increase with a second episode of complicated diverticulitis. Elective segmental colectomy typically has been recommended to patients after two to three episodes of complicated diverticulitis and in young patients even after a first episode. However, recent evidence suggests that the risk of complicated diverticulitis after recovery from uncomplicated diverticulitis is only about 5% and is actually lower, not higher, after subsequent episodes of uncomplicated diverticulitis. However, prophylactic elective surgery is probably preferable in patients who have either three or more episodes of acute diverticulitis within 2 years or have persistent abdominal complaints for more than 3 months after a confirmed episode of left-sided diverticulitis.[A13–A15]

Acute diverticulitis can be complicated by colitis or late stricture formation. About 40% of patients with complicated diverticulitis have significant morbidity, and their mortality rate is about 6%, but it is only about 2% in patients without perforation. There is no convincing evidence that a high-fiber diet prevents recurrent diverticular disease or that nuts or any particular foods should be favored or avoided.

OTHER INTESTINAL INFLAMMATORY CONDITIONS

SMALL INTESTINAL ULCERS

Most primary idiopathic ulcers are found in the mid- to distal ileum, where they can be solitary or multiple. A careful history is necessary to exclude other precipitating causes of small intestinal ulcers, including drug exposure and other systemic diseases (Table 128-3). Pathologically, these ulcers can be differentiated from Crohn disease or chronic ulcerative jejunoileitis by the absence of granulomas. Barium contrast studies including enteroclysis can make the diagnosis, and CT or magnetic resonance enterography also can be helpful. In the absence of bowel obstruction, video capsule endoscopy is often the preferred test. Therapy with anti-inflammatory or immunosuppressive medications has not proven helpful. Therapy is typically directed to complications, including perforation and obstruction, with segmental surgical resection. However, the risk of ulcer recurrence is high.

Drug-induced ulcerations are common and can result from nonsteroidal anti-inflammatory drugs (NSAIDs), potassium chloride preparations, vasoactive medications, antimetabolites, and cocaine. Video capsule endoscopy can make the diagnosis (Fig. 128-7). NSAID-induced injury is similar to Crohn disease, with transmural injury and the risk of stricture formation. Treatment is aimed at avoiding the offending agent, if possible. A recent randomized trial demonstrated that adding a proton pump inhibitor to a non-selective NSAID actually increased the short-term risk of drug-induced small bowel injury.[A16]

A variety of systemic conditions also can manifest with small intestinal ulcerations. Patients with Crohn disease (Chapter 127) can have ulcers of

TABLE 128-3 CAUSES OF SMALL INTESTINAL ULCERS

CATEGORY	CAUSES
Acidic	Meckel diverticulum, Zollinger-Ellison syndrome
Drug-induced	Potassium chloride, NSAID, antimetabolite
Idiopathic	Primary ulcer, Behçet disease
Infectious	Tuberculosis, typhoid, *Yersinia*, *Strongyloides* superinfection
Inflammatory	Crohn disease, SLE, chronic jejunoileitis
Metabolic	Uremia
Neoplastic	Malignant histiocytosis, lymphoma, adenocarcinoma
Radiation	Radiation enteritis
Vascular	Mesenteric vascular insufficiency, vasculitis, arteritis

NSAID = nonsteroidal anti-inflammatory drug; SLE = systemic lupus erythematosus.

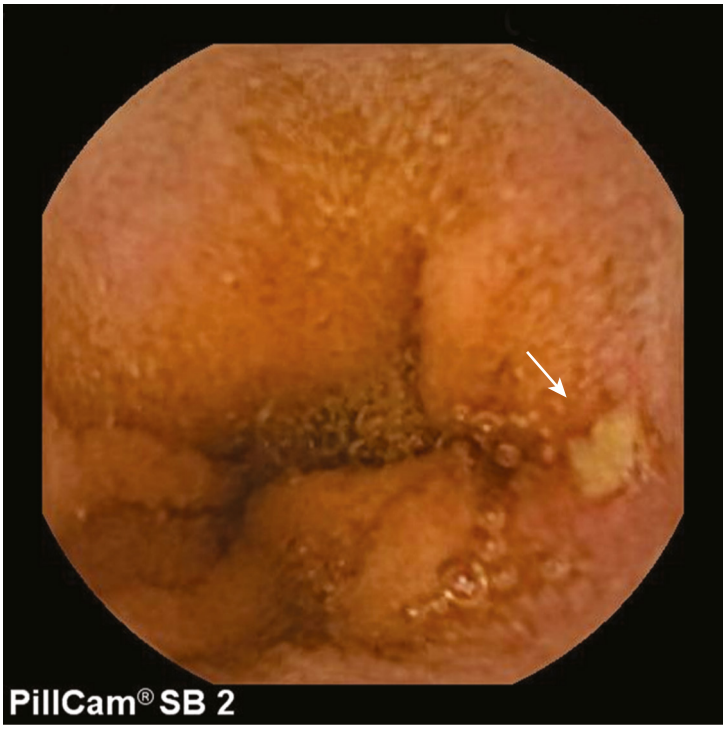

FIGURE 128-7. Nonsteroidal anti-inflammatory drug (NSAID)–induced enteropathy. The wireless capsule endoscopy appearance of a jejunal ulceration (*arrow*) caused by NSAID use.

any portion of the GI tract. Systemic lupus erythematosus (Chapter 245), rheumatoid arthritis (Chapter 243), scleroderma (Chapter 246), polyarteritis nodosa (Chapter 249), and Henoch-Schönlein purpura (Chapter 249) can present with small intestinal ulcerations that are thought to be secondary to microthrombosis and vasculitis. Mesenteric vasculitis presents as nausea, vomiting, fever, and GI bleeding.

Behçet disease (Chapter 249) is a systemic process that causes intestinal ulcers, typically in the ileocecal region, in fewer than 1% of cases. Although symptoms are similar to those of Crohn disease, pathologically Behçet disease-related ulcers are deep and do not have surrounding inflammation or granulomas. The optimal treatment of this disease has yet to be delineated. Patients frequently are treated with immunomodulators (Chapter 249), and surgery is reserved for ulcer-related complications.

Sarcoidosis (Chapter 83) uncommonly involves the intestine. Its presentation is similar to Crohn disease, with small and large intestinal ulceration and noncaseating granulomas. Patients commonly have nausea, vomiting, diarrhea, abdominal pain, and protein-losing enteropathy. Treatment is targeted to controlling the systemic disease.

Mycobacterium tuberculosis (Chapter 299) typically involves the distal ileum and cecum. A waxing and waning course can mimic the symptoms and location commonly seen in Crohn disease. The diagnosis is suspected based on a history of exposure, particularly in endemic regions, and confirmed by colonoscopy with biopsy, stains, and culture. Treatment is as for disseminated tuberculosis (Chapter 299).

Histoplasma capsulatum (Chapter 308) presents with ulcerations and polypoid masses that mimic tumors, typically in an immunocompromised patient. Patients present with diarrhea, bleeding, and obstruction. The granulomas seen on biopsy must be differentiated from Crohn disease, tuberculosis, and sarcoidosis. Treatment involves managing the systemic infection.

Neutropenic enterocolitis, or typhlitis (E-Fig. 128-2),[20] is an inflammation of the intestine or colon, usually during the neutropenic phase 10 to 14 days after high-dose induction chemotherapy. It involves right lower quadrant abdominal pain, distention, and diarrhea, sometimes with bleeding. These findings in themselves are nonspecific and are similar to *Clostridioides difficile*–associated colitis (Chapter 271) and ischemic colitis (Chapter 129). Diagnosis is based on typical CT scan findings of thickened bowel wall; bowel distention, especially of the cecum; and associated inflammatory changes. Treatment is conservative, with bowel rest and decompression when bowel dilation is present, and broad-spectrum antibiotics. Leukocyte-stimulating agents are often used to reverse the neutropenia (Chapter 153). Treatment of bleeding is supportive with transfusions and correction of any coagulopathy. Surgery is indicated in the setting of intractable bleeding or perforation. The symptoms resolve rapidly with resolution of neutropenia.

VISCERAL ANGIOEDEMA

Visceral angioedema can be idiopathic, or it can be a complication of hereditary and acquired C1 esterase inhibitor deficiency (Chapter 232), hypocomplementemia, drugs (especially angiotensin-converting enzyme inhibitors), or foods. Patients with GI angioedema commonly present with abdominal pain and distention, nausea, vomiting, and diarrhea. Some patients also have evidence of mucous membrane swelling, hives, wheezing, or dyspnea. On CT scan, thickened, fluid-filled loops of small bowel and ascites also may be seen. Symptoms commonly occur episodically, persist for 1 to 3 days and may recur periodically. The diagnosis is established by discontinuing the implicated drug or food, low serum levels of C4, low C1 esterase quantitative levels, or reduced C1 esterase functional activity. C1 esterase inhibitor deficiency can be treated successfully with C1 inhibitor therapy (Chapter 232).

RADIATION ENTERITIS

Radiation injury[21] can occur in the small or large intestine as a result of therapy for gynecologic, urologic, rectal, or retroperitoneal tumors. Acute injury, which can occur during the course of treatment, is associated with nausea, diarrhea, and abdominal or rectal discomfort. The risk is related to radiation dose. Chronic injury typically presents 6 months to 2 years after treatment and presents with progressive bowel obstruction owing to continued inflammation and fibrosis. Patients with radiation proctitis present with rectal pain, bleeding, and occasionally diarrhea.

Acute radiation injury is usually self-limited to the period of treatment, but up to 5% of patients can progress to chronic radiation injury to the small intestine, and up to 15% of patients experience chronic radiation proctitis. Radiation enteritis and stricture formation can be seen on barium radiographs or CT scans. The characteristic neovascularization pattern of telangiectasias from radiation proctitis is seen on endoscopy.

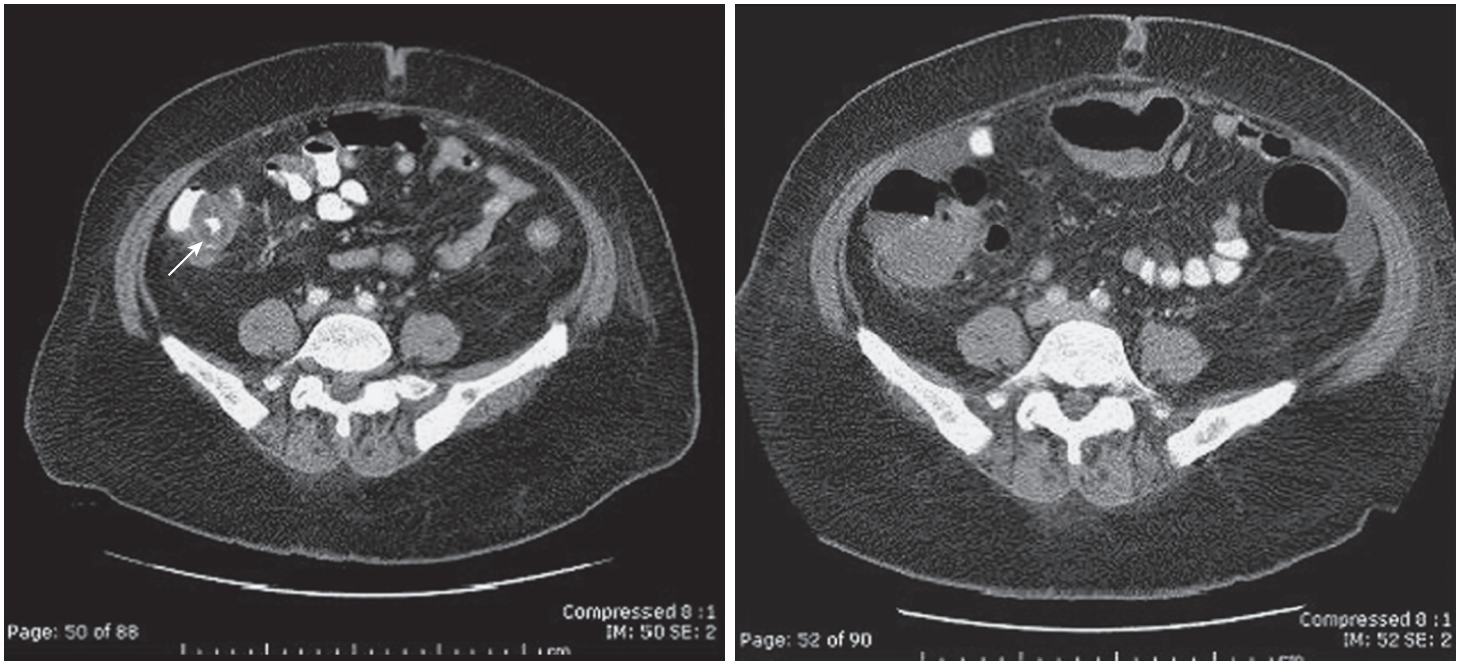
One-third to one-half of patients develop bleeding, which can be minor and intermittent or more substantial. Whereas patients who do not require transfusion have a 70% chance of remission, patients with chronic radiation enteritis who need transfusion have a low rate of remission (20%) and have subsequent high morbidity and even mortality rates. Radiation proctitis can be difficult to treat.

Two therapies, endoscopic argon plasma coagulation and rectal formalin infusion, were demonstrated to have similar efficacy in a recent RCT.[A17] Surgery for intestinal radiation enteritis, which can be required in up to one third of patients with strictures or bleeding, is associated with a high complication rate and should be avoided if possible.

PERITONEAL DISORDERS

PERITONITIS

Peritonitis, which is a local or generalized inflammation that involves the visceral and parietal peritoneum, can occur as a primary or secondary process. Primary peritonitis in adults is the spontaneous infection of ascites in a patient with cirrhosis (Chapter 139) in the absence of an overt intra-abdominal source. The use of acid-suppressive therapy appears to increase the risk of



E-FIGURE 128-2. Computed tomography scans showing neutropenic colitis. The *left* scan shows a thickened cecal wall (*arrow*). Eight days later, a follow-up scan shows resolution (*right* scan). (Courtesy of Charlene Prather, MD.)

developing spontaneous bacterial peritonitis three-fold in hospitalized patients with cirrhosis.

Secondary peritonitis develops when disease or injury to the intestine results in bacterial contamination from a perforated viscus (e.g., peptic ulcer disease, appendicitis, diverticulitis, penetrating trauma, or iatrogenic), from iatrogenic causes (e.g., peritoneal dialysis or surgical contamination), from granulomatous disease (e.g., tuberculosis or fungal infections), or from chemical or aseptic exposures (e.g., bile, urine, or radiographic barium).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Abdominal pain is the hallmark of peritonitis. It can be sudden in onset in the setting of a perforated viscus or more insidious in nature in the setting of granulomatous or chemical causes. Patients with peritonitis typically lie supine with flexed knees and exhibit shallow breathing. Physical examination reveals a distended abdomen with tenderness to palpation, localized or generalized guarding, and rigidity. Associated symptoms include fever, nausea, vomiting, and leukocytosis with a left shift. Some patients with bacterial peritonitis rapidly develop septic shock (Chapter 94).

Granulomatous peritonitis has a more insidious presentation, and 70% of patients have symptoms for 4 months before diagnosis. Systemic symptoms include fever, malaise, anorexia, and weight loss. The abdomen is diffusely tender. Leukocytosis can be absent.

Patients with tuberculous peritonitis (Chapter 299) often have a positive skin test result or infiltrates on their chest radiograph. The peritoneal fluid typically has a high protein level (<3 g/dL), a low glucose (<30 mg/dL), and elevated leukocytes (<250 cells/μL); fluid stains and cultures are unhelpful, but polymerase chain reaction (PCR)–based tests can be diagnostic. The laparoscopic appearance of tuberculous peritonitis is characteristic, with fibrous masses from the parietal peritoneum and granulomas.

Plain abdominal radiographs may show evidence of paralytic ileus, and free air under the diaphragm on upright views confirms the presence of a perforated viscus. CT scan is more sensitive, 70 to 100%, than plain radiographs for detecting free air and may also demonstrate the underlying cause (Fig. 128-8). CT/positron emission tomography can be useful for distinguishing tuberculous peritonitis from peritoneal carcinomatosis.[22]

In young patients, appendicitis and a perforated duodenal ulcer (Chapter 125) are common causes. In older patients, perforated diverticula and cancer (Chapter 179) are more common. In women of child-bearing age, tubal pregnancy and a ruptured tubo-ovarian abscess must be considered (Chapters 264 and 275). Secondary peritonitis is usually caused by a mixed flora of bacteria, including *Escherichia coli, Streptococcus faecalis, Pseudomonas aeruginosa, Klebsiella mirabilis, Bacteroides fragilis, Clostridium* spp, and anaerobic streptococci.

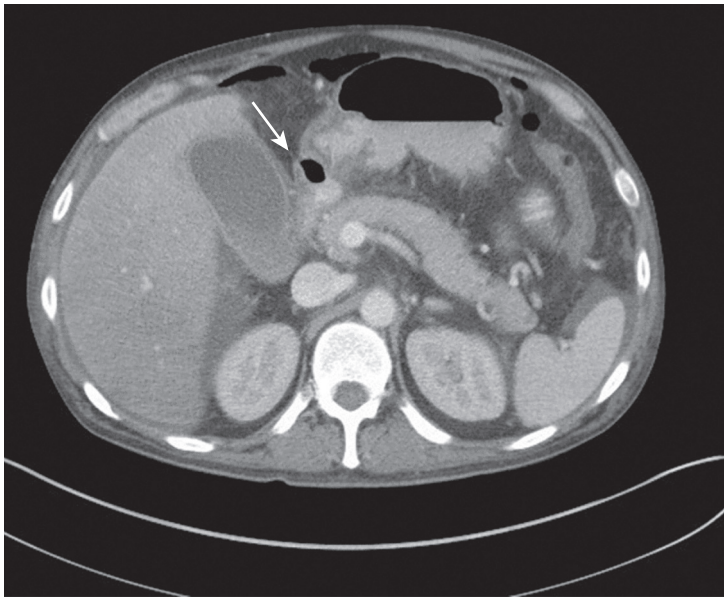


FIGURE 128-8. Peritonitis. A computed tomography scan in a patient with peritonitis showing a thickened duodenal wall from a perforated duodenal ulcer (*arrow*) found at the time of surgical exploration.

TREATMENT AND PROGNOSIS

Treatment of acute suppurative peritonitis relies on prompt adequate resuscitation with IV fluids and broad-spectrum IV antibiotics. Treatment regimens include: piperacillin–tazobactam, 3.375 g every 6 hours; ampicillin–sulbactam, 3.0 g every 6 hours; ciprofloxacin, 500 mg every 12 hours, and metronidazole, 1 g every 12 hours; levofloxacin, 750 mg every 24 hours; cefepime, 2 g every 12 hours, and metronidazole, 1 g every 12 hours; or imipenem–cilastatin sodium, 500 mg every 6 hours.[A18] Early diagnosis and surgical intervention for acute peritonitis from perforated viscus is critical. The mainstay of treatment for tuberculous peritonitis is at least 6 months of a multidrug regimen (Chapter 299).

Chemical aseptic peritonitis can be complicated by secondary bacterial infection. Treatment is similar to that of acute suppurative peritonitis, with intervention to control the source of peritoneal contamination.

The outcome of peritonitis depends on its cause as well as the rapidity of treatment. The mortality rate can be as low as 15% in patients who have correctable causes, such as a perforated appendix, and who do not develop multiorgan failure before treatment but as high as 50% for postoperative infective peritonitis.

PERITONITIS AS A COMPLICATION OF CHRONIC AMBULATORY PERITONEAL DIALYSIS

The most common complication of chronic ambulatory peritoneal dialysis is infectious peritonitis from bacterial contamination (Chapter 117), which commonly results from poor technique. In contrast to polymicrobial acute suppurative peritonitis, peritonitis complicating chronic ambulatory peritoneal dialysis is typically monomicrobial with gram-positive cocci in the majority of cases and gram-negative species in the remainder of cases. Fungal peritonitis is rare. Symptoms can be milder than in other forms of peritonitis, with patients often presenting with diffuse abdominal pain, low-grade fever, and leukocytosis. The exchange fluid is characteristically turbid and may be the only sign of infection. The diagnosis is based on these physical findings, turbid dialysate with less than 100 leukocytes/μL, and a positive dialysate culture that determines the microbe involved. Treatment is with intraperitoneal antibiotics. The dialysis catheter should be removed in the setting of an inadequate response to therapy, fungal or tuberculous peritonitis, or concomitant skin infection. The risk of peritonitis can be reduced by the judicious use of prophylactic intravenous vancomycin and oral nystatin or fluconazole.[A19]

ADHESIONS

Peritoneal adhesions, which are the most commonly observed cause of bowel obstruction,[23] can occur at any time after a laparotomy,[24] with rates about one-third lower with laparoscopic as compared with open surgery.[25] Adhesions are also the most common cause of small bowel obstruction in patients who have not had prior abdominal surgery.[26] Patients who have had intra-abdominal infection, ischemia, and peritonitis are at increased risk. Patients present with complete or incomplete bowel obstruction, which is usually manifested as colicky abdominal pain, nausea, and vomiting (including feculent vomiting), abdominal distention, and an absence of flatus or stooling. Bowel obstruction can be diagnosed on plain radiographs or CT scan from the presence of dilated bowel and air-fluid levels, with decompressed bowel distal to the site of obstruction (Fig. 128-9). Treatment of bowel obstructions is with NG tube decompression and fluid resuscitation. A nonoperative approach can be attempted in cases of partial bowel obstruction or in patients who have had numerous prior laparotomies, which make surgical exploration more complicated. However, urgent laparotomy for lysis of adhesions must be performed before bowel ischemia develops. In patients with chronic abdominal pain, surgical exploration for the intent of lysing adhesions without clear evidence of obstructing adhesions should be avoided. Patients who develop postoperative adhesions can progress to bowel obstruction and develop recurrent adhesions despite surgical lysis of the adhesions.

PERITONEAL CARCINOMATOSIS AND MALIGNANT ASCITES

Peritoneal carcinomatosis results when malignancy spreads throughout the peritoneal cavity and eventually encases the viscera. The cause can be primary tumors of the peritoneal cavity (e.g., mesothelioma and sarcoma), dissemination of an intra-abdominal malignancy (e.g., gastric, colon, pancreatic, ovarian, or neuroendocrine tumors), lymphomas, metastatic spread from extra-abdominal malignancy (e.g., breast, lung, or melanoma), and pseudomyxoma peritonei (a rare condition with gelatinous peritoneal implants from mucinous neoplasms of the appendix or ovary).

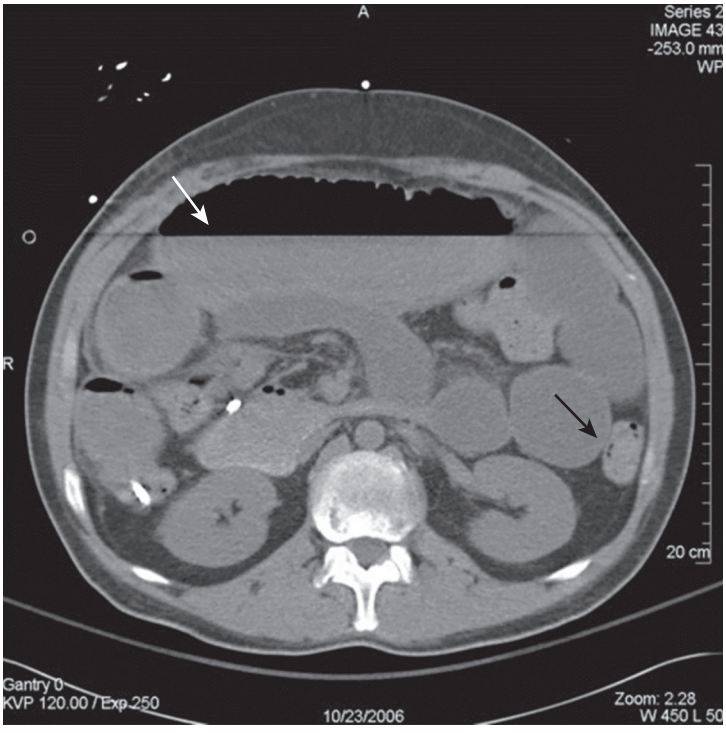

FIGURE 128-9. Small bowel obstruction. A computed tomography scan shows dilated, fluid-filled small bowel (*white arrow*) and a nondilated colon (*black arrow*) in a patient with a small bowel obstruction from adhesions found at the time of surgical exploration.

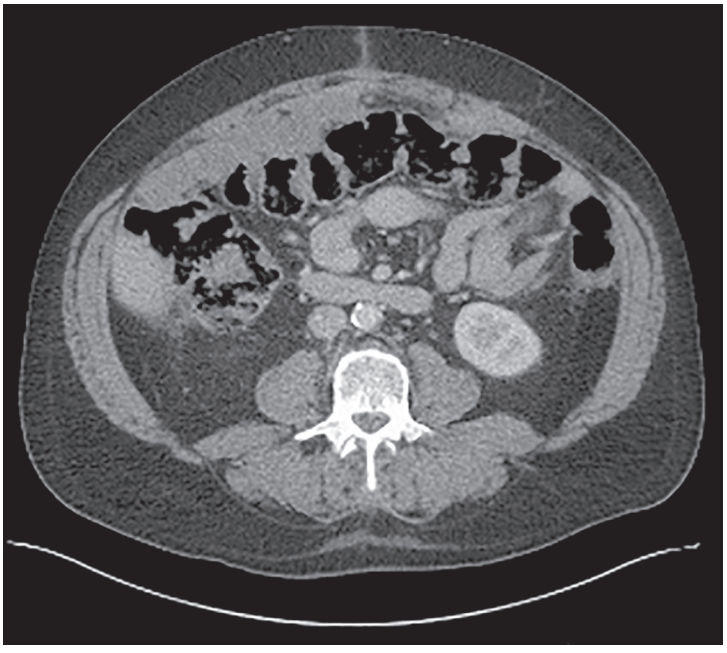

FIGURE 128-10. Carcinomatosis. A computed tomography scan shows peritoneal carcinomatosis in a patient with colon cancer.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The presentation of peritoneal carcinomatosis is nonspecific, with complaints of abdominal pain, anorexia, nausea, vomiting, malaise, and weight loss. Ascites is the most common physical finding. Malignant ascites is rare, accounting for less than 10% of cases of ascites.

Although ultrasound examination may document ascites, CT is preferred to identify carcinomatosis and the origin of the underlying cause (Fig. 128-10). Diagnostic paracentesis can be performed to obtain cell count and differential, culture, and cytologic examination. A serum to ascites albumin ratio of less than 1.1 mg/dL suggests malignant ascites, but the differential diagnosis also includes pancreatic ascites (Chapter 130), nephrotic syndrome (Chapter 107), and peritoneal tuberculosis. Laparoscopy can disclose the typical tumor implant stubbing the peritoneum. Biopsy and appropriate stains can verify the presence of mesothelioma (Chapters 86 and 177) by detecting hyaluronic acid on Alcian stain in a specimen that has a negative carcinoembryonic antigen stain and no mucin on a periodic acid–Schiff stain. By contrast, carcinomas have no hyaluronic acid but show mucin and have a positive carcinoembryonic antigen stain.

TREATMENT AND PROGNOSIS

Treatment is typically palliative owing to the late presentation of disease. Malignant ascites responds poorly to diuretic therapies, and repeated therapeutic paracentesis may be needed. Recent data suggest some benefit from cytoreductive surgery and hyperthermic intraperitoneal chemotherapy.

DISEASES OF THE MESENTERY AND OMENTUM

The differential diagnosis of mesenteric and omental disorders include a variety of rare disorders, including inflammation, cysts, and tumors that can be benign or malignant (Table 128-4).

Mesenteric panniculitis presents in middle or later age with a slight male predilection. Symptoms typically include nonspecific abdominal pain, weight loss, nausea, vomiting, and low-grade fever, but patients occasionally can present with an acute abdomen. A palpable mass is felt in the majority of patients. The diagnosis can be confirmed by CT scan. Lesions should be biopsied to exclude malignancy but generally are not amenable to complete resection. Significant improvement in the symptoms of this generally self-limited process has been reported with progesterone, corticosteroids, azathioprine, or cyclophosphamide, but evidence to recommend their general use is lacking.

TABLE 128-4 MESENTERIC DISEASES

PRIMARY INFLAMMATORY DISEASE
Panniculitis
Retractile mesenteritis
CYSTS
Developmental
Traumatic
Neoplastic
Infectious
TUMORS
Benign tumors
Lipoma
Leiomyoma
Hemangioma
Malignant tumors
Liposarcoma
Leiomyosarcoma
Rhabdomyosarcoma
Metastatic tumor
Mesenteric fibromatosis

Mesenteric and omental cysts and solid tumors are rare disorders. Patients present with a constellation of nonspecific symptoms. They can be identified with CT scan. Surgical resection will provide the definitive diagnosis and determine whether a benign or malignant condition is present.

Mesenteric fibromatosis (desmoid tumors) is a rare noninflammatory condition that may be associated with familial adenomatosis polyposis (Chapter 179). Fibromatoses are locally aggressive tumors that may present as stable or rapidly growing intra-abdominal masses. They have a high rate of recurrence after incomplete surgical resection, in patients with multicentric disease, or if precipitated by surgical trauma itself.

129 VASCULAR DISEASES OF THE GASTROINTESTINAL TRACT

CHARLES J. KAHI

INTESTINAL ISCHEMIA

Intestinal ischemia can be caused by a variety of disorders that result in decreased blood supply to the bowel. The injury itself, as well as its presentation, management, and outcome, vary depending on acuity, the splanchnic vessel(s) affected, the presence or absence of collateral circulation, the segment and the length of bowel involved, and whether the arterial or venous circulation is compromised. Recognition and appropriate management are crucial to improve patients' outcomes.[1]

EPIDEMIOLOGY

About 1 in 1000 hospital admissions is related to intestinal ischemia. Intestinal ischemia can be occlusive or nonocclusive, and can also be classified as acute or chronic, arterial or venous, and small bowel or colonic ischemia. Risk factors for intestinal ischemia include older age and conditions that predispose to arterial disease (e.g., atherosclerosis, fibromuscular dysplasia, abdominal aortic aneurysm, trauma, vasculitis), embolism (e.g., cardiac arrhythmias, cardioversion, heart failure, cardiomegaly, dyskinesia, valvular heart disease, recent myocardial infarction, cardiac catheterization, intracardiac thrombus, atheromatous cholesterol embolism), low-flow states (e.g., sepsis, dialysis, reduced cardiac output, vasoconstrictive drugs), or pathologic thromboses (hypercoagulable and hyperviscosity states, portal hypertension, trauma, malignancy, inflammation). Intestinal arterial and venous thrombosis have also been seen as complications of severe acute respiratory syndrome coronavirus 2 (Chapter 336).[2]

PATHOBIOLOGY

Blood flow to the digestive system is largely supplied by the celiac axis, superior mesenteric artery, and inferior mesenteric artery. The celiac axis gives rise to the left gastric artery, common hepatic artery, and splenic artery. These arteries and their branches (gastroduodenal, right gastroepiploic, and anterior superior pancreaticoduodenal) supply portions of the esophagus (also supplied from the aorta, right intercostal, bronchial, inferior thyroid, short gastric, and left phrenic arteries), stomach, duodenum, pancreas, and liver. The superior mesenteric artery supplies the majority of the small intestine and right colon via the inferior (anterior and posterior) pancreaticoduodenal arteries, the middle colic, right colic, and ileocolic arteries. The inferior mesenteric artery supplies the left colon via the left colic artery and proximal rectum via the superior rectal artery. The distal rectum receives its arterial supply from the internal iliac artery. Collateral vessels connect the three major systems: the superior and inferior mesenteric arteries can communicate through the marginal artery of Drummond, which runs along the mesenteric border, the meandering mesenteric artery (arc of Riolan) at the base of the mesentery, and the central anastomotic artery. The celiac axis and superior mesenteric artery are connected via the pancreaticoduodenal arcade (formed from the superior pancreaticoduodenal branch of the celiac axis and inferior pancreaticoduodenal branch of the superior mesenteric artery), the arc of Barkow, and the arc of Buhler. Collateral vessels vary from person to person, but in general, the stomach, duodenum, and rectum have extensive collaterals and are thus more resistant to ischemic events. Conversely, the splenic flexure and descending colon have more limited collaterals, thereby creating "watershed" areas that are more vulnerable to ischemia during low blood flow states.

Blood flow to the intestine is regulated by the sympathetic nervous system, angiotensin II, vasopressin, and prostaglandins. Under normal conditions, intestinal blood flow accounts for nearly 10% of cardiac output, and it may increase to 25% in the postprandial state. The bowel can withstand a 75% reduction of blood flow for up to 12 hours, whether due to arterial, venous, occlusive, or nonocclusive causes. This adaptability is because only a fraction of mesenteric capillaries are open under normal circumstances, and the bowel responds to reduced blood flow by increasing capillary flow and the efficiency of oxygen extraction. However, prolonged and severe reduction in blood flow can result in generalized mesenteric vasoconstriction, which diminishes flow through collaterals, thereby leading to potentially irreversible ischemia even if the underlying cause is corrected. Diminished delivery of oxygen and nutrients to the bowel results in ischemic injury; reperfusion after an ischemic episode can also injure the bowel. These insults are mediated by oxygen radicals, reduced endothelial synthesis of nitric oxide, and an enhanced cellular inflammatory response. In early stages, the damage involves the bowel mucosa, but it may progress to transmural necrosis.

ACUTE MESENTERIC ISCHEMIA

Acute mesenteric ischemia of the small bowel is considered a medical emergency, and delays in identification and management can result in death within a short period of time. Acute mesenteric ischemia should be distinguished from colonic ischemia, which has a generally better prognosis. Categories of acute mesenteric ischemia include superior mesenteric artery embolus or thrombosis, nonocclusive mesenteric ischemia, focal segmental ischemia, and mesenteric venous thrombosis.

CLINICAL MANIFESTATIONS

A high index of suspicion is critical so the diagnosis can be made before the intestine suffers irreversible damage. A cardinal symptom is abdominal pain, which is typically out of proportion to the amount of abdominal tenderness elicited on physical examination.[3] The pain can be periumbilical or ill-defined. In general, acute mesenteric ischemia should be considered in older patients who develop rapid-onset abdominal pain in the context of a cardiac arrhythmia, heart failure, a recent myocardial infarction, a retrograde aortic catheterization, or hypotension. It should also be suspected in younger patients who have hypercoagulable states (Chapter 67) or who use vasoactive substances (Chapter 365) and who have persistent and unexplained abdominal pain. Other features at presentation may include fever, nausea and vomiting, diarrhea, and abdominal distention. In elderly patients, the presenting symptoms may be nonspecific, such as an altered mental state.

129 VASCULAR DISEASES OF THE GASTROINTESTINAL TRACT

CHARLES J. KAHI

INTESTINAL ISCHEMIA

Intestinal ischemia can be caused by a variety of disorders that result in decreased blood supply to the bowel. The injury itself, as well as its presentation, management, and outcome, vary depending on acuity, the splanchnic vessel(s) affected, the presence or absence of collateral circulation, the segment and the length of bowel involved, and whether the arterial or venous circulation is compromised. Recognition and appropriate management are crucial to improve patients' outcomes.[1]

EPIDEMIOLOGY

About 1 in 1000 hospital admissions is related to intestinal ischemia. Intestinal ischemia can be occlusive or nonocclusive, and can also be classified as acute or chronic, arterial or venous, and small bowel or colonic ischemia. Risk factors for intestinal ischemia include older age and conditions that predispose to arterial disease (e.g., atherosclerosis, fibromuscular dysplasia, abdominal aortic aneurysm, trauma, vasculitis), embolism (e.g., cardiac arrhythmias, cardioversion, heart failure, cardiomegaly, dyskinesia, valvular heart disease, recent myocardial infarction, cardiac catheterization, intracardiac thrombus, atheromatous cholesterol embolism), low-flow states (e.g., sepsis, dialysis, reduced cardiac output, vasoconstrictive drugs), or pathologic thromboses (hypercoagulable and hyperviscosity states, portal hypertension, trauma, malignancy, inflammation). Intestinal arterial and venous thrombosis have also been seen as complications of severe acute respiratory syndrome coronavirus 2 (Chapter 336).[2]

PATHOBIOLOGY

Blood flow to the digestive system is largely supplied by the celiac axis, superior mesenteric artery, and inferior mesenteric artery. The celiac axis gives rise to the left gastric artery, common hepatic artery, and splenic artery. These arteries and their branches (gastroduodenal, right gastroepiploic, and anterior superior pancreaticoduodenal) supply portions of the esophagus (also supplied from the aorta, right intercostal, bronchial, inferior thyroid, short gastric, and left phrenic arteries), stomach, duodenum, pancreas, and liver. The superior mesenteric artery supplies the majority of the small intestine and right colon via the inferior (anterior and posterior) pancreaticoduodenal arteries, the middle colic, right colic, and ileocolic arteries. The inferior mesenteric artery supplies the left colon via the left colic artery and proximal rectum via the superior rectal artery. The distal rectum receives its arterial supply from the internal iliac artery. Collateral vessels connect the three major systems: the superior and inferior mesenteric arteries can communicate through the marginal artery of Drummond, which runs along the mesenteric border, the meandering mesenteric artery (arc of Riolan) at the base of the mesentery, and the central anastomotic artery. The celiac axis and superior mesenteric artery are connected via the pancreaticoduodenal arcade (formed from the superior pancreaticoduodenal branch of the celiac axis and inferior pancreaticoduodenal branch of the superior mesenteric artery), the arc of Barkow, and the arc of Buhler. Collateral vessels vary from person to person, but in general, the stomach, duodenum, and rectum have extensive collaterals and are thus more resistant to ischemic events. Conversely, the splenic flexure and descending colon have more limited collaterals, thereby creating "watershed" areas that are more vulnerable to ischemia during low blood flow states.

Blood flow to the intestine is regulated by the sympathetic nervous system, angiotensin II, vasopressin, and prostaglandins. Under normal conditions, intestinal blood flow accounts for nearly 10% of cardiac output, and it may increase to 25% in the postprandial state. The bowel can withstand a 75% reduction of blood flow for up to 12 hours, whether due to arterial, venous, occlusive, or nonocclusive causes. This adaptability is because only a fraction of mesenteric capillaries are open under normal circumstances, and the bowel responds to reduced blood flow by increasing capillary flow and the efficiency of oxygen extraction. However, prolonged and severe reduction in blood flow can result in generalized mesenteric vasoconstriction, which diminishes flow through collaterals, thereby leading to potentially irreversible ischemia even if the underlying cause is corrected. Diminished delivery of oxygen and nutrients to the bowel results in ischemic injury; reperfusion after an ischemic episode can also injure the bowel. These insults are mediated by oxygen radicals, reduced endothelial synthesis of nitric oxide, and an enhanced cellular inflammatory response. In early stages, the damage involves the bowel mucosa, but it may progress to transmural necrosis.

ACUTE MESENTERIC ISCHEMIA

Acute mesenteric ischemia of the small bowel is considered a medical emergency, and delays in identification and management can result in death within a short period of time. Acute mesenteric ischemia should be distinguished from colonic ischemia, which has a generally better prognosis. Categories of acute mesenteric ischemia include superior mesenteric artery embolus or thrombosis, nonocclusive mesenteric ischemia, focal segmental ischemia, and mesenteric venous thrombosis.

CLINICAL MANIFESTATIONS

A high index of suspicion is critical so the diagnosis can be made before the intestine suffers irreversible damage. A cardinal symptom is abdominal pain, which is typically out of proportion to the amount of abdominal tenderness elicited on physical examination.[3] The pain can be periumbilical or ill-defined. In general, acute mesenteric ischemia should be considered in older patients who develop rapid-onset abdominal pain in the context of a cardiac arrhythmia, heart failure, a recent myocardial infarction, a retrograde aortic catheterization, or hypotension. It should also be suspected in younger patients who have hypercoagulable states (Chapter 67) or who use vasoactive substances (Chapter 365) and who have persistent and unexplained abdominal pain. Other features at presentation may include fever, nausea and vomiting, diarrhea, and abdominal distention. In elderly patients, the presenting symptoms may be nonspecific, such as an altered mental state.

ABSTRACT

The vascular diseases of the gastrointestinal tract encompass a wide variety of disorders. Intestinal ischemia is caused by reduced blood flow to the digestive tract, thereby resulting in injuries that depend on acuity, splanchnic vessel involvement, and other factors. Acute mesenteric ischemia involving the small bowel is considered a medical emergency, and prompt recognition and management are critical to improve patient outcomes. The most common causes are thrombotic, embolic, nonocclusive, and mesenteric venous thrombosis. Diagnosis depends on a high index of suspicion in the appropriate clinical context and imaging of the mesenteric vessels. Multidisciplinary management includes supportive measures, antibiotics, anticoagulants, vasodilators, and surgical or radiologic revascularization. Colon ischemia generally has a better prognosis than acute mesenteric ischemia, except in the case of isolated right-sided colon ischemia. The systemic vasculitides can affect the gastrointestinal tract, and the manifestations depend on the size of the vessels affected. Vascular anomalies of the digestive tract are common, especially in older age; endoscopic treatment is effective and indicated if there is evidence of blood loss.

vasculitis

The pattern and rapidity of the onset of symptoms can offer clues to the etiology. Patients with an embolism can present with abrupt abdominal pain and forceful bowel movements, whereas a more indolent onset and course are generally seen in mesenteric venous thrombosis. In nonocclusive mesenteric ischemia, pain may be absent or not a dominant feature. Occult gastrointestinal bleeding is common in acute mesenteric ischemia, but overt bleeding is not (in contrast to colonic ischemia); its occurrence is usually a late and ominous development, which suggests intestinal infarction. If acute mesenteric ischemia progresses, abdominal findings may become more apparent and include tenderness, distention, and peritoneal signs.

DIAGNOSIS

Laboratory findings may initially be normal and generally lack sufficient reliability for early diagnosis.[4] D-dimer is a sensitive early marker, but it has high false-positive rates. Leukocytosis (>15,000/mL with a neutrophilic shift) and elevations in levels of serum amylase, phosphate, lactate dehydrogenase, creatine kinase, aminotransferases, and lactate may be seen, but these are usually associated with later-stage disease and lack sufficient sensitivity and specificity. Novel serologic markers are actively being studied but have not yet entered routine practice.

Plain radiographs are usually unrevealing in early acute mesenteric ischemia. With progression of the ischemic injury, abnormalities may include ileus, thumbprinting (due to submucosal hemorrhage), pneumatosis linearis, or portal venous gas. Although these findings are nonspecific, their presence correlates with a worse prognosis, and plain radiographs are useful to exclude other conditions. Doppler ultrasonography is generally not recommended because it only allows evaluation of the proximal aspects of the celiac axis and superior mesenteric artery, and it is not reliable in the assessment of nonocclusive mesenteric ischemia. Computed tomography (CT) scans of the abdomen and pelvis may be normal in early acute mesenteric ischemia or may reveal bowel wall thickening, submucosal hemorrhage, mesenteric venous thrombosis, mesenteric stranding, pneumatosis, or portal venous gas in more advanced cases (Fig. 129-1).

Standard contrasted CT is most useful for the diagnosis of mesenteric venous thrombosis, but it is generally less helpful for diagnosing acute mesenteric ischemia, especially in its early stages. CT angiography is the diagnostic imaging modality of choice,[5] with a sensitivity and specificity of about 95%, while also allowing concomitant evaluation of other abdominal structures. CT angiography should be performed without oral contrast owing to the risk of obscuring the mesenteric vessels and delaying diagnosis. Magnetic resonance (MR) angiography also has high diagnostic accuracy and may be preferred for patients who are hypersensitive to iodinated contrast dye, but it is less readily available and more time-consuming to obtain than CT angiography. Although CT angiography and MR angiography perform well for occlusive acute mesenteric ischemia, they are both less reliable for nonocclusive mesenteric ischemia. The gold standard for the diagnosis and specific classification of acute mesenteric ischemia is selective mesenteric angiography, which also has therapeutic applications for the delivery of medications or the placement of a stent. However, given its wide availability and ease of performance, CT angiography has largely replaced conventional angiography for the primary diagnosis of acute mesenteric ischemia.

PROGNOSIS

Untreated acute mesenteric ischemia resulting in intestinal infarction is associated with a mortality rate of over 70%, but prompt diagnosis and treatment significantly improve outcomes. Two-year survival rates are nearly 90% using intensive multidisciplinary and multimodal approaches.

TREATMENT

Arterial acute mesenteric ischemia involving the small bowel is associated with high mortality (greater than 70% if there is intestinal infarction). Prompt diagnosis and management are essential,[6] and patients benefit from a multidisciplinary approach (Fig. 129-2).

Initial management for all patients should include intravascular volume resuscitation, broad-spectrum antibiotics with gram-negative and anaerobic coverage to prevent sepsis secondary to bacterial translocation from the gut (e.g., a third-generation cephalosporin or fluoroquinolone plus metronidazole and piperacillin-tazobactam; see Table 266-4), and attention to any underlying precipitating factors such as heart failure (Chapter 46) or cardiac arrhythmias (Chapters 52 and 53). The presence of peritoneal signs or of imaging findings suggestive of transmural intestinal necrosis should prompt urgent exploratory laparotomy. If feasible, preoperative angiography is useful because it can help tailor the surgical approach and is associated with significantly lower postoperative morbidity and mortality, particularly for occlusive acute mesenteric ischemia. Depending on the subtype of mesenteric ischemia and severity of the patient's condition, surgery may include embolectomy, thrombectomy, resection of necrotic bowel, and vascular bypass.[7] Papaverine (60-mg bolus followed by 30 to 60 mg/hr continuous infusion for 12 to 48 hours) is a phosphodiesterase inhibitor that is used pre- and postoperatively for occlusive acute mesenteric ischemia (superior mesenteric artery embolism and superior mesenteric artery thrombosis) and as a primary treatment modality for nonocclusive mesenteric ischemia to minimize splanchnic vasoconstriction and decrease the risk of reperfusion injury. Other vasodilators such as alprostadil (20-μg bolus followed by 60 to 80 μg/24 hr infusion until clinical improvement) can also be used.[8] Options for selected patients with occlusive acute mesenteric ischemia who do not require surgery include thrombolysis and endovascular stent placement. Long-term care involves addressing underlying predisposing factors (e.g., smoking cessation, lipid-lowering therapy), lifelong therapy with aspirin in patients who undergo surgery, and dual antiplatelet therapy (usually with aspirin plus clopidogrel) in patients who undergo endovascular intervention (Chapter 59).

SPECIFIC ACUTE MESENTERIC ISCHEMIA SYNDROMES

Superior Mesenteric Artery Thrombosis

Superior mesenteric artery thrombosis, also referred to as acute mesenteric arterial occlusive disease, is estimated to account for more than 50% of cases of acute mesenteric ischemia. It can occur in the context of preexisting symptomatic chronic mesenteric ischemia (see later) in 20 to 50% of cases. These patients typically report preexisting postprandial abdominal pain, weight loss, and sitophobia (fear of eating). Atherosclerotic disease involving other vascular beds (coronary, carotid, peripheral arterial) is common, and risk factors overlap with those of atherosclerosis in general (age, smoking, hypertension, diabetes, hyperlipidemia). The most common site of thrombosis is just distal to the origin of the superior mesenteric artery. The diagnosis can be established by CT angiography or MR angiography, although selective mesenteric catheter angiography is often used to direct and administer therapy. Papaverine (e.g., a 60-mg bolus followed by 30 to 60 mg/hr continuous infusion for 12 to 48 hours) or another vasodilator such as alprostadil (20- μg bolus followed by 60 to 80 μg/24 hr infusion until clinical improvement) is administered into the superior mesenteric artery to

alleviate reflex splanchnic vasoconstriction. Thrombolytic therapy (using tissue plasminogen activator infused at a rate of 0.5 to 1 mg/hr), with or without angioplasty and endovascular stenting, is an option in selected cases; however, most patients require surgical thrombectomy and bypass grafting.

Superior Mesenteric Artery Embolism

Superior mesenteric artery embolism is responsible for about 30% of cases of acute mesenteric ischemia. It usually results from left atrial or left ventricular mural thrombi (due to atrial fibrillation, for example), which tend to lodge just distal to the origin of the superior mesenteric artery (E-Fig. 129-1). Selected patients with minor emboli (distal to the ileocolic artery take-off) or with incomplete occlusion may be candidates for thrombolytic therapy with tissue plasminogen activator, administered via a catheter inserted in the vicinity of the embolus, to lyse clot material and alleviate abdominal pain. Emboli that occur proximal to the take-off of the ileocolic artery are termed major, and such patients usually require laparotomy, as do patients with peritoneal signs. Surgical interventions, including embolectomy and bowel resection, depend on operative findings. Some patients will require a second-look surgery within 24 hours to reassess the viability of the small bowel and the adequacy of resection. Vasodilators such as papaverine or alprostadil are used similarly to the management of superior mesenteric artery thrombosis. Patients with superior mesenteric artery embolism may benefit from systemic anticoagulation with unfractionated heparin to prevent clot propagation and further distal embolization, although this benefit must be balanced against the risk of hemorrhage. If surgery is performed, anticoagulation is resumed 24 hours postoperatively. Patients with atrial fibrillation and embolic events generally require long-term anticoagulation (Chapter 52).

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia is the cause of up to 20% of cases of acute mesenteric ischemia. The syndrome results from splanchnic vasoconstriction, which initially occurs as a protective mechanism during low arterial blood flow to the intestine, such as seen in patients with cardiac arrhythmias, heart failure, myocardial infarction, shock, sepsis, burns, pancreatitis, hemorrhage, dialysis, and vasospasm due to vasoactive substances (e.g., cocaine, digoxin, vasopressin, amphetamines). In patients with nonocclusive mesenteric ischemia, the splanchnic vasoconstriction persists despite correction of the precipitating event, thereby leading to bowel ischemia. Abdominal pain may not be a major hallmark and is sometimes overshadowed by other clinical features, such as cardiovascular instability. Given the underlying pathophysiology, the standard of care for nonocclusive mesenteric ischemia is correction of the precipitating event(s), diagnosis by selective mesenteric angiography, and treatment with a continuous infusion of a vasodilator (see earlier) into the superior mesenteric artery to reverse splanchnic vasoconstriction. The infusion is continued until angiography (generally repeated daily) demonstrates that the vasoconstriction is resolved (Figs. 129-3A and 129-3B). Surgical exploration with resection of necrotic bowel is indicated in the presence of peritoneal signs.

Focal Segmental Ischemia

Focal segmental ischemia has a better prognosis than other forms of acute mesenteric ischemia because the length of involved bowel and the extent of necrosis are usually more limited. Causes include atheromatous emboli (Chapter 66), vasculitis (see later), strangulated hernias (Chapter 128), radiation therapy (Chapter 18), and oral contraceptives (Chapter 220). Some patients may develop a chronic enteritis with strictures that can mimic Crohn disease. Treatment is surgical resection of the involved bowel.

Mesenteric Venous Thrombosis

Splanchnic[9] and mesenteric venous thromboses, which account for nearly 10% of cases of acute mesenteric ischemia, have acute and subacute forms that are distinguished based on the duration since the onset of symptoms. Patients with subacute mesenteric venous thrombosis may present with fluctuating symptoms (abdominal pain, nausea, distention, diarrhea) persisting weeks to months. Many patients have an underlying inherited or acquired hypercoagulable state (Table 129-1) or portal hypertension, but some have no identifiable cause. The superior mesenteric vein, often with involvement of the portal and splenic veins, is most frequently thrombosed, and the inferior mesenteric vein is rarely affected. Presenting symptoms in acute thrombosis are similar to those of the arterial forms of acute mesenteric ischemia, notably pain out of proportion to physical examination findings. Gastrointestinal bleeding, if present, usually indicates bowel infarction.

CT with IV contrast has greater than 90% accuracy for the diagnosis of mesenteric venous thrombosis and is the modality of choice given its availability and ease of performance. Findings may include thickening and enhancement of the bowel wall, distention, hazy mesentery, indistinct bowel wall margins, new ascites, and enlargement of the superior mesenteric vein with an intraluminal thrombus. MR venography has very high diagnostic accuracy but is less readily available, more time-consuming, and more costly. Selective mesenteric angiography can help establish the diagnosis and guide therapy (Fig. 129-4) but is generally not needed when standard CT is diagnostic.

Therapy follows similar principles as for arterial acute mesenteric ischemia: fluid resuscitation, antibiotics with gram-negative and anaerobic coverage (e.g., a third-generation cephalosporin or fluoroquinolone plus metronidazole and piperacillin-tazobactam; see Table 266-4), avoidance of vasoconstrictors,

and systemic anticoagulation with heparin (Table 68-6).[10] The presence of peritoneal signs or other findings suspicious for bowel infarction require laparotomy with or without bowel resection and infusion of a vasodilator. Selected patients may benefit from thrombolytic therapy. Patients with mesenteric venous thrombosis and an underlying hypercoagulable state should receive lifelong anticoagulation therapy with warfarin or a direct-acting oral

anticoagulant (Table 70-6);[11] otherwise, a 3- to 6-month course of anticoagulation is thought to be adequate. The prognosis of mesenteric venous thrombosis is generally better than that of the arterial variants of acute mesenteric ischemia.

Chronic mesenteric venous thrombosis is distinct from the acute and subacute forms; patients may present with gastrointestinal bleeding from esophageal or gastric varices owing to portal or splenic vein thrombosis in the absence of symptoms at the time of the initial thrombotic event. Treatment is aimed at controlling hemorrhage and underlying portal hypertension.

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia, which is almost always caused by atherosclerotic disease of the mesenteric vessels, generally involves the origins of at least two of the three major mesenteric arteries (celiac axis, superior mesenteric artery, inferior mesenteric artery) (Fig. 129-5). The risk factors are the same as for atherosclerosis (Chapter 40), including age, smoking, hypertension, diabetes, and hyperlipidemia, and many patients have atherosclerotic disease involving other vascular beds.

CLINICAL MANIFESTATIONS

A hallmark symptom is postprandial pain in the upper or mid-abdomen, starting within 30 minutes after eating, increasing in severity, and gradually subsiding over a few hours. Weight loss may occur as a result of sitophobia; other symptoms include nausea, vomiting, bloating, diarrhea, and constipation. The syndrome may progress with time, and episodes of pain may become more prolonged and unrelated to eating, indicative of worsening vascular narrowing and increased risk of acute thrombosis. The occurrence of sudden severe pain in a patient with known or suspected chronic mesenteric ischemia implies a superimposed acute thrombotic event. Uncommon associations are unexplained gastroduodenal ulcerations that do not heal with acid suppression, small bowel biopsy findings of villous atrophy, and delayed gastric emptying. Physical findings in patients with advanced disease may include cachexia or an abdominal bruit.

DIAGNOSIS

The diagnosis of chronic mesenteric ischemia may be challenging: the prevalence of atherosclerosis is high in older patients, and abdominal pain may not

FIGURE 129-6. Magnetic resonance angiography in a patient with chronic mesenteric ischemia. This image shows severe stenosis at the origins of the celiac axis and the superior mesenteric artery. (Courtesy Thomas Casciani, MD.)

necessarily be due to mesenteric vascular occlusive disease. Available imaging modalities, such as CT angiography, can reveal stenoses in the mesenteric vessels but cannot ascertain whether ischemia is present. Doppler ultrasonography can screen for stenoses in the proximal aspects of the celiac axis and superior mesenteric artery; increased flow velocities of at least 200 cm/sec (celiac axis) and 275 cm/sec (superior mesenteric artery) are associated with a stenosis of at least 70%. Both CT angiography and MR angiography (Fig. 129-6 and Video 129-1) are useful for detecting arterial stenoses, but neither is sensitive enough to exclude chronic mesenteric ischemia when the pretest probability is high. Gastric tonometry exercise testing, which measures the gastric-arterial P_{CO_2} gradient (an increase after exercise is indicative of ischemia), has shown promise for diagnosing ischemia but is not widely available. Selective mesenteric angiography remains a cornerstone of the evaluation, because the diagnosis requires the presence of clinical symptoms, occlusion of at least two of the three major mesenteric vessels, and exclusion of other potential causes of postprandial abdominal pain (e.g., cancer, gastroparesis, volvulus, bowel obstruction, pancreatobiliary disease, paraesophageal hernias).

TREATMENT

In patients who have symptoms consistent with chronic mesenteric ischemia, have appropriate angiographic findings, and have no other potential causes, revascularization is indicated. Mesenteric angioplasty with or without stent placement is the treatment of choice, with open surgery reserved for selected younger patients and patients who are not suitable for endovascular repair,[12,13] and is associated with shorter hospital stay and lower morbidity. However, surgery is more effective long-term because it is associated with better long-term patency rates and a lower risk of recurrent symptoms.

COLON ISCHEMIA

Colon ischemia is the most common ischemic syndrome of the bowel. It is diagnosed in about 10 to 20% of patients who present to the hospital with lower gastrointestinal bleeding, and its incidence is estimated at about 16 per 100,000 person-years in the general population. Colon ischemia is also referred to as "ischemic colitis"; however, an inflammatory phase is not consistently found, so the preferred term is colon ischemia. Colon ischemia encompasses a spectrum of injury, including reversible colopathy (most common, about 50%), transient colitis, chronic colitis, stricture, gangrene, and fulminant universal colitis. Most cases occur in older patients (>60 years old), in whom the most common cause is transient nonocclusive hypoperfusion of a colonic segment, often without apparent cause. Although older patients are prone to colon ischemia in "watershed areas" of the colon (splenic flexure-descending colon), a segmental pattern of involvement is common, most often involving the left colon. In younger patients, colon ischemia is more likely to be caused by the use of vasoactive substances (e.g., cocaine, methamphetamines), vasculitis, or hypercoagulable states (Table 129-2).

Adapted from Brandt LJ, Feuerstadt P, Longstreth GF, et al. ACG clinical guideline: epidemiology, risk factors, patterns of presentation, diagnosis, and management of colon ischemia (CI). *Am J Gastroenterol.* 2015;110:18-44.

CLINICAL MANIFESTATIONS

Most patients with colon ischemia present acutely with abdominal pain, often in the left lower quadrant, associated with fecal urgency, diarrhea, and hematochezia. Passage of maroon stool may also occur, but bleeding is rarely severe. Patients may have fever and tachycardia. The physical examination typically reveals tenderness over the affected portion of colon, as well as abdominal distention. Patients with isolated right-sided colon ischemia tend to have more severe pain, which overshadows bleeding. As with acute mesenteric ischemia, the presence of peritoneal signs mandates prompt surgical consultation. About 25% of cases of colon ischemia are isolated right-side colon ischemia, which can complicate low-flow states such as hypotension and sepsis, chronic kidney disease, and hemodialysis, presumably secondary to intravascular fluid shifts.

DIAGNOSIS

No single test can conclusively diagnose colon ischemia, but the diagnosis can be established with judicious use of diagnostic modalities in the appropriate clinical context.[14] The differential diagnosis includes inflammatory bowel disease (ulcerative colitis and Crohn disease; Chapter 127), infectious colitis

FIGURE 129-7. Colon ischemia. There is mural thickening (*arrows*) of the proximal descending colon and submucosal edema. (From Gore RM, Yaghmai V, Thakrar KH, et al. Imaging in intestinal ischemic disorders. *Radiol Clin North Am*. 2008;46:845-875.)

(Chapter 126), and mechanical obstruction due to colorectal cancer (Chapter 179), fecal impaction, or stricture.

Laboratory findings may be normal, but the presence of leukocytosis and elevated blood levels of urea nitrogen and lactate are indicative of a more severe course. Plain radiographs may be normal or show thumbprinting. A CT scan with IV contrast, which is useful to exclude other diagnostic possibilities and to assess the severity and distribution of the ischemic process, may show segmental colonic edema and inflammation with or without pericolonic inflammatory stranding (Fig. 129-7); however, these findings are nonspecific and can also be seen in inflammatory bowel disease, infectious colitis, and diverticulitis. Colonoscopy is the best test to diagnose colon ischemia, because it allows direct visualization of the mucosal biopsy and assessment of the distribution and severity of the disease process. Most colonoscopic findings are nonspecific (erythema, edema, segmental patchy ulcerations, subepithelial hemorrhages), but the presence of a "single stripe sign" (E-Fig. 129-2) in the left colon is a reliable indicator of colon ischemia. Visceral angiography is typically not required. However, patients with isolated right-sided colon ischemia tend to have a more aggressive course. This is because the superior mesenteric artery supplies blood to the right side of the colon and most of the small intestine, so ischemia confined to the right colon may be a sentinel event for ischemia involving the small intestine (E-Fig. 129-3).

Unlike patients with left-sided colon ischemia, those with isolated right-sided colon ischemia should undergo CT angiography or traditional angiography to evaluate the mesenteric circulation for possible occlusion of the superior mesenteric artery.

TREATMENT

Colon ischemia is usually self-limited, and symptoms generally resolve within 2 to 3 days with supportive care: volume replacement, bowel rest, correction of conditions leading to hypoperfusion such as systemic hypotension, avoidance of vasoconstrictive medications, and broad-spectrum antibiotics (e.g., third-generation cephalosporin or fluoroquinolone plus metronidazole, and piperacillin-tazobactam; see Table 266-4) with gram-negative and anaerobic coverage, especially in patients with severe colon ischemia (Fig. 129-8). Surgery is reserved for patients with signs and symptoms of gangrene, perforation, or massive bleeding.[15] Patients with persistent symptoms have a higher incidence of complications, including gangrene, perforation, segmental colitis, and stricture. Strictures, which can form over weeks to months, may require surgical resection.

VASCULITIS

Vasculitis (Chapter 249) can involve the gastrointestinal tract, usually in association with systemic involvement. The gastrointestinal manifestations, which depend on the size of the vessels involved, include abdominal pain, nausea or vomiting, diarrhea, and overt bleeding. The ischemic process is typically due to immune complex deposition that leads to the activation of complement and resulting inflammation, which may then lead to focal segmental ischemia. Treatment usually requires immunosuppressive medications (Chapter 28) or surgical resection in selected situations.

LARGE VESSEL VASCULITIS

Takayasu disease and *giant cell arteritis* (Chapter 63) rarely involve the mesenteric circulation. Takayasu arteritis most often affects young women of Asian background and has been associated with ulcerative colitis and Crohn disease (Chapter 127).

MEDIUM VESSEL VASCULITIS

Polyarteritis nodosa (Chapter 249) is the most common underlying diagnosis in vasculitis involving the gastrointestinal tract. The disease is characterized by segmental microaneurysms, which occur more frequently in the small bowel than in the colon. The gallbladder, spleen, liver, and pancreas may be involved. The syndrome may be associated with chronic hepatitis B infection (Chapter 135). Abdominal pain is the most common symptom, but gastrointestinal bleeding and perforation have also been reported.

Infantile febrile mucocutaneous lymph node syndrome (Kawasaki disease; Chapter 249) is a necrotizing vasculitis that can affect young children and cause abdominal pain, ileus, obstruction, and perforation.

Malignant atrophic papulosis (Degos disease) is a rare occlusive vascular disease affecting mainly the skin and intestine. Spontaneous perforation may occur owing to ischemia, and the disease has a poor prognosis.

SMALL VESSEL VASCULITIS

Systemic lupus erythematosus (Chapter 245) is associated with a variety of gastrointestinal manifestations.[16] Lupus vasculitis involving the mesenteric vessels may present with a clinical syndrome of focal segmental ischemia or chronic mesenteric ischemia, but some patients develop significant gastrointestinal bleeding. Lupus mesenteric vasculitis requires prompt recognition and immunosuppressive management.

Antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis includes granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome; Chapter 249). Gastrointestinal tract involvement is variable, with abdominal pain and bleeding the most common symptoms.

Henoch-Schönlein purpura (Chapter 249) typically presents in children with palpable purpura, arthritis, and abdominal pain. The cause is deposition of immunoglobulin A immune complexes in blood vessel walls. Gastrointestinal involvement is common and usually manifested by pain and bleeding owing to mucosal and submucosal hemorrhages.

Hypersensitivity vasculitis rarely involves the splanchnic vessels and is associated with a variety of drugs, chemicals, and infections.

Behçet disease (Chapter 249) is characterized by oral and genital ulcers. Both large-vessel and small-vessel vasculitis may occur. Gastrointestinal manifestations include abdominal pain, diarrhea, overt bleeding, and perforation due to deep ulcerations. The ileocecal area is most commonly involved.[17]

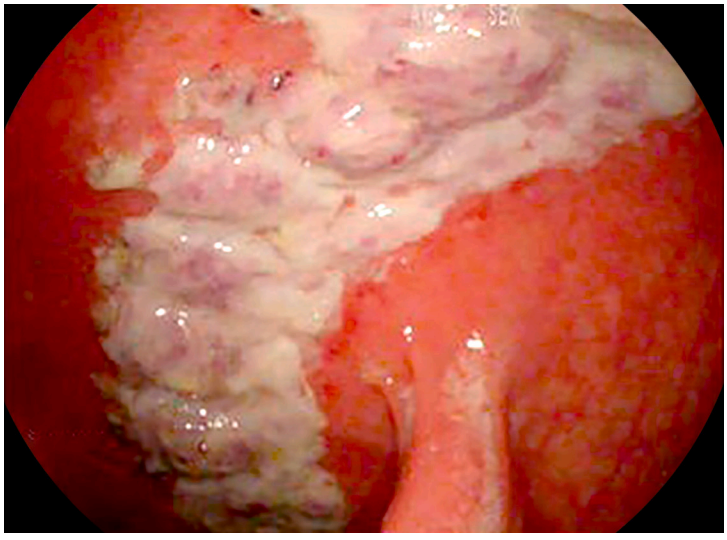
For each of these conditions, treatment is aimed at the underlying vasculitis.

VASCULAR ANOMALIES AND DISORDERS

Vascular anomalies of the gastrointestinal tract are common, especially with older age. *Angioectasia* (also referred to as vascular ectasia) is a general term that refers to the process whereby a blood vessel is lengthened or dilated. *Angiodysplasia* has often been used interchangeably with angioectasia. *Telangiectasia* is similar, but the term is usually used in the context of systemic disorders, such as hereditary hemorrhagic telangiectasia and scleroderma. *Arteriovenous malformation* is a congenital lesion, whereas *angioma* is a vascular neoplasm that can be benign (hemangioma) or malignant (angiosarcoma).

ANGIOECTASIA

Angioectasia is the most common vascular abnormality of the gastrointestinal tract, and its prevalence increases with age. Angioectasias consist



E-FIGURE 129-2. "Single stripe sign," a linear ulceration along the longitudinal axis of the colon. (From Brandt LJ, Feuerstadt P. Beyond low flow: how I manage ischemic colitis. *Am J Gastroenterol*. 2016;111:1672-1674.)

(From Brandt LJ, Feuerstadt P, Longstreth GF, et al. ACG clinical guideline: epidemiology, risk factors, patterns of presentation, diagnosis, and management of colon ischemia [CI]. *Am J Gastroenterol*. 2015;110:18-44.)

of thin-walled, distorted mucosal and submucosal arterioles, venules, and capillaries. Angioectasias are most frequently located in the cecum and ascending colon, can be single or multiple, and can sometimes be found concomitantly in the small intestine and stomach. Associations include systemic sclerosis (Chapter 246), chronic renal failure (Chapter 116), von Willebrand disease (Chapter 159), aortic stenosis (Chapter 60), and left ventricular assist devices (Chapter 93).

CLINICAL MANIFESTATIONS

Most angioectasias are asymptomatic and found incidentally during endoscopy. However, some may cause painless bleeding, which can be occult or overt (hematochezia, melena, hematemesis).[18] The bleeding is typically recurrent and mild, but about 15% of patients develop massive bleeding.

DIAGNOSIS

The diagnosis is most often established at endoscopy, either incidentally or during investigations for anemia or gastrointestinal bleeding (Fig. 129-9). The lesions may be difficult to discern in patients who are hypovolemic or have received meperidine for sedation; in the latter situation, naloxone can be considered to reverse the opioid effect and improve visualization. Small bowel angioectasias beyond the reach of endoscopes require videocapsule endoscopy[19] or small bowel balloon-assisted enteroscopy for diagnosis and treatment (Chapter 121).

TREATMENT

Incidental angioectasias found at endoscopy or colonoscopy in asymptomatic individuals do not require intervention. Endoscopic modalities, which can effectively control hemorrhage from angioectasias, include bipolar electrocoagulation, argon plasma coagulation (E-Figs. 129-4A and 129-4B), and application of hemoclips. Rebleeding occurs in some patients and requires repeat intervention. When endoscopic hemostasis is not feasible owing to active bleeding or inaccessible lesion location, visceral angiography can be diagnostic and therapeutic by allowing embolization of the bleeding lesion. Thalidomide (25 mg orally 4 times daily) has antiangiogenic properties and has been reported to be effective in some patients with refractory bleeding from intestinal angioectasias. Other pharmacologic options include octreotide (50 to 100 μg subcutaneously twice a day) and bevacizumab (5 mg/kg every 2 weeks for a total of six infusions).

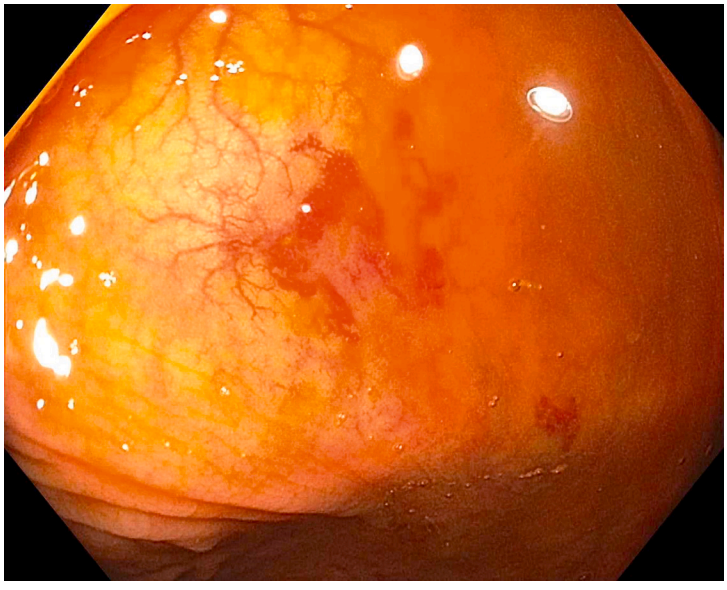

FIGURE 129-9. Colonic angioectasia.

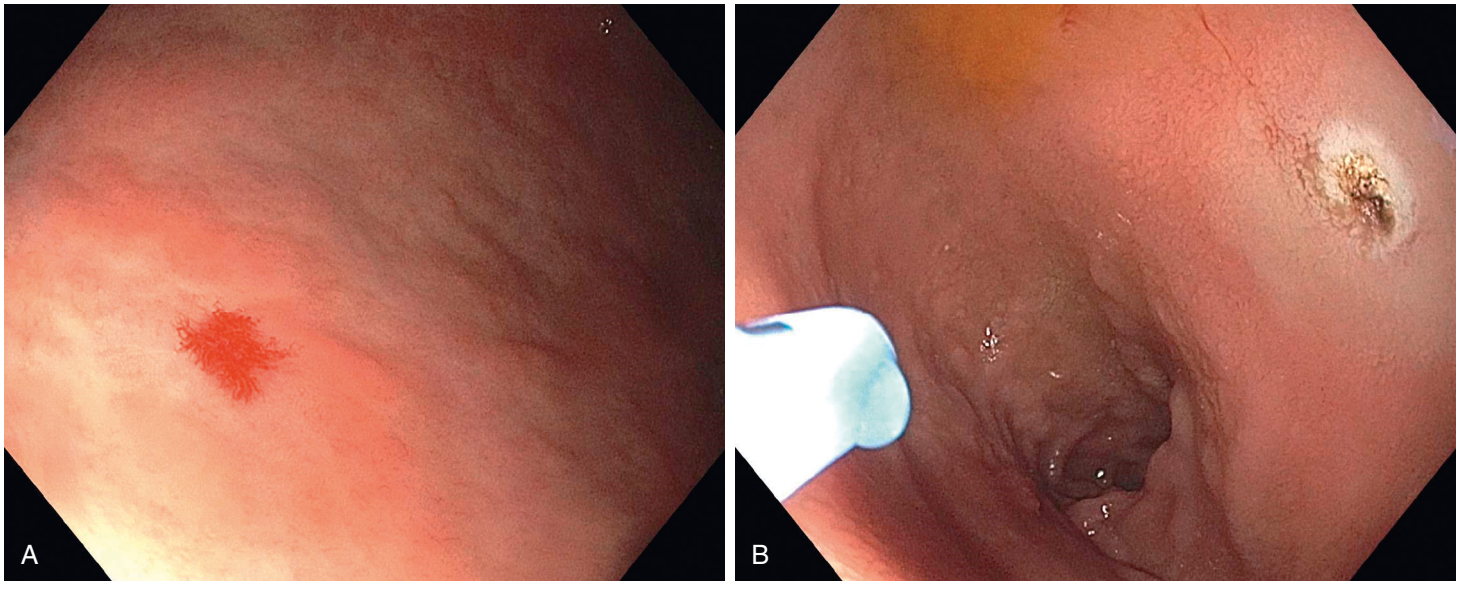
DIEULAFOY LESION

Dieulafoy lesion is a persistently large submucosal artery with an overlying mucosal defect. This lesion is most often found in the proximal portion of the stomach within 6 cm of the gastroesophageal junction, but it has also been reported in the esophagus, small intestine, colon, and rectum. Clinical manifestations include overt bleeding (Chapter 121), which can be brisk, massive, and recurrent (Fig. 129-10). In some patients, diagnosis may be delayed because the vascular protuberance can be subtle and difficult to visualize at endoscopy.



E-FIGURE 129-4. **Gastric angioectasia. A,** Gastric angioectasia in a patient with iron deficiency anemia. **B,** After ablation with argon plasma coagulation.

FIGURE 129-10. Brisk bleeding from a Dieulafoy lesion in the stomach of a patient with melena.

Endoscopic treatment is usually effective.[20] Options include injection, electrocoagulation, argon plasma coagulation, band ligation, and hemoclip application.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia, also known as Osler-Weber-Rendu disease (Chapter 159), is an inherited autosomal dominant disorder. Patients typically have visible telangiectasias on their lips and mucous membranes, as well as telangiectasias in their gastrointestinal tract and other organs. The spectrum of symptoms varies with age: affected children tend to have frequent epistaxis, whereas overt recurrent gastrointestinal bleeding predominates in older age groups. Telangiectasias on the lips (see Fig. 159-3), buccal mucosa, and tongue are highly suggestive. Most patients have recurrent melena (sometimes compounded by swallowed blood from epistaxis), and some patients become transfusion-dependent. Diagnosis is based on clinical criteria (epistaxis, telangiectasias, visceral lesions, hereditary hemorrhagic telangiectasia in a first-degree relative) and can be confirmed by testing for mutations in the endoglin and activin receptor-like kinase-1 genes. Endoscopic therapy is the mainstay of management, particularly for actively bleeding lesions.

OTHER ECTASIAS

Patients with *Turner syndrome* (Chapter 217), *scleroderma* (Chapter 246), and *CREST syndrome* (Chapter 246) may also have gastrointestinal tract telangiectasias. In patients with portal hypertension (Chapter 139), vascular ectasias can involve venules and capillaries in the stomach (*congestive gastropathy*), in the small bowel (*congestive enteropathy*), and in the colon (*congestive colopathy*). In the stomach, ectasia and thrombosis can result in so-called watermelon stomach (gastric antral vascular ectasia), in which erythematous streaks, similar to the stripes on a watermelon, are visible by endoscopy in the antrum and radiate toward the pylorus and even the gastric cardia. Occult bleeding is common, and melena can occur. If iron replacement alone is not adequate, argon plasma coagulation is the treatment of choice.

AORTOENTERIC FISTULAS

After abdominal aortic aneurysm surgery (Chapter 63), an *aortoenteric fistula* can develop, often because of infection of the graft. Fistulas typically communicate with the third or fourth portion of the duodenum and can occur several years after surgery. Massive and even fatal gastrointestinal bleeding may result. When gastrointestinal bleeding develops in patients who have had prior abdominal aortic surgery, the evaluation must include urgent upper endoscopy to exclude another definitive source of the bleeding. CT aids the diagnosis, which should be suspected in the appropriate clinical context. If no alternative bleeding source can be definitively found, explorative surgery is indicated.

An *atrioesophageal fistula* may be caused by thermal damage to the heart or esophagus. Examples of precipitating events include radiofrequency ablation procedures for arrhythmias (Chapter 54) or for Barrett esophagus (Chapter 124).

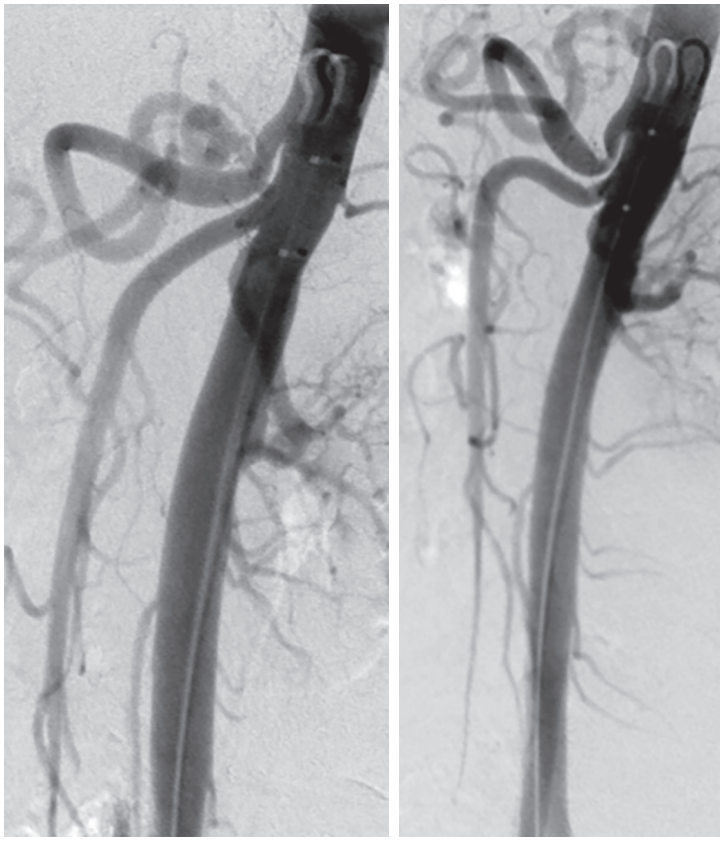


FIGURE 129-11. Celiac artery compression syndrome is caused by a low-lying median arcuate ligament, which results in compression of the celiac artery. This phenomenon is accentuated during expiration. (Courtesy Himanshu Shah, MD.)

CELIAC ARTERY COMPRESSION SYNDROME

Celiac artery compression syndrome, also known as median arcuate ligament syndrome, is a rare and poorly understood pseudo-ischemic syndrome. Most patients are young and otherwise healthy. Postprandial upper abdominal pain and diarrhea may be caused by extrinsic compression of the celiac axis by the median arcuate ligament of the diaphragm or by pressure on the celiac ganglion itself. Sitophobia can result in considerable weight loss, and some patients have an epigastric bruit that intensifies with expiration. Visceral angiography supports the diagnosis (Fig. 129-11), although asymptomatic patients also can have a localized bruit and even celiac axis compression on angiography. Surgical therapy is an option if patients have otherwise unexplained symptoms that are consistent with the syndrome.

SUPERIOR MESENTERIC ARTERY SYNDROME

Superior mesenteric artery syndrome refers to impingement of the duodenum by the superior mesenteric artery owing to narrowing of the angle between the superior mesenteric artery and aorta. The resulting mechanical obstruction can cause rapid weight loss because gastric outlet obstruction results in abdominal pain and postprandial vomiting. Imaging typically shows evidence of obstruction in the third portion of the duodenum, with a cutoff and proximal dilation. Treatment of the underlying condition (adequate nutrition and weight gain) can be curative, but surgery is sometimes needed.

HEMANGIOMAS

Hemangiomas are uncommon, usually benign vascular tumors that can be found throughout the gastrointestinal tract, often in the rectum or colon. They may be single or multiple and can be classified as cavernous, capillary, or mixed. Cavernous rectal hemangiomas tend to be large and bleed profusely, but colonic hemangiomas may cause slow, occult bleeding. Small hemangiomas can be treated endoscopically, but large or multiple lesions may require

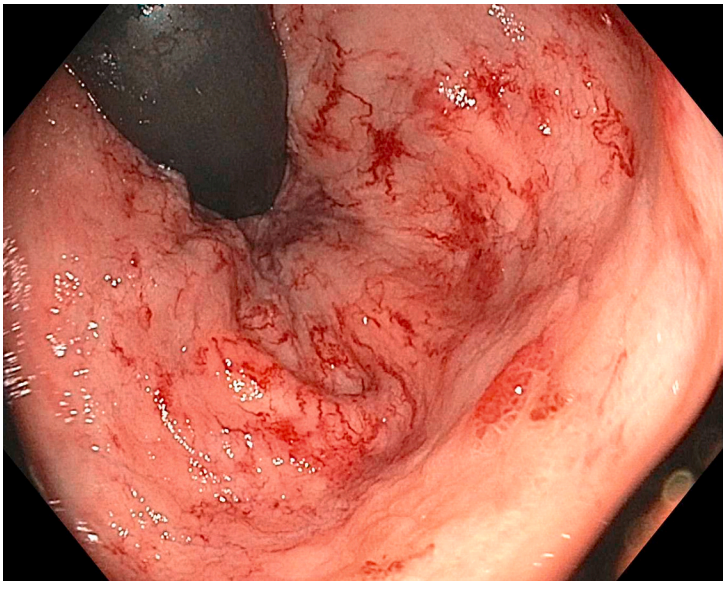

FIGURE 129-12. Radiation proctopathy. Retroflexed view of the rectum showing multiple large and serpiginous vascular ectasias in a patient with hematochezia and history of radiation for prostate cancer.

surgical resection. Rare vascular malignant neoplasms of the gastrointestinal tract include *angiosarcomas* and *hemangioendotheliomas*.

RADIATION PROCTOPATHY

A common radiation-mediated injury to the gastrointestinal tract is radiation proctopathy (Chapter 128), typically in patients treated for prostate cancer. Patients with acute radiation proctopathy (within 6 weeks of therapy) can present with tenesmus and diarrhea, whereas those with chronic radiation proctopathy (onset 6 to 24 months after therapy) can have significant hematochezia owing to radiation-associated vascular ectasias. Endoscopy reveals mucosal fibrosis and a proliferation of vascular ectasias, which are the source of bleeding (Fig. 129-12). Argon plasma coagulation is usually an effective treatment for bleeding.

HEPATIC AND SPLENIC VASCULAR DISEASE

Abnormalities of the hepatic and splenic arteries and veins affect fewer than 1 person per 2000.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome can be the result of any process that interferes with the normal outflow of blood through the hepatic vein, such as constrictive pericarditis (Chapter 62) and veno-occlusive disease (Chapter 136). The most common cause is thrombosis of one, two, or all three of the major hepatic veins, with or without extension of thrombus and even occlusion into the inferior vena cava.[21] More than 50% of cases of Budd-Chiari syndrome are related to a hypercoagulable state (Chapter 67), such as a factor V (Leiden) gene mutation, antiphospholipid antibody syndrome, protein C deficiency, protein S deficiency, antithrombin III deficiency, a chronic myeloproliferative disorder (e.g., polycythemia vera [Chapter 152], essential thrombocythemia [Chapter 152], myeloid metaplasia [Chapter 152]), paroxysmal nocturnal hemoglobinuria, or other hypercoagulable state conditions (Chapter 67). Other causes include malignancies (direct compression or invasion of hepatic veins), infections (liver abscess), pregnancy, inflammatory disorders (e.g., sarcoidosis, inflammatory bowel disease, connective tissue disease), membranous obstruction (webs) of the inferior vena cava, or spontaneous thrombosis, owing to a hypercoagulable state (Chapter 67).

CLINICAL MANIFESTATIONS

Budd-Chiari syndrome usually progresses insidiously over weeks to months as patients develop hepatomegaly, upper abdominal pain, and ascites. Rare patients may present acutely with encephalopathy, jaundice, ascites, and liver failure.

DIAGNOSIS

Most patients have only mild to moderate nonspecific elevations in serum aspartate and alanine aminotransferase levels. *JAK2* mutation analysis may detect a chronic myeloproliferative disorder. Screening for factor V (Leiden); antiphospholipid antibodies; and deficiencies in protein C, protein S, and antithrombin III is appropriate if the cause is not clear. Doppler ultrasound of the liver is the initial diagnostic test of choice[22]; contrast CT scanning or MR angiography can detect the absence of hepatic venous flow or venous thrombosis (or both). The diagnosis can be confirmed by hepatic venography (see Fig. 129-7), which also can guide therapy.

TREATMENT

Therapy includes diagnosis and treatment of underlying conditions, anticoagulation (intravenous heparin; see Table 68-6 in Chapter 68) to prevent the propagation of thrombi, and treatment of the ascites (e.g., diuretics; Chapter 139). Most patients require interventional radiologic procedures, such as angioplasty, stenting, or transjugular intrahepatic portosystemic shunts, to restore hepatic venous flow.[23] If endovascular procedures are not successful, a surgical shunt can drain the portal and/or mesenteric veins into the inferior vena cava. Liver transplantation (Chapter 140) should be considered for fulminant liver failure or cirrhosis, or both. Most patients require lifelong anticoagulation with warfarin or a newer oral anticoagulant (Chapter 70), even after liver transplantation.

PROGNOSIS

The 5-year survival rate is more than 80%, but about 50% of patients will have a major bleed, often related to invasive therapy.

PORTAL VEIN THROMBOSIS

The most common causes of acute portal vein thrombosis are cirrhosis, hypercoagulable states, intra-abdominal malignancy, inflammatory disorders (e.g., pancreatitis, Crohn disease), and medical procedures (e.g., splenectomy, cholecystectomy, gastrectomy, liver transplantation, transjugular intrahepatic portosystemic shunt). As with Budd-Chiari syndrome, many patients have a *JAK2* mutation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations include portal hypertension with variceal bleeding and ascites (Chapter 139).[24] Abdominal pain may indicate intestinal ischemia as the thrombus extends into the superior mesenteric vein. Fever, chills, and liver tenderness suggest pylephlebitis, which can result in systemic sepsis. The diagnosis is usually established by Doppler ultrasound or by CT or MR angiography.

TREATMENT

Anticoagulation with warfarin (Tables 70-2 and 70-4) to an international normalized ratio (INR) of 2 to 3 or enoxaparin (1 mg/kg subcutaneously twice a day) is recommended for at least 3 months and should be continued chronically in patients who have persistent risk factors for thrombosis or whose thrombus extends into the mesenteric veins.[25] Pylephlebitis usually requires intravenous parenteral antibiotics (e.g., piperacillin/tazobactam, ticarcillin/clavulanate, carbapenem, or a third-generation cephalosporin plus metronidazole; see Chapter 266). Parenteral antibiotics are typically given for about 2 weeks, and total treatment duration is at least 6 weeks, with the choice of antibiotics guided by blood culture results.

In patients who have cirrhosis complicated by acute or chronic portal vein thrombosis, endoscopy is recommended to diagnose and treat esophageal varices (Chapter 120).

Patients with *chronic* portal vein thrombosis can be asymptomatic but often have portal hypertension and hypersplenism. A biliary cholangiopathy may cause jaundice that requires biliary stenting. After varices are treated, noncirrhotic patients benefit from rivaroxaban (15 mg daily) if they do not have major risk factors for thrombosis[A1] and may benefit from chronic warfarin anticoagulation (Chapter 68) if they have ongoing risk factors for thrombosis. Transjugular intrahepatic portosystemic shunting is more effective than endoscopic band ligation plus propranolol to prevent future variceal bleeding in such patients (Chapter 139).[A2]

PROGNOSIS

Mortality rates in treated patients are less than 10%.

SPLENIC VEIN THROMBOSIS

Splenic vein thrombosis is usually caused by a tumor (e.g., pancreatic cancer), pancreatitis, or trauma. Isolated gastric varices and splenomegaly often develop. Liver function and portal pressure are normal. Doppler ultrasound, MR, and

CT can help make the diagnosis. In symptomatic patients, splenectomy is the treatment of choice.

HEPATIC AND SPLENIC ARTERIAL DISEASE

Nonocclusive hepatic arterial disease (*ischemic hepatitis*) develops if the arterial blood supply to the liver is inadequate, usually as a result of severe or sustained shock (Chapter 92), hypotension, volume depletion, or sepsis. Aminotransferase levels typically rise acutely to greater than 1000 U/L and return to their baseline by about 40 to 60% per day after restoration of adequate hepatic arterial blood.

Hepatic artery thrombosis is extremely rare except after liver transplantation (Chapter 140), where it can present with abnormal liver function tests, bile duct injury (e.g., biliary stricture, cholangitis, liver abscess), or liver failure. Doppler ultrasound and angiography will confirm the diagnosis. Patients often require biliary stenting with drainage of any abscesses, followed by surgical reconstruction of the hepatic artery or repeat liver transplantation.

Splenic or hepatic artery aneurysms are usually caused by atherosclerosis, vasculitis, trauma, portal hypertension, pancreatitis, infection, or pregnancy. Clinical manifestations can include abdominal pain and intra-abdominal hemorrhage. Hepatic artery aneurysms can cause hemobilia. The diagnosis is established by angiography. Symptomatic aneurysms (generally 1 cm or larger in the hepatic artery and 2 cm or larger in the splenic artery) require surgery. When a splenic artery aneurysm is discovered during pregnancy, the high likelihood of bleeding is an indication for treatment, usually by interventional radiology.

Fistulas from the hepatic artery to the portal vein are rarely seen in hereditary hemorrhagic telangiectasia or as a result of trauma or malignancy. The resultant portal hypertension may cause abdominal pain, ascites, and gastrointestinal bleeding. Involvement of the hepatic artery may lead to biliary strictures and hepatobiliary infection. Radiographic embolization, surgery, or liver transplantation may be required.

MISCELLANEOUS VASCULAR DISORDERS

Blue rubber bleb nevus syndrome is characterized by purple-blue cutaneous venous malformations, which can affect the gastrointestinal tract, most commonly the small intestine. Gastrointestinal bleeding may occur, but endoscopic therapy is usually contraindicated because the lesions can involve the full thickness of the bowel. Surgical resection is usually needed.

In *Klippel-Trenaunay* syndrome, port-wine-colored cutaneous hemangiomas, hemihypertrophy, and varicose veins are seen. The *Parkes Weber* form includes arteriovenous fistulas; gastrointestinal involvement is uncommon.

In *Ehlers-Danlos syndrome type IV* (Chapter 239), small bowel ischemia and perforation as well as arterial rupture may develop. Patients with *pseudoxanthoma elasticum type I* (Chapter 239) are at risk for gastrointestinal or intraperitoneal hemorrhage, as are patients with *visceral arterial aneurysms* that result from atherosclerosis, fibrodysplasia, vasculitis, trauma, portal hypertension, pancreatitis, or pregnancy.

Thromboangiitis obliterans (Berger disease; Chapter 66) typically affects young men who smoke cigarettes. Mesenteric involvement is uncommon and usually manifested by distal occlusions of the mesenteric circulation.

Malignant atrophic papulosis (Degos disease) is a rare occlusive vascular disease affecting mainly the skin and intestine. Spontaneous perforation may occur owing to ischemia, and the disease has a poor prognosis.

PANCREATITIS

CHRIS E. FORSMARK

ACUTE PANCREATITIS

DEFINITION

Acute pancreatitis is a discrete episode of cellular injury and inflammation in the pancreas, usually with symptoms of abdominal pain, nausea, and vomiting. It is accompanied by elevations in serum levels of amylase or lipase and/or radiographic evidence of pancreatic inflammation, edema, or necrosis. Although the pancreas can recover normal function and appearance after an episode, recovery may not be complete, especially if the necrosis is substantial. In patients with recurrent episodes, there can be a shift from acute inflammation, necrosis, and apoptosis to chronic inflammation and fibrosis that are characteristic of chronic pancreatitis. Acute and chronic pancreatitis are on a continuum, and it may be difficult to differentiate acute relapsing pancreatitis from evolving chronic pancreatitis.

EPIDEMIOLOGY

The incidence of acute pancreatitis in the United States is around 40 cases per 100,000 population, with about 300,000 hospital admissions annually, thereby making acute pancreatitis one of the most common gastrointestinal discharge diagnoses in U.S. hospitals. The cost of caring for these patients is about $4 to $6 billion annually. The incidence of acute pancreatitis is increasing in the United States and many other countries,[1] owing to more frequent use of diagnostic tests and to an increasing prevalence of gallstones and other risk factors in the setting of the obesity epidemic.

PATHOBIOLOGY

Acute pancreatitis is caused by premature activation of digestive enzymes within pancreatic acinar cells. Increased intracellular calcium and the activation of trypsinogen to trypsin appear to be the critical initial steps, with trypsin then activating other proteases within the gland.[2] These activated enzymes produce cell injury and necrosis. Necrosis can involve the pancreas as well as surrounding fat and structures, thereby leading to fluid extravasation into the surrounding retroperitoneal spaces ("third space" losses). Necrosis sufficient to be visible on a contrast-enhanced computed tomographic (CT) scan is termed acute necrotizing pancreatitis and distinguished from the milder interstitial pancreatitis, in which necrosis is not visible on a CT scan. In addition to the pancreatic damage, the release of pro-inflammatory cytokines and activated digestive enzymes into the systemic circulation can produce a systemic inflammatory response syndrome and organ system failure, including hypotension, renal failure, and acute respiratory distress syndrome (Chapter 90). Gallstones (Chapter 141) and alcohol (Chapter 364) together account for around two thirds of all cases of acute pancreatitis, but causes vary by age and sex, and the cause is unknown in a significant proportion of cases (Table 130-1).

Gallstones (Chapter 141)

Passage of a gallstone through the ampulla of Vater with transient obstruction of the pancreatic duct is the initiating event for gallstone pancreatitis. Only about 5% of all patients with gallstones develop pancreatitis, and patients with smaller gallstones (≤5 mm), which can pass the cystic duct and reach the ampulla, are at highest risk. Microlithiasis, defined as tiny gallstones and/or biliary sludge that are not easily visible on routine imaging, is often the cause in patients initially labeled as having acute idiopathic pancreatitis.

Alcohol (Chapter 364)

More than 5 years of alcohol intake averaging more than 5 to 8 drinks daily is usually required before pancreatitis develops, but most people with this level of intake do not develop pancreatitis.[3] A variety of cofactors have been proposed, including a high-fat diet, genetic variability in detoxifying enzymes, coexistent genetic mutations, and cigarette smoking. The evidence is strongest for smoking. By the time patients have a first clinical episode of acute alcoholic pancreatitis, most already have evidence of underlying chronic pancreatitis.

CT can help make the diagnosis. In symptomatic patients, splenectomy is the treatment of choice.

HEPATIC AND SPLENIC ARTERIAL DISEASE

Nonocclusive hepatic arterial disease (*ischemic hepatitis*) develops if the arterial blood supply to the liver is inadequate, usually as a result of severe or sustained shock (Chapter 92), hypotension, volume depletion, or sepsis. Aminotransferase levels typically rise acutely to greater than 1000 U/L and return to their baseline by about 40 to 60% per day after restoration of adequate hepatic arterial blood.

Hepatic artery thrombosis is extremely rare except after liver transplantation (Chapter 140), where it can present with abnormal liver function tests, bile duct injury (e.g., biliary stricture, cholangitis, liver abscess), or liver failure. Doppler ultrasound and angiography will confirm the diagnosis. Patients often require biliary stenting with drainage of any abscesses, followed by surgical reconstruction of the hepatic artery or repeat liver transplantation.

Splenic or hepatic artery aneurysms are usually caused by atherosclerosis, vasculitis, trauma, portal hypertension, pancreatitis, infection, or pregnancy. Clinical manifestations can include abdominal pain and intra-abdominal hemorrhage. Hepatic artery aneurysms can cause hemobilia. The diagnosis is established by angiography. Symptomatic aneurysms (generally 1 cm or larger in the hepatic artery and 2 cm or larger in the splenic artery) require surgery. When a splenic artery aneurysm is discovered during pregnancy, the high likelihood of bleeding is an indication for treatment, usually by interventional radiology.

Fistulas from the hepatic artery to the portal vein are rarely seen in hereditary hemorrhagic telangiectasia or as a result of trauma or malignancy. The resultant portal hypertension may cause abdominal pain, ascites, and gastrointestinal bleeding. Involvement of the hepatic artery may lead to biliary strictures and hepatobiliary infection. Radiographic embolization, surgery, or liver transplantation may be required.

MISCELLANEOUS VASCULAR DISORDERS

Blue rubber bleb nevus syndrome is characterized by purple-blue cutaneous venous malformations, which can affect the gastrointestinal tract, most commonly the small intestine. Gastrointestinal bleeding may occur, but endoscopic therapy is usually contraindicated because the lesions can involve the full thickness of the bowel. Surgical resection is usually needed.

In *Klippel-Trenaunay* syndrome, port-wine-colored cutaneous hemangiomas, hemihypertrophy, and varicose veins are seen. The *Parkes Weber* form includes arteriovenous fistulas; gastrointestinal involvement is uncommon.

In *Ehlers-Danlos syndrome type IV* (Chapter 239), small bowel ischemia and perforation as well as arterial rupture may develop. Patients with *pseudoxanthoma elasticum type I* (Chapter 239) are at risk for gastrointestinal or intraperitoneal hemorrhage, as are patients with *visceral arterial aneurysms* that result from atherosclerosis, fibrodysplasia, vasculitis, trauma, portal hypertension, pancreatitis, or pregnancy.

Thromboangiitis obliterans (Berger disease; Chapter 66) typically affects young men who smoke cigarettes. Mesenteric involvement is uncommon and usually manifested by distal occlusions of the mesenteric circulation.

Malignant atrophic papulosis (Degos disease) is a rare occlusive vascular disease affecting mainly the skin and intestine. Spontaneous perforation may occur owing to ischemia, and the disease has a poor prognosis.

PANCREATITIS

CHRIS E. FORSMARK

ACUTE PANCREATITIS

DEFINITION

Acute pancreatitis is a discrete episode of cellular injury and inflammation in the pancreas, usually with symptoms of abdominal pain, nausea, and vomiting. It is accompanied by elevations in serum levels of amylase or lipase and/or radiographic evidence of pancreatic inflammation, edema, or necrosis. Although the pancreas can recover normal function and appearance after an episode, recovery may not be complete, especially if the necrosis is substantial. In patients with recurrent episodes, there can be a shift from acute inflammation, necrosis, and apoptosis to chronic inflammation and fibrosis that are characteristic of chronic pancreatitis. Acute and chronic pancreatitis are on a continuum, and it may be difficult to differentiate acute relapsing pancreatitis from evolving chronic pancreatitis.

EPIDEMIOLOGY

The incidence of acute pancreatitis in the United States is around 40 cases per 100,000 population, with about 300,000 hospital admissions annually, thereby making acute pancreatitis one of the most common gastrointestinal discharge diagnoses in U.S. hospitals. The cost of caring for these patients is about $4 to $6 billion annually. The incidence of acute pancreatitis is increasing in the United States and many other countries,[1] owing to more frequent use of diagnostic tests and to an increasing prevalence of gallstones and other risk factors in the setting of the obesity epidemic.

PATHOBIOLOGY

Acute pancreatitis is caused by premature activation of digestive enzymes within pancreatic acinar cells. Increased intracellular calcium and the activation of trypsinogen to trypsin appear to be the critical initial steps, with trypsin then activating other proteases within the gland.[2] These activated enzymes produce cell injury and necrosis. Necrosis can involve the pancreas as well as surrounding fat and structures, thereby leading to fluid extravasation into the surrounding retroperitoneal spaces ("third space" losses). Necrosis sufficient to be visible on a contrast-enhanced computed tomographic (CT) scan is termed acute necrotizing pancreatitis and distinguished from the milder interstitial pancreatitis, in which necrosis is not visible on a CT scan. In addition to the pancreatic damage, the release of pro-inflammatory cytokines and activated digestive enzymes into the systemic circulation can produce a systemic inflammatory response syndrome and organ system failure, including hypotension, renal failure, and acute respiratory distress syndrome (Chapter 90). Gallstones (Chapter 141) and alcohol (Chapter 364) together account for around two thirds of all cases of acute pancreatitis, but causes vary by age and sex, and the cause is unknown in a significant proportion of cases (Table 130-1).

Gallstones (Chapter 141)

Passage of a gallstone through the ampulla of Vater with transient obstruction of the pancreatic duct is the initiating event for gallstone pancreatitis. Only about 5% of all patients with gallstones develop pancreatitis, and patients with smaller gallstones (≤5 mm), which can pass the cystic duct and reach the ampulla, are at highest risk. Microlithiasis, defined as tiny gallstones and/or biliary sludge that are not easily visible on routine imaging, is often the cause in patients initially labeled as having acute idiopathic pancreatitis.

Alcohol (Chapter 364)

More than 5 years of alcohol intake averaging more than 5 to 8 drinks daily is usually required before pancreatitis develops, but most people with this level of intake do not develop pancreatitis.[3] A variety of cofactors have been proposed, including a high-fat diet, genetic variability in detoxifying enzymes, coexistent genetic mutations, and cigarette smoking. The evidence is strongest for smoking. By the time patients have a first clinical episode of acute alcoholic pancreatitis, most already have evidence of underlying chronic pancreatitis.

ABSTRACT

Acute pancreatitis, which is most often caused by gallstones and alcohol, can cause systemic organ failure, pancreatic necrosis, and death. However, complications can be reduced and recurrence can be prevented by urgent diagnosis, an accurate identification of the cause, and effective management. Chronic pancreatitis, which has numerous genetic and environmental risk factors, can be difficult to diagnose early in its clinical course. Management includes identification of complications, assessment of residual pancreatic function, and treatment of pain, exocrine insufficiency, and endocrine insufficiency.

endocrine insufficiency

TABLE 130-1 CAUSES OF ACUTE PANCREATITIS

ETIOLOGY	EXAMPLES
Gallstones	Gallstones (Chapter 141) Microlithiasis
Drugs and toxins	Ethyl and methyl alcohol (Chapters 364 and 96) Tobacco (Chapter 363) Azathioprine, 6-mercaptopurine, pentamidine, didanosine, sulfonamides, thiazides, aminosalicylates, valproic acid, and others Scorpion venom (Chapter 98) Organophosphate insecticides (Chapter 96)
Metabolic	Hypertriglyeridemia (Chapter 190) Hypercalcemia (Chapter 227)
Trauma	Post-ERCP (Chapter 120) Blunt or penetrating trauma Postoperative
Obstruction of the pancreatic duct	Benign pancreatic duct stricture Benign ampullary stricture (e.g., celiac disease, Crohn disease, diverticulum) Ampullary adenoma or adenocarcinoma (Chapter 181) Pancreatic ductal adenocarcinoma (Chapter 180) Intraductal papillary mucinous neoplasm (Chapter 180)
Infections	Cytomegalovirus (Chapter 347), mumps (Chapter 340), rubella (Chapter 339), Coxsackie B (Chapter 349), *Candida* (Chapter 310), histoplasmosis (Chapter 308), *Ascaris* (Chapter 327)
Genetics	*PRSS1* mutations *CFTR* mutation *SPINK1* mutation Other mutations
Autoimmune pancreatitis	Type 1 Type 2
Idiopathic pancreatitis	

ERCP = endoscopic retrograde cholangiopancreatography.

The peak of alcoholic pancreatitis is in ages of 20 to 50, and it is more common in men. The mechanism of alcoholic pancreatic injury involves a mixture of direct toxicity, oxidative stress, and alterations in pancreatic enzyme secretion.

Drugs, Toxins, and Metabolic Factors

Drug-induced pancreatitis is a rare and generally idiosyncratic event. Although many drugs have been implicated, the evidence is most compelling for 6-mercaptopurine and azathioprine (up to a 4% attack rate), as well as for valproic acid (the leading cause in an analysis of over 1000 cases of drug-induced acute pancreatitis).[4] Other agents include L-asparaginase, didanosine, pentamidine, valproic acid, furosemide, mesalamine, ciprofloxacin, prednisone, olanzapine, sulfonamides, and aminosalicylates. Toxins that may cause acute pancreatitis include methyl alcohol, organophosphate insecticides, and venom from certain scorpions.

Levels of serum triglycerides above 500 mg/dL, and usually greater than 1000 mg/dL, can cause acute pancreatitis, but the mechanism is not known.[5] The risk appears to be higher in overweight persons.[6] Hypercalcemia is an exceedingly rare cause of acute pancreatitis.

Trauma

Iatrogenic trauma to the pancreas and pancreatic duct during performance of an endoscopic retrograde cholangiopancreatography (ERCP; Chapter 120) can cause pancreatitis, with the risk averaging less than 5% for patients with simple common bile duct stones or malignancy but up to 20% in some high-risk subgroups.

Penetrating and blunt trauma, ranging from a contusion to severe crush injury and even transection of the gland, can cause pancreatitis. Acute presentation is the rule, but some patients with milder injury may present in a subacute or chronic fashion. Ischemic injury to the gland can occur after surgical procedures, especially cardiopulmonary bypass, and cause severe pancreatitis.

Obstruction of the Pancreatic Duct

Obstruction of the pancreatic duct by a pancreatic ductal adenocarcinoma (Chapter 180), an ampullary adenoma or carcinoma, or an intraductal papillary mucinous neoplasm can cause acute pancreatitis. The diagnosis of pancreatic duct obstruction is usually established with magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) or with endoscopic ultrasound. Benign strictures of the pancreatic duct at the ampulla of Vater may be caused by celiac disease (Chapter 126), duodenal Crohn disease (Chapter 127), and periampullary diverticulum. Current evidence does not support the role of sphincter of Oddi dysfunction as a cause of acute pancreatitis. Studies of pancreas divisum as a potential cause of acute pancreatitis are ongoing.

Infections

Ascaris lumbricoides (Chapter 327) may cause pancreatitis by obstructing the pancreatic duct as the worms migrate through the ampulla of Vater. Viruses that may infect the pancreatic acinar cells directly and may cause pancreatitis include cytomegalovirus (Chapter 347), Coxsackie B virus (Chapter 349), adenovirus (Chapter 349), and mumps virus (Chapter 340).

Autoimmune Pancreatitis

Two forms of autoimmune pancreatitis have been identified.[7] The most common presentation is obstructive jaundice that mimics pancreatic adenocarcinoma or chronic pancreatitis. These are discussed under "Chronic Pancreatitis."

Genetics

Mutations in the cationic trypsinogen gene *(PRSS1)*, which have been identified in families with hereditary pancreatitis, are more commonly seen in association with chronic pancreatitis but can present early in the course as acute pancreatitis. Many additional mutations and polymorphisms are associated with both acute and chronic pancreatitis. These affected genes include the cystic fibrosis conductance regulator *(CFTR)*, serine protease inhibitor kazal type 1 *(SPINK1)*, chymotrypsin C, calcium-sensing receptor, carboxy ethyl lipase, claudins, and others.

CLINICAL MANIFESTATIONS

Abdominal pain, nausea, and vomiting are the hallmark symptoms of acute pancreatitis. The abdominal pain is usually in the epigastric region and often radiates to the back. The pain is steady, reaches its maximum intensity over 30 to 60 minutes, and persists for days. These characteristic symptoms may be masked in patients who present with delirium, multiple organ system failure, or coma.

The physical examination usually reveals tachycardia. Hypotension, tachypnea, dyspnea, and low-grade fever are observed in more severe cases. Confusion, delirium, and, rarely, even coma may be present. The abdomen is often distended with diminished bowel sounds. Tenderness to palpation of the abdomen, which may be epigastric or more diffuse, is typical, whereas rebound and guarding are unusual. Dullness to percussion in the lower lung fields may be noted owing to pleural effusion. Rare physical findings include ecchymoses of the flank (Grey-Turner sign) or umbilicus (Cullen sign), which occur when fluid and blood track into these spaces from the retroperitoneum. Jaundice may be present if there is biliary obstruction by a stone. The presence of systemic inflammatory response syndrome (Chapter 94) is predictive of more severe pancreatitis. Tachycardia, dyspnea, tachypnea, orthostatic hypotension, pleural effusion, oxygen desaturation, or shock signals more substantial third-space losses, a higher likelihood of a variety of complications, and a worse prognosis. More severe pancreatitis is characterized by more substantial pancreatic and peripancreatic necrosis, more peripancreatic fluid collections, and more dysfunction of extrapancreatic organs.

DIAGNOSIS

The diagnosis of acute pancreatitis is suggested by clinical features and confirmed by laboratory and imaging studies that exclude other serious intra-abdominal conditions and help define the severity and most likely cause of the pancreatitis.[8]

The diagnosis of acute pancreatitis requires at least two of the following three criteria: abdominal pain consistent with pancreatitis, serum amylase or lipase of at least three times the upper limit of normal, or imaging findings consistent with acute pancreatitis on imaging (contrast CT, MRI, or ultrasound). Patients with mild pancreatitis have no local (pancreatic fluid collection or necrosis) or systemic complications (organ failure complications), patients with moderate pancreatitis have local complications and/or transient organ system failure that persists for less than 48 hours, and patients with severe pancreatitis have organ failure that persists for more than 48 hours.

Laboratory Tests

Amylase and Lipase

Most patients with acute pancreatitis have elevations in serum levels of amylase or lipase within a few hours of the onset of symptoms. Lipase is generally preferred over amylase as a diagnostic test because of its superior specificity. Although elevation to more than three times the upper limit of normal is the recommended cutoff for diagnosing acute pancreatitis, up to 25% of cases may not reach this threshold. Lipase levels tend to remain elevated longer than amylase levels, but both decline gradually over several days. Elevations more than three times the upper limit of normal are most specific for acute pancreatitis. Amylase and lipase levels may be normal in patients with acute pancreatitis, particularly if the measurement is delayed for several days after the onset of symptoms, and marked hypertriglyceridemia can interfere with their accurate measurement. Both enzymes are cleared by the kidney, and renal failure can falsely raise the level of these enzymes up to five times the upper limit of normal in the absence of pancreatitis.

Amylase and lipase levels also can be elevated in a variety of other conditions that may mimic acute pancreatitis, including intestinal ischemia and infarction (Chapter 129), bowel obstruction (Chapter 128), cholecystitis (Chapter 141), and choledocholithiasis (Chapter 141). In addition, amylase levels may be elevated from ectopic pregnancy, acute salpingitis, and a variety of extra-abdominal conditions such as parotitis (Chapter 340), lung cancer (Chapter 177), and head trauma (Chapter 368).

In some patients, only the amylase level or the lipase level may be elevated. Serial measurements of amylase or lipase in patients with established acute pancreatitis are not useful in clinical decision making. In patients with recurrent attacks of pancreatitis, the peak level of amylase or lipase tends to diminish progressively.

Other Laboratory Tests

In severe pancreatitis, leukocytosis, azotemia, and hemoconcentration may be seen. Failure of the blood urea nitrogen (BUN) level or hematocrit to normalize with fluid resuscitation is associated with more substantial third-space losses and a worse prognosis. Hyperglycemia, hypocalcemia, and mild hypertriglyceridemia also can develop. Elevations in alanine aminotransferase levels more than three times the upper limit of normal are most suggestive of gallstones, although any significant elevation in liver chemistries should raise the possibility of gallstone pancreatitis (Chapter 141).

Determining Etiology

To identify the cause of acute pancreatitis, the history should focus on alcohol and tobacco use, previous biliary colic, drug history, family history, and recent trauma. Because gallstones are the leading cause of acute pancreatitis, accounting for about 40% of cases, all patients should have an abdominal ultrasound examination to look for gallstones. Gallstone pancreatitis should be suspected if stones or a dilated bile duct is seen on imaging studies or if abnormal liver chemistries are present.

A careful history, often with corroboration from family members, will help diagnose alcoholic pancreatitis, which accounts for about 20% of cases, as well as medication- or toxin-induced pancreatitis and traumatic pancreatitis. Serum chemistries will help identify unusual cases caused by severe (>1000 mg/dL) hypertriglyceridemia.

If these initial approaches are unrevealing, MRI with MRCP or endoscopic ultrasound (EUS) can detect small gallstones, microlithiasis, or underlying premalignant or malignant causes (particularly in patients over age 40 years).[9] More specialized investigations, such as genetic testing, are usually reserved for patients who have had multiple attacks of unexplained pancreatitis.

Of the 25% of patients who do not have an identified cause after a basic initial evaluation, microlithiasis is the most common underlying explanation. With additional evaluation and testing, only about 10% of patients are ultimately labeled as having truly idiopathic pancreatitis. Idiopathic pancreatitis is more common in women, and especially elderly women, than in men.

Imaging Studies

Imaging studies are used not only in establishing the diagnosis but also in determining the cause and prognosis. In most patients, both ultrasound and CT are used in a complementary fashion.

Abdominal ultrasonography can confirm the presence of acute pancreatitis by documenting pancreatic enlargement, edema, or associated peripancreatic fluid collections. Visualization of the pancreas may be limited owing to body habitus or overlying intestinal gas. In patients with gallstone pancreatitis, ultrasonography is more accurate than CT in identifying gallstones in the gallbladder or a dilated common bile duct.

CT is more accurate than ultrasonography in confirming the diagnosis of acute pancreatitis and in documenting the presence of pancreatic necrosis and peripancreatic fluid collections. CT is also particularly helpful in excluding intra-abdominal conditions that can mimic acute pancreatitis. Pancreatic parenchyma that opacifies on CT with intravenous contrast is still viable, whereas parenchyma that does not enhance is necrotic (Fig. 130-1). The extent of pancreatic necrosis has prognostic importance but is generally not clearly visible on CT until at least 3 days after presentation. CT scans are not routinely required in all patients with acute pancreatitis but should be performed when the diagnosis is not clear and in patients who have a first attack, severe disease, systemic complications, or disease that is slow to improve.

MRI is equivalent to CT in its ability to document acute pancreatitis, identify necrosis, and diagnose or exclude other diseases that could mimic acute pancreatitis. In addition, MRCP is much better than CT for identifying gallstones. In critically ill patients, MRI is more difficult than CT to perform.

ERCP and endoscopic ultrasonography are important in both diagnosis and therapy of acute pancreatitis. Endoscopic ultrasonography, which is primarily used to establish the cause when the initial evaluation is unrevealing, is particularly accurate in identifying underlying malignancy, premalignant lesions such as ampullary adenoma, and small gallstones or microlithiasis. ERCP is not used for diagnosis, but it can be very useful for therapeutic purposes.

Determining Severity

Severe pancreatitis is characterized by organ system failure and by local pancreatic complications such as necrosis, fluid collections, or pseudocysts.[10] Organ failure can be single or multiple, early- or late-onset, and progressive, persistent, or transient. In severe acute pancreatitis, renal failure, pulmonary failure, and circulatory failure most commonly occur as part of the systemic inflammatory response.

During the acute attack, poorly demarcated fluid collections around the pancreas track into various retroperitoneal and peritoneal spaces. Much of this inflammatory fluid will resolve, but some will form into a more rounded and circumscribed fluid collection, called a pseudocyst (Fig. 130-2). Similarly, areas of pancreatic and peripancreatic necrosis will eventually develop a surrounding wall and begin to soften and liquefy, thereby becoming "walled-off pancreatic necrosis." For both fluid and necrosis, this process usually takes several weeks. It is important to distinguish pseudocysts from walled-off pancreatic necrosis; they appear similar on a CT scan but are easily distinguishable on MRI or endoscopic ultrasonography, because necrotic collections contain both solid and liquid material. Greater degrees or amounts of necrosis generally correlate with a higher risk of an adverse outcome, particularly if infection develops in the devitalized necrotic tissue. Although many patients with pancreatic

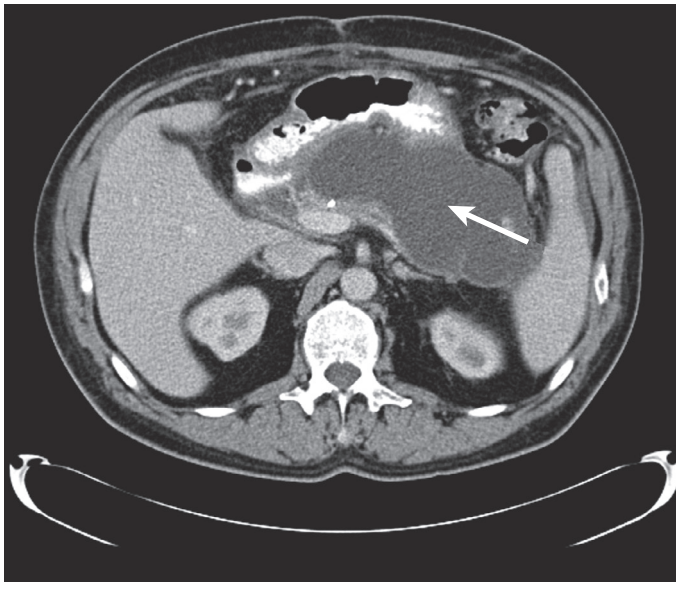

FIGURE 130-1 A computed tomographic scan demonstrating a large area of pancreas that does not enhance with intravenous contrast (*arrow*), consistent with pancreatic necrosis.

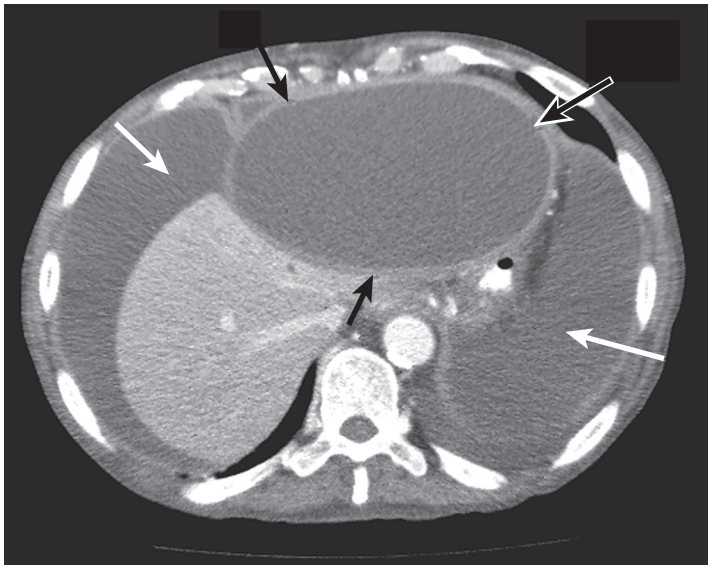

FIGURE 130-2. **A large pseudocyst is seen (*black arrows*). In addition, ascites surrounding the liver (*white arrows*) is noted due to a leak from the pseudocyst (pancreatic ascites).**

necrosis may not develop organ system failure, organ system failure is quite rare in the absence of pancreatic necrosis.

Risk Stratification

A number of clinical features identify patients at higher risk, including patients who are older, obese, or have more serious or more numerous comorbid conditions. Obesity in particular dramatically increases the risk of more severe pancreatitis. Additional clinical features that can be predictive include the presence of the systemic inflammatory response syndrome, particularly if it persists for more than 48 hours, and laboratory features consistent with intravascular volume depletion (elevated hematocrit or BUN). In addition to this qualitative estimate of prognosis, a number of multiple-factor scoring systems have been developed in an attempt to help guide clinicians in gauging prognosis, but there is no evidence that these complex multiple-factor scoring systems are superior to experienced clinical judgment.

TREATMENT

General Supportive Care

The majority of patients will recover within several days, but it is usually not possible to identify these patients at the time of admission.

All patients should initially be given nothing by mouth (NPO). Pain control often requires parenteral narcotics, and hydromorphone (in divided doses of 1 to 2 mg IV every 4 to 6 hours initially, with titration as needed) is generally preferred.

However, nonsteroidal anti-inflammatory agents (NSAIDs) may be as successful as narcotics by 24 hours.[A1] Patients with significant third-space loss, often augmented by prior poor oral intake or fluid losses through vomiting, will have evidence of intravascular fluid depletion. Even in mild pancreatitis, fluid losses may be substantial. Appropriate fluid resuscitation (Chapter 92) is recommended in all practice guidelines.[11] Moderate fluid resuscitation (1.5 mL/kg/hour of lactated Ringer solution in all patients, preceded by a 10 mL/kg bolus only if the patient is hypovolemic), with reassessments and adjustments at 12, 24, 48, and 72 hours[A2] to correct blood pressure and pulse, to reduce the hematocrit and BUN to normal, and to ensure a urine output of at least 0.5 mL/kg/hour, is preferred. More aggressive infusion of fluid worsens outcomes, primarily by increasing the risk of respiratory failure owing to fluid overload but also by increasing the risk of organ system failure, heart failure, and an abdominal compartment syndrome. To avoid these potential adverse effects, fluid therapy must be guided by whether the patient has the physiologic reserve to handle it.

Treatment of nausea and vomiting may be needed, and 5-HT3 antagonists (Table 118-5) are generally preferred. Nasogastric suction is rarely needed.

Patients with mild or moderate pancreatitis can be fed when they feel able to tolerate it, even before enzyme levels are completely normalized or pain is entirely absent. Beginning oral feeding within 48 hours after hospitalization is as safe as starting later and also reduces hospital length of stay. There is no need to begin with a clear liquid diet: feeding can be initiated with a low-fat solid diet as the first meal.

TABLE 130-2 COMPLICATIONS OF ACUTE PANCREATITIS

COMPLICATION	EXAMPLES
Systemic complications	Hypotension and shock Adult respiratory distress syndrome Acute renal failure Disseminated intravascular coagulation Hypocalcemia Hypertriglyceridemia Hyperglycemia Encephalopathy and coma
Gastrointestinal bleeding	Stress ulceration Pseudoaneurysm
Local (pancreatic) complications	Acute peripancreatic fluid collection Pseudocyst (infected and sterile) Acute necrotic collection Walled-off pancreatic necrosis (infected and sterile) Duodenal and biliary obstruction

In patients with more severe pancreatitis (based upon early organ system failure, substantial third-space fluid losses, or comorbid conditions), admission to an intermediate care unit or intensive care unit (ICU) is appropriate. Careful monitoring for progressive organ system failure, metabolic complications, and fluid status is critical in these patients. In patients with severe pancreatitis, enteral nutrition (oral or tube feeding) is safer and less expensive than total parenteral nutrition, which should be utilized exceedingly rarely. Patients who appear to have sufficiently severe disease that they might not be able to eat for 5 to 7 days can be considered for tube feeding. Alternatively, waiting for up to 5 days to see if patients with severe acute pancreatitis can eat is reasonable, with tube feeding reserved for those who are unable to eat after 5 days.[12] In patients given tube feeding, there is no difference if the tube is nasogastric, nasoduodenal, or nasojejunal. In addition, there is no evidence that elemental or semi-elemental formulas are better than standard polymeric formulas.

Treatment of Complications

Most patients who develop acute gallstone pancreatitis have already passed the offending stone into the duodenum, but patients with a persistent or multiple stones are at higher risk of developing cholangitis and (possibly) more severe pancreatitis. Current practice guidelines recommend urgent ERCP in patients whose gallstone pancreatitis is complicated by evidence of cholangitis (e.g., fever, jaundice, right upper quadrant pain) and early ERCP for patients with evidence of a persistent bile duct stone (e.g., visible persistent stone on imaging study, jaundice, persistently dilated bile duct, or worsening liver chemistries at 48 hours after admission). In patients who have severe pancreatitis, as evidenced by early and progressive organ system failure but who do not have cholangitis, early ERCP is not better than conservative care.[A3]

The systemic complications (Table 130-2) that develop in patients with severe acute pancreatitis include some that are similar to those commonly encountered in other ICU patients (e.g., ventilator-associated pneumonia, line sepsis) as well as the specific metabolic complications of severe pancreatitis[13] Hyperglycemia is common and may contribute to higher rates of infections. In severe acute pancreatitis, ionized calcium levels are usually normal, but hypocalcemia is common owing to a diminished serum albumin level; treatment is not needed in the absence of signs of hypocalcemia, such as tetany or a Chvostek sign (Chapter 227). Mild hypertriglyceridemia is common, but underlying hypertriglyceridemia does not cause acute pancreatitis unless triglyceride levels surpass 1000 mg/dL. Triglyceride levels drop promptly when the patient is made NPO.

Infections in patients with acute pancreatitis include urinary tract infections, pneumonia, line infections, and *Clostridioides difficile*. High-quality nursing care, antibiotic stewardship, and careful attention to catheters and lines can minimize these infections. In addition, patients with necrotizing pancreatitis may develop infected pancreatic necrosis. Although infected necrosis has a substantial impact on prognosis, prophylactic antibiotics are not beneficial for patients with sterile necrosis. Infected necrosis typically occurs 2 to 3 weeks into the illness and is heralded by fever, leukocytosis, and worsening abdominal pain. The responsible organisms are usually gram-negative rods and other gut flora, but *Staphylococcus aureus* is an important agent as well. If infected necrosis is suspected, a contrast CT scan should be obtained. The finding of gas in the necrotic collection is a specific but not sensitive sign of infected necrosis. A CT-directed fine-needle aspiration of the necrotic area can be obtained for culture and Gram stain but is not required in patients in whom clinical features, such as fever, leukocytosis, and worsening abdominal pain, are strongly suggestive of infected pancreatic necrosis. Antibiotics with deferred surgery if needed is as good as immediate surgical drainage for infected necrotizing pancreatitis.[A4] Antibiotics with appropriate penetration into necrosis (e.g., imepenem/cilastatin 500 mg IV/q 8 hours, meropenem 500 mg IV/q 8 hours, metronidazole 500 mg

IV/q 8 hours plus ciprofloxacin 400 mg IV/q 8 hours, or ceftazidime 500 mg IV/q 8 hours; see Table 266-4 in Chapter 266) should be initiated if infection is suspected or documented, and the specific regimen can be tailored to the organism if known. Intravenous antibiotics should be continued for several weeks to allow the necrotic material to demarcate fully, begin to liquefy, and become encapsulated. If patients become septic, it is reasonable to place a percutaneous drain into the collection to stabilize the patient. When this walled-off necrosis is sufficiently liquefied to allow less invasive approaches, therapy can include percutaneous, endoscopic, or minimally invasive surgical therapy.[14] Endoscopic transgastric necrosectomy is generally preferred, although minimally invasive surgical approaches are also effective.[A5-A7] Open surgical drainage should be avoided.

Fluid collections around the pancreas (acute peripancreatic fluid collections) are common in acute pancreatitis and do not require any specific therapy. Most will resolve spontaneously, but some will mature into an encapsulated pseudocyst. It is important to distinguish a pseudocyst (usually outside the confines of the pancreas and filled with fluid) from an area of necrosis (usually inside the confines of the pancreas and a mixture of solid and liquid material). Therapy also is not needed for asymptomatic pseudocysts, even if they are large, but therapy is indicated for pseudocysts that cause abdominal pain, obstruct a surrounding hollow viscus, or are associated with infection or bleeding. A pseudocyst can be treated successfully using endoscopic, percutaneous, or minimally invasive surgical techniques, and the choice among these approaches can be determined by local expertise and anatomic location.

Bleeding may complicate a pseudocyst, and bleeding into the cyst may reach the intestine through the pancreatic duct. In some patients, bleeding into the pseudocyst may be caused by a pseudoaneurysm of a nearby visceral artery; this type of bleeding may be massive. Unexplained gastrointestinal bleeding or a sudden, unexplained drop in the hematocrit in a patient with pancreatitis or a pseudocyst should prompt an emergent contrast CT scan, followed by embolization if a pseudoaneurysm is identified.

Treatment to Prevent Relapsing Pancreatitis

Preventing relapse requires a clear knowledge of the precipitating cause. Abstinence from alcohol and tobacco should be strongly encouraged, including referral to appropriate resources. Cholecystectomy prevents subsequent attacks of gallstone pancreatitis and should be accomplished within the index hospitalization.[A8] In patients with presumed "idiopathic" acute pancreatitis, an empiric cholecystectomy can be considered, provided that alternative causes have been excluded,[15] because many of these patients have gallstones as the etiology.[A9] In patients who have gallstone pancreatitis but who are not surgical candidates, endoscopic biliary sphincterotomy provides reasonable protection from subsequent attacks. Control of serum lipids prevents subsequent attacks of hypertriglceridemic pancreatitis. Therapy of lesions that obstruct the pancreatic duct, such as strictures and ampullary adenomas, may also prevent relapse.

The risk of post-ERCP pancreatitis is reduced with careful patient selection, the use of peri-procedural NSAID suppositories, by aggressive intravenous hydration, or by the placement of small-caliber temporary pancreatic duct stents.[A10]

PROGNOSIS

More than 80% of all patients with acute pancreatitis recover promptly without developing severe pancreatitis, but up to 30% may ultimately develop diabetes or exocrine pancreatic insufficiency. Mortality is usually from progressive multiple organ system failure, either from the acute pancreatitis itself or from hospital-acquired infections, including infection of pancreatic fluid collections or necrotic pancreatic tissue. Early organ failure (within 24 hours of admission), multiple organ system failure, and persistent or progressive (present beyond 48 hours after admission) organ failure are associated with prolonged hospitalization, ICU admission, need for surgery, and death. Overall mortality is about 2%, but it can approach 30% in patients with more severe comorbid conditions (and particularly obesity) and in patients who develop pancreatic necrosis, infection, or organ system failure. Although high-quality ICU care reduces mortality, no specific therapy is currently proven to reduce these risks.

For patients with acute alcoholic pancreatitis, long-term mortality is about four-fold higher than in the general population, mostly owing to alcohol-related conditions. Acute pancreatitis due to hypertriglyceridemia also has an adverse prognosis. For other causes, long-term mortality is minimally elevated compared with the general population.

CHRONIC PANCREATITIS

DEFINITION

Chronic pancreatitis is a syndrome associated with a wide spectrum of predisposing risk factors and environmental triggers. Chronic pancreatitis usually evolves after episodes of recurrent acute pancreatitis, and the transition between acute and chronic pancreatitis may be difficult to identify. Common features include abdominal pain, exocrine and/or endocrine insufficiency, and imaging evidence of pancreatic atrophy, calcification, or dilated pancreatic duct.[16] The progression of chronic pancreatitis is variable, but it often culminates in irreversible and widespread pancreatic fibrosis with chronic inflammation and damage to nerves, ducts, acini, and islets.

EPIDEMIOLOGY

The prevalence of symptomatic chronic pancreatitis in Western countries is about 40 to 70 per 100,000 persons, with an estimated incidence of 5 to 8 cases/100,000. In the United States, chronic pancreatitis accounts for about 125,000 outpatient visits and 25,000 hospitalizations annually. Interestingly, the prevalence of histologic evidence of chronic pancreatitis in autopsy studies approaches 5%, indicating that many people develop some pancreatic damage as a consequence of normal aging, other diseases (e.g., diabetes), or exposure to toxins (such as smoking or consumption of alcohol) but do not develop any symptoms or signs of chronic pancreatitis during life.

PATHOBIOLOGY

Multiple genetic polymorphisms and mutations can predispose to chronic pancreatitis, and various environmental and immunologic triggers can initiate the disease.[17] Episodes of acute inflammation, whether clinical or subclinical, eventually change the inflammatory milieu of the pancreas, with a shift to chronic inflammation, cell injury, cell death, the activation of pancreatic stellate cells, and the progression to fibrosis. This process becomes self-sustaining and produces the characteristic histologic damage.

The mechanisms of pain of chronic pancreatitis are complex. Damage to pancreatic nociceptive nerves and neuroimmune interaction driven by the chronic inflammatory state is the primary cause of pain, but the chronic pain can eventually produce visceral, spinal cord, and central hyperalgesia.

Alcohol and Tobacco

Alcohol causes about 50% of all cases of chronic pancreatitis in the United States. The risk is dose dependent, but it usually requires sustained ingestion of alcohol of 4 to 5 drinks daily over more than 5 years. The majority of people (95%) who consume this much alcohol do not develop chronic pancreatitis, pointing to important cofactors such as genetic risk factors and cigarette smoking. Smoking increases the risk of chronic pancreatitis by two- to three-fold, with a dose-dependent effect. Smoking is estimated to account for 25% of the attributable risk of chronic pancreatitis, and continued smoking after diagnosis accelerates the course of the disease. These risks also appear to be synergistic, such that the combination of alcohol and tobacco is more than an additive effect.

Genetic

Hereditary pancreatitis is an autosomal dominant disease characterized by early onset of acute and chronic pancreatitis, the development of exocrine and endocrine pancreatic insufficiency, and a high risk of pancreatic adenocarcinoma (Chapter 180). Mutations in the *PRSS1* gene in these families appear to cause a gain in function in which the mutant trypsinogen, once activated to trypsin, is difficult to inactivate. This trypsin, if present in an amount that overwhelms normal protective mechanisms, can activate other pancreatic enzymes and lead to pancreatic damage and eventually to chronic pancreatitis. One of the protective mechanisms is a trypsin inhibitor called the *SPINK1* protein. Loss-of-function mutations in *SPINK1* predispose to chronic pancreatitis. Major mutations in the *CFTR* lead to cystic fibrosis (Chapter 77), which may be associated with chronic pancreatitis and pancreatic atrophy, depending upon the location of the mutation. Certain mutations in *CFTR* predispose to chronic pancreatitis, without causing the sinopulmonary features of classic cystic fibrosis. A number of additional genetic polymorphisms in the calcium-sensing receptor, chymotrypsin C, carboxyethyl lipase, claudins, and others are also associated with chronic pancreatitis. With the exception of *PRSS1*, these polymorphisms predispose to chronic pancreatitis and may function as modifying genes but are not sufficient to cause chronic pancreatitis.

Pancreatic Duct Obstruction

Chronic obstruction of the pancreatic duct by benign, premalignant, and malignant conditions can cause chronic pancreatitis to develop in the gland upstream from the obstruction. Examples include duodenal diseases causing obstruction at the ampulla (celiac disease, Crohn disease, ampullary adenoma or carcinoma) and benign (after severe pancreatitis, pancreatic surgery, or

abdominal trauma) and malignant pancreatic duct strictures (pancreatic ductal adenocarcinoma, intraductal papillary mucinous neoplasms).

Other Causes

Autoimmune pancreatitis is a disease that most often presents as a masslike lesion in the pancreas with obstructive jaundice, mimicking cancer, but it also may present as chronic pancreatitis and rarely as acute pancreatitis.[18] Because cancer is more common than autoimmune pancreatitis, it must be excluded (usually with endoscopic ultrasonography). Type 1 autoimmune pancreatitis is characterized by diffuse swelling of the pancreas, elevation of the serum IgG4 level, and involvement of other organs, especially with biliary strictures, salivary gland inflammation, retroperitoneal fibrosis, and renal lesions. Histologically, these organs are infiltrated by chronic inflammatory cells, especially plasma cells bearing IgG4 on their surface, as is part of the spectrum of IgG4-related disease.[19] Type 2 autoimmune pancreatitis, which affects only the pancreas and is not associated with elevations in IgG4, may have potential overlap with autoimmune cholangitis.

Although most chronic pancreatitis follows multiple episodes of acute pancreatitis, a single severe acute attack that causes substantial pancreatic necrosis can cause a ductal stricture or destroy enough gland to produce exocrine and endocrine insufficiency. Other diseases that cause repeated attacks of pancreatitis can lead to chronic pancreatitis. For example, hypertriglyceridemia causes recurrent acute pancreatitis that leads to chronic pancreatitis.

CLINICAL MANIFESTATIONS

Abdominal pain is the most common symptom and is responsible for the greatest negative impact on quality of life. The pain may be episodic or constant, and it is generally present in the epigastrium with radiation to the back.[20] Some patients will present initially with an episode of acute pancreatitis and thereafter develop evidence of chronic pancreatitis, but others will have obvious chronic pancreatitis at their first presentation. If pain is episodic, the patient may be labeled as having acute pancreatitis or an acute flare of chronic pancreatitis. When pain is severe, nausea and vomiting may occur. Pain may worsen, improve, or remain stable over time. Up to 5% of patients do not have pain and instead present with exocrine (steatorrhea, weight loss) or endocrine (diabetes mellitus) pancreatic insufficiency. The disease tends to be progressive over time, even if the original cause (e.g., alcohol) is removed. The pain also may become self-perpetuating even if therapy is successful.

DIAGNOSIS

The diagnosis may be suspected based on the clinical features but should be confirmed by tests that identify structural damage to the pancreas or derangements in pancreatic function (Table 130-3).[21] Serum levels of amylase or lipase are not useful for diagnosing chronic pancreatitis. Serum trypsinogen (also called trypsin) is abnormally low in patients with chronic pancreatitis that is advanced enough to cause steatorrhea but is often normal in patients with less advanced disease. Serum glucose levels will be elevated in patients with endocrine insufficiency.

Chronic pancreatitis is a slowly progressive disease in which visible damage to the gland (e.g., on a CT scan) and functional failure (e.g., steatorrhea or diabetes mellitus) may not be apparent for years. All diagnostic tests are most accurate when the disease is far advanced, and all are far less accurate in the early stages of disease.

TABLE 130-3 DIAGNOSTIC TESTS FOR CHRONIC PANCREATITIS*

STRUCTURAL	FUNCTIONAL
Biopsy	Hormonal (secretin) test
Endoscopic ultrasonography	Fecal elastase
Magnetic resonance imaging with magnetic resonance cholangiopancreatography, with or without secretin infusion	Serum trypsin level
	Fecal fat
	Blood glucose level
Computed tomography	
Endoscopic retrograde cholangiopancreatography	
Ultrasonography	
Plain abdominal radiography	

*Listed in approximate order of decreasing sensitivity.

From a practical perspective, the diagnosis is established in most patients by CT or MRI.[22] The diagnostic challenge lies with patients who present with a severe pain syndrome suggestive of chronic pancreatitis but who have a normal or minimally abnormal CT or MRI. In these patients, MRI with secretin-MRCP or endoscopic ultrasonography is the best choice, unless a secretin-based pancreatic function test is available. ERCP should not be used for diagnostic purposes alone.

In about 20% of patients, no clear cause of chronic pancreatitis is identified, and this may be more common in women. Some patients may have underlying genetic mutations, and others may be surreptitiously using alcohol and/or tobacco. Two general forms of idiopathic chronic pancreatitis are observed. In the first, pain is the predominant feature, and the onset of disease is in young adulthood. In the second, the onset is in middle age, and exocrine and endocrine insufficiency, rather than abdominal pain, are the major clinical manifestations. As more genetic polymorphisms are identified, the relative prevalence of idiopathic pancreatitis is shrinking.

Tests of Pancreatic Structure

Plain abdominal radiographs may demonstrate diffuse or focal pancreatic calcification in patients with advanced chronic pancreatitis). Although specific for chronic pancreatitis, these findings are detected only after years of disease.

Abdominal ultrasound is of limited utility because overlying gas often limits the ability to visualize the pancreas. An abnormal pancreatic duct, pancreatic calcifications, gland atrophy, or changes in echotexture are seen in about 60% of patients.

CT is the most widely used diagnostic test for chronic pancreatitis, and high-quality images can be obtained of the pancreas and pancreatic duct. Characteristic findings include a dilated pancreatic duct, ductal or parenchymal calcifications, and atrophy (Fig. 130-3). These structural changes take years to develop, so CT is not as accurate in early or less advanced disease. Like CT, MRI allows detailed images of the pancreas, and the addition of MRCP allows even better assessment of pancreatic duct morphology. Secretin can be administered at the time of MRCP to allow better visualization of the pancreatic duct. MRI with secretin-MRCP is more sensitive for detecting the early changes of chronic pancreatitis than is CT.

Endoscopic ultrasonography allows very detailed images of the pancreatic parenchyma and duct (Fig. 130-4). Normal endoscopic ultrasonography essentially excludes chronic pancreatitis, whereas very abnormal endoscopic ultrasonography is highly consistent with chronic pancreatitis. ERCP provides the most detailed images of the pancreatic duct, as well as the opportunity to provide therapy (see later). Changes in the duct include dilation, irregularity, ductal stones, and strictures (Fig. 130-5). However,

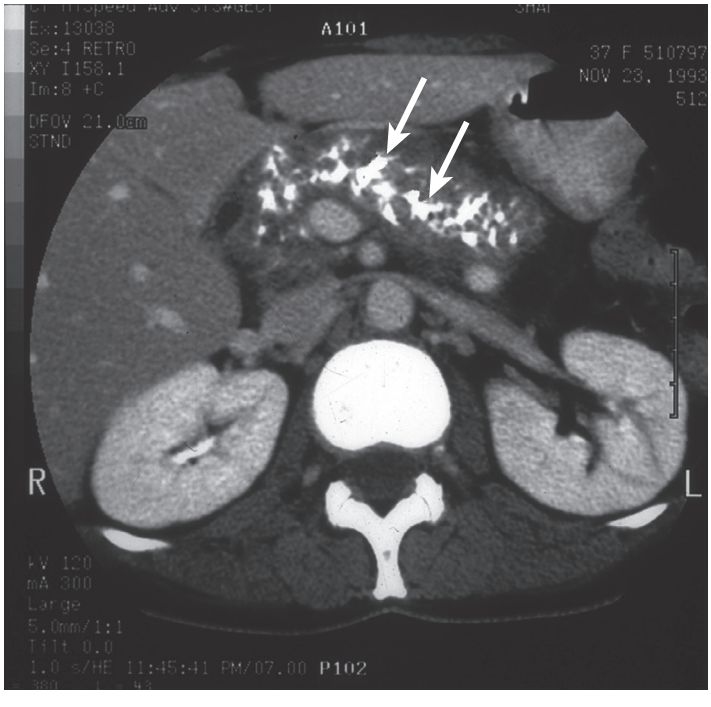

FIGURE 130-3. A computed tomographic scan demonstrating diffuse pancreatic calcification in a patient with long-standing chronic pancreatitis (*arrows*).

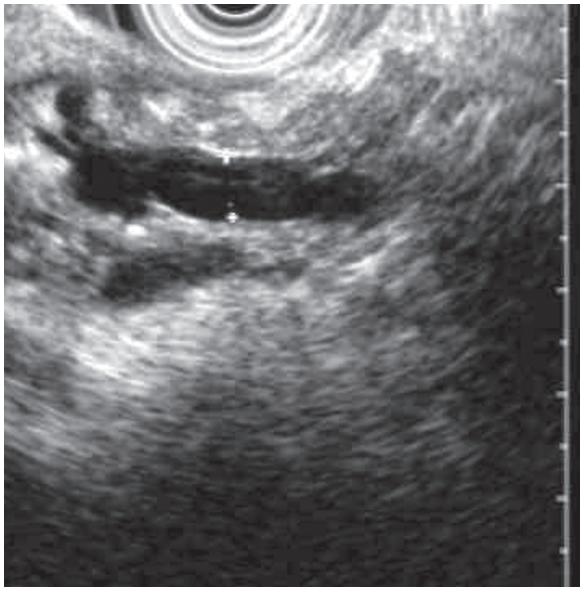

FIGURE 130-4. An endoscopic ultrasound in a patient with chronic pancreatitis, demonstrating a dilated pancreatic duct (*marks on margin of main duct*).

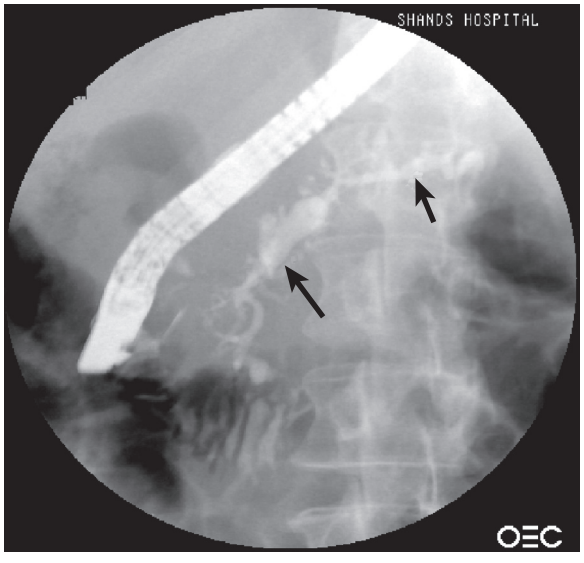

FIGURE 130-5. An endoscopic retrograde cholangiopancreatography demonstrating a very irregular pancreatic duct with areas of dilation and stricturing in a patient with chronic pancreatitis (*arrows*).

ERCP carries a risk of causing pancreatitis, so it should be utilized only when therapy is planned.

Tests of Pancreatic Function

Quantification of fat in stool during a 72-hour collection while on a high-fat diet can be used to document steatorrhea but is rarely performed. Qualitative analysis of fat with Sudan staining of a stool specimen has poor sensitivity and specificity. Fecal levels of pancreatic elastase are diminished to less than 200 µg/g in patients with exocrine pancreatic insufficiency. The test can be performed while patients are taking pancreatic enzyme therapy.

For a direct pancreatic function test, a tube or endoscope is passed into the duodenum, where pancreatic secretions are collected and analyzed for bicarbonate concentration, after a supraphysiologic dose of secretin is administered. A normal study is defined by at least one of the samples having a bicarbonate concentration of 80 mEq/L or more. The test becomes abnormal earlier in the disease process than any other test, so it is best suited to diagnose chronic pancreatitis earlier in its clinical course. However, the test is not widely available or used.

TREATMENT

Medical therapy starts with vigorous attempts to assist patients in stopping alcohol and tobacco, if applicable.

Treatment of Pain

Many patients will require analgesics. It is appropriate to start with the less potent agents first (such as NSAIDs or tramadol 50 to 100 mg every 6 hours). In most patients, it is helpful to add an adjunctive agent such as a gabapentoid (e.g., pregabalin starting at 75 mg two times daily), a tricyclic antidepressant (e.g., amitriptyline starting at 50 mg at night or nortriptyline starting at 10 mg at night), a selective serotonin reuptake inhibitor, or a combined serotonin and norepinephrine uptake inhibitor at the usual starting dose (Table 362-5).[23] Combinations of these adjunctive agents are also utilized. Antioxidants (mixtures of selenium, vitamins E and C, β-carotene, and methionine) may also have some beneficial effect on pain in selected patients with preexisting deficiencies.

Sudden worsening of pain should lead to a search for specifically treatable complications, including pseudocyst, obstruction of a surrounding hollow organ (e.g., duodenum or bile duct), or superimposed carcinoma. A good-quality CT or MRI is usually sufficient to exclude these possibilities. These imaging tests may also help in choosing appropriate therapy. Patients with a dilated duct (generally >5 mm) are the best candidates for endoscopic and surgical therapy for pain. Patients without ductal dilation are not suitable for most endoscopic and surgical therapy and must rely instead on medical therapy (Table 130-4). Unfortunately, pain often persists despite therapy. A celiac plexus block using bupivacaine can be performed relatively easily and safely, but substantial relief of pain is unpredictable and at best is achieved for only weeks.

Other Medical Therapy

Pancreatic enzyme therapy is commonly used to treat exocrine insufficiency and occasionally to treat pain, although evidence is lacking on its effectiveness for

TABLE 130-4 TREATMENT FOR PAIN

Medical therapy	Analgesics and adjunctive agents • Tramadol 50 mg, 1-2 three times daily • Pregabalin, starting at 75 mg two times daily • Gabapentin, starting at 100 mg at night • Amitryptiline, starting at 50 mg at night • Nortriptyline, starting at 10 mg at night • SSRIs (e.g., citalopram, fluoxetine, sertraline, paroxetine) at recommended starting dose (see Table 362-5) Antioxidants • Typical mixture containing vitamin C (1000 mg), vitamin E (300 IU), selenium (500 µg), methionine (2 g), and β-carotene (10,000 IU) total daily dose
Nerve block	Endoscopic ultrasonography–guided nerve block
Endoscopic therapy	Stent Stone removal, lithotripsy
Surgical therapy	Pancreaticojejunostomy (modified Puestow operation) Partial pancreatic resection (Whipple operation, duodenum preserving pancreatic head resection, others) Total pancreatectomy with islet-cell auto-transplantation

CT = computed tomography; SSRI = selective serotonin reuptake inhibitor.

TABLE 130-5 ENZYME THERAPY FOR EXOCRINE PANCREATIC INSUFFICIENCY

PRODUCT	FORMULATION	LIPASE CONTENT/CAPSULE OR PILL*
Zenpep	Enteric-coated porcine	3000; 5000; 10,000; 15,000; 20,000; 25,000; 40,000
Creon	Enteric-coated porcine	3000; 6000; 12,000; 24,000; 36,000
Pancreaze	Enteric-coated porcine	4200; 10,500; 16,800; 21,000; 37,000
Pertzye	Enteric-coated porcine with bicarbonate	4000; 8000; 16,000; 24,000
Viokace	Non–enteric-coated porcine tablet†	10,440; 20,880

*In USP units.
†Must be co-administered with an H_2 blocker (e.g., famotidine 20 mg twice daily) or a proton pump inhibitor (e.g., omeprazole 20 mg/day).

pain. Autoimmune pancreatitis responds promptly to steroid therapy (usually 40 mg of prednisone daily for 4 weeks, with a taper of 5 mg/week over the next 7 weeks), but relapse commonly occurs, particularly in patients with biliary obstruction. Continuing prednisone at a low daily dose (e.g., 5 to 7.5 mg for 3 years),[A11] or the use of alternative agents (e.g., azathioprine or rituximab, under the direction of a specialist), may be required to maintain remission.

Endoscopic Therapy and Lithotripsy

ERCP can be used to dilate strictures and place stents across the stricture. Ductal stones, if they are not too large and are not impacted, may also be removed. Larger stones usually require lithotripsy to reduce the stone to fragments that are manageable. ERCP is most useful in patients who have a dominant obstruction in the pancreatic head with upstream ductal dilation. Such ERCP therapy is technically successful in more than 80% of carefully selected patients, and pain relief may be seen in 70 to 80% of patients, although treatment usually requires several endoscopic procedures.[24]

Surgical Therapy

Surgery also generally requires a dilated pancreatic duct and is somewhat more effective and more durable than is endoscopic therapy.[A12] Surgery can involve decompression of the pancreatic duct, resection of the pancreas, or a combination of the two. The most commonly performed procedure, the modified Puestow procedure, involves a longitudinal incision of the pancreatic duct from the body of the pancreas to as close to the duodenum as possible, and this duct is overlaid with a defunctionalized small intestinal limb to drain it. At the time of surgery, ductal strictures can be incised and ductal stones can be removed. The procedure is relatively simple in patients with a dilated pancreatic duct (>5 mm). Pain relief in the short term is good (>80%), with about 50% obtaining long-term relief of pain. Alternative surgical procedures for pain include partial resection of the pancreas, typically the head of the gland. These operations, which include the classic pancreatico-duodenectomy (Whipple operation), as well as several variations of a duodenum-preserving pancreatic head resection, provide equal short-term pain relief[A13] and better long-term pain relief than a modified Puestow but perhaps with higher morbidity. Some evidence suggests surgery earlier in the clinical course is more effective.[A14] Total pancreatectomy, usually coupled with auto-transplantation of harvested islet cells, is currently considered a therapy of last resort in adults.

Exocrine Insufficiency

Steatorrhea and maldigestion do not occur until approximately 90% of pancreatic enzyme secretion is lost, usually after at least 5 to 10 years of disease. Patients may note weight loss and oily stools but often do not complain of diarrhea.[25] Patients with chronic pancreatitis and exocrine insufficiency maldigest fat, protein, and carbohydrates, but fat maldigestion is usually most severe (including fat-soluble vitamins, particularly vitamin D). The diagnosis of exocrine insufficiency is usually suggested by symptoms of oily or floating stools and weight loss. A formal 72-hour stool fat analysis is the most accurate method to document steatorrhea and to gauge effectiveness of therapy but is rarely done. Instead, the clinical features and a fecal elastase lower than 200 µg/g stool, coupled with an appropriate response to enzyme replacement therapy, is the best substitute for 72-hour fecal fat testing.

Pancreatic enzyme replacement therapy (Table 130-5) can normalize fat and fat-soluble vitamin absorption, maintain normal nutrition and weight, and prevent complications such as osteoporosis.[A15] Both enteric-coated capsules and non–enteric-coated tablets are available. Enzymes are identified by the lipase content of the pill or capsule, although they all contain proteases and amylase as well. The goal of enzyme therapy is to provide at least 10% of normal pancreatic output with each meal (90,000 USP units of lipase/meal). Since most patients are still producing some enzymes (including gastric lipase), it may not be necessary to prescribe the full dosage of 90,000 USP units with each meal; 40,000 to 50,000 is a reasonable starting point.

If non–enteric-coated preparations are selected, cotreatment with an H_2-blocker (e.g., famotidine 20 mg twice daily or equivalent) or proton pump inhibitor (e.g., omeprazole 20 mg daily or equivalent) is required to prevent acid denaturation of lipase; such cotreatment is not needed with enteric-coated preparations. Enzymes should be taken during the meal. Supplementation with vitamin D (400 to 1000 IU daily) and calcium (1.0 to 1.5 g daily) is appropriate because of the risks of osteoporosis (Chapter 225) and osteopenia. Measurement of fat-soluble vitamin levels and periodic bone mineral density testing are recommended. The success of enzyme therapy is generally defined as weight gain, reduction or absence of visible oil in the stool, and correction of fat-soluble vitamin levels. Failure of enzyme therapy is most often due to an inadequate dose. Increasing the dose up to the full 90,000 USP units during meals and encouraging compliance is appropriate as a first step. No generic products are available in the United States, so cost may be a major cause of noncompliance. Some patients may not respond owing to the presence of a second disease that also causes malabsorption, such as small intestinal bacterial overgrowth.

Endocrine Insufficiency

Similar to exocrine insufficiency, diabetes mellitus (Chapter 210) is a very late complication of chronic pancreatitis, occurring years or decades after the onset of disease. In contrast to type 1 diabetes mellitus, destruction of the entire islet, which has been termed type 3C diabetes mellitus, reduces secretion of both insulin and glucagon.[26] The absence of glucagon increases the risk that overly aggressive insulin therapy may lead to hypoglycemia. In most patients, therefore, insulin treatment is not aimed at exceedingly tight glucose control. Unfortunately, these patients are at similar risk for microvascular complications as are all other patients with diabetes.

Pancreatic Pseudocyst

Pancreatic pseudocysts, when they are discovered in patients with chronic pancreatitis, are generally mature and have a visible capsule surrounding them. As in acute pancreatitis, benign pseudocysts in chronic pancreatitis do not require therapy if they are not producing symptoms and are not infected. However, some cystic structures in and around the pancreas are cystic neoplasms (Chapter 180), not pseudocysts. Symptomatic pseudocysts require drainage, whereas neoplasms require resection. Features that suggest a cystic neoplasm include a cyst with a thick or nodular wall, a cyst with multiple internal septations, or a cyst occurring in a patient who does not have a history of pancreatitis. Any combination of these features should lead to further investigation, generally with endoscopic ultrasonography and aspiration.

Symptomatic pseudocysts can be treated with endoscopic, percutaneous, or surgical therapy with equal efficacy. In most centers, endoscopic ultrasonography-guided drainage is becoming first-line therapy with excellent short- and long-term results. Complications of pseudocysts include infection, bleeding (discussed earlier), and rupture. Pseudocysts may leak into the peritoneal compartment (pancreatic ascites) or track into the chest (pancreatic pleural effusion). Patients usually present with abdominal distension or dyspnea, rather than abdominal pain. Amylase level in the fluid is usually greater than 4000 U/L. Endoscopic therapy with stent placement across the connection between pseudocyst and pancreatic duct is highly effective in this situation.

Malignancy

Chronic pancreatitis is a strong risk factor for pancreatic ductal adenocarcinoma (Chapter 180), with a lifetime risk of about 4%, which is 8- to 16-fold above the general population.[27] *KRAS* mutations may be found in chronic pancreatitis. The risk of cancer is higher in patients who have hereditary pancreatitis and who also smoke, in whom the risk may be as high as 40%. Other genetic causes and smoking also increase the risk of secondary pancreatic malignancy, as may type 3C diabetes mellitus. It may be difficult to visualize cancer in an already diseased pancreas.

PREVENTION

Currently, there are no reliable methods to prevent chronic pancreatitis. Patients at risk for chronic pancreatitis, such as members of families with hereditary pancreatitis or patients with strong genetic predispositions, should avoid alcohol and tobacco. Similarly, patients with established chronic pancreatitis should avoid these agents, which hasten the progression of the disease.

PROGNOSIS

With prolonged follow-up of 10 to 20 years, the majority of patients will develop exocrine or endocrine insufficiency. Overall mortality is increased three- to six-fold compared with age-matched controls. Patients who are older, smoke, or have alcohol as the cause are at highest risk of mortality. Overall, 10-year survival approximates 70%, and 20-year survival is about 45%. Death is usually not due to pancreatitis itself but rather to malignancy, postoperative complications, and complications of alcohol (Chapter 364) or tobacco (Chapter 363).

131 DISEASES OF THE RECTUM AND ANUS

ROBERT D. MADOFF AND GENEVIEVE B. MELTON

ANATOMY

The Rectum

The rectum and anal canal make up the final portion of the hindgut. In general, the colon transitions distally to the rectum at the level of the sacral promontory, where the taeniae coli splay to form a continuous longitudinal muscle layer and then extends approximately 12 to 18 cm distally. The peritoneum covers the upper two thirds of the rectum anteriorly and is usually more limited laterally. The rectum and its mesentery are surrounded posteriorly by endopelvic fascia, and this anatomic package contains the relevant lymphovascular structures that should be removed intact during rectal cancer surgery. The rectum also has two or three curves within its lumen created by submucosal folds called the valves of Houston. The second valve is often used as a rough guideline for the intraperitoneal cavity anteriorly.

Blood supply to the rectum originates from the inferior mesenteric artery proximally and internal iliac arteries distally. The inferior mesenteric artery terminates as the superior rectal artery, which supplies the rectum and the upper one third of the anal canal. Additionally, internal iliac arteries give off the middle rectal arteries and the inferior rectal arteries (inferior via the internal pudendal artery) to supply the distal rectum and anal canal. The proximal rectum drains predominantly into the superior rectal venous plexus and then to the inferior mesenteric vein and portal venous system. By contrast, the caudal rectum and anal canal drain mainly into the systemic venous circulation through the inferior and middle rectal veins into the internal iliac veins and inferior vena cava. Generally, the lymphatic drainage of the rectum follows the arterial supply, so the lymphatic spread of rectal tumors is to the inferior mesenteric and internal iliac lymph nodes. As a result of the rectum's dual blood supply and drainage, pulmonary metastatic spread occurs earlier and more often with rectal cancers than with colon cancers. Innervation to the rectum involves both the sympathetic and parasympathetic plexus. The sympathetic nerves arise from the first three lumbar segments of the spinal cord, whereas the parasympathetic nerve supply originates from the caudal three sacral nerve roots.

The Anal Canal

The anal canal, which begins at the level of the *levator ani* muscle and extends to the anal verge opening, is about 2.5 to 5 cm in length and is surrounded by the internal and external anal sphincter muscles. The anorectal junction, which can be easily appreciated on digital rectal examination, is the point where the rectum angulates posteriorly from the axis of the anal canal. The internal anal sphincter, which is responsible for about 70% of the resting anal tone, is an extension of the inner circular smooth muscle layer of the rectum. The external sphincter muscle comprises skeletal muscle and is under voluntary control. The dentate line is located about 2 cm proximal to the anal verge (anal opening). Hemorrhoids are classified as internal versus external according to their relative location proximal or distal to the dentate line.

The mucosal lining changes histologically along the course of the anal canal. Superiorly, the anal canal consists of columnar epithelium that mirrors the rectum. Approximately 1 to 2 cm above the level of the dentate line is a transitional zone, where columnar, cuboidal, transitional, and squamous epithelia cells are found. This admixture of cells constitutes the derivation of the term "basaloid" as it relates to anal canal cancers and marks the proximal boundary for anal cancer surveillance. Distal to this line, the squamous epithelium extends to the anal verge and perianal skin, eventually adding glandular and hair follicles that resemble skin elsewhere on the body. Infected anal glands are a frequent cause of perianal abscess and fistula. Below the dentate line, lymphatic drainage generally goes to the inguinal nodes. The external anal sphincter is innervated by fibers from S4 and the internal pudendal nerve. Somatic sensation of the anal canal comes from the inferior rectal nerve via the pudendal nerve. This somatic sensation ceases 1 to 2 cm above the dentate line, which explains why some procedures such as hemorrhoid ligation can be performed in the office without anesthesia.

SPECIFIC ANORECTAL CONDITIONS

Hemorrhoids

EPIDEMIOLOGY AND PATHOBIOLOGY

An estimated 15 million or more individuals, about 5 to 12% of adults, in the United States experience symptoms related to hemorrhoids each year, and these individuals generate over 4 million annual office visits. However, the true incidence and prevalence of hemorrhoids are unknown because several anorectal conditions that are commonly attributed to "hemorrhoids" are actually caused by other conditions.

Despite a commonly held notion that hemorrhoids are always abnormal, they actually are normal structures that are identifiable even in the fetus. Hemorrhoids are vascular cushions that consist of connective tissue, smooth muscle, and both arterioles and veins. Functionally, they likely aid with overall fecal continence by serving as a malleable gasket that improves the seal of the anal canal.

Hemorrhoids are *not* rectal varices, which are distinct vascular entities that can develop in the setting of portal hypertension. *Hemorrhoidal disease* is a more appropriate term to describe the pathologic state with hemorrhoids that generates symptoms. The hemorrhoidal arteriolar component explains why hemorrhoidal bleeding is typically bright red in color and can be copious in quantity. Causative factors that can provoke hemorrhoidal symptoms include constipation, diarrhea, older age, pregnancy, and prolonged straining with defecation. Over time, repeated stretching of the anal canal damages the supporting tissue and results in downward displacement of the vascular cushions. Although none of these precipitating factors has been established rigorously, each can cause either increased abdominal pressure or obstruction of venous return, thereby leading to engorgement and enlargement of the vascular cushions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptom of internal hemorrhoids is bright red bleeding. This bleeding is typically painless and is most often seen on the toilet tissue or in the toilet bowl. The quantity of blood is variable, but patients may occasionally describe blood dripping or squirting into the toilet bowl. Passage of dark blood or blood mixed in the stool suggests a more proximal source. Internal hemorrhoids are classified based on the symptoms they cause. As internal hemorrhoids enlarge, they are also associated with redundant rectal mucosa that protrudes from the anus with defecation. Early hemorrhoids bleed but do not prolapse (grade 1). Initial protrusion reduces spontaneously (grade 2); more advanced protrusion requires digital reduction (grade 3) and, at its most advanced form, becomes irreducible (grade 4) (Fig. 131-1). Internal hemorrhoids are insensate and do not themselves result in pruritus, but they can cause itching owing to associated perianal soiling or mucus deposition caused by mucosal prolapse. Additionally, patients may complain of anal discomfort or pressure, mucus discharge, extra tissue at the verge (i.e., mucosal prolapse), or a sensation of incomplete evacuation.

131 DISEASES OF THE RECTUM AND ANUS

ROBERT D. MADOFF AND GENEVIEVE B. MELTON

ANATOMY

The Rectum

The rectum and anal canal make up the final portion of the hindgut. In general, the colon transitions distally to the rectum at the level of the sacral promontory, where the taeniae coli splay to form a continuous longitudinal muscle layer and then extends approximately 12 to 18 cm distally. The peritoneum covers the upper two thirds of the rectum anteriorly and is usually more limited laterally. The rectum and its mesentery are surrounded posteriorly by endopelvic fascia, and this anatomic package contains the relevant lymphovascular structures that should be removed intact during rectal cancer surgery. The rectum also has two or three curves within its lumen created by submucosal folds called the valves of Houston. The second valve is often used as a rough guideline for the intraperitoneal cavity anteriorly.

Blood supply to the rectum originates from the inferior mesenteric artery proximally and internal iliac arteries distally. The inferior mesenteric artery terminates as the superior rectal artery, which supplies the rectum and the upper one third of the anal canal. Additionally, internal iliac arteries give off the middle rectal arteries and the inferior rectal arteries (inferior via the internal pudendal artery) to supply the distal rectum and anal canal. The proximal rectum drains predominantly into the superior rectal venous plexus and then to the inferior mesenteric vein and portal venous system. By contrast, the caudal rectum and anal canal drain mainly into the systemic venous circulation through the inferior and middle rectal veins into the internal iliac veins and inferior vena cava. Generally, the lymphatic drainage of the rectum follows the arterial supply, so the lymphatic spread of rectal tumors is to the inferior mesenteric and internal iliac lymph nodes. As a result of the rectum's dual blood supply and drainage, pulmonary metastatic spread occurs earlier and more often with rectal cancers than with colon cancers. Innervation to the rectum involves both the sympathetic and parasympathetic plexus. The sympathetic nerves arise from the first three lumbar segments of the spinal cord, whereas the parasympathetic nerve supply originates from the caudal three sacral nerve roots.

The Anal Canal

The anal canal, which begins at the level of the *levator ani* muscle and extends to the anal verge opening, is about 2.5 to 5 cm in length and is surrounded by the internal and external anal sphincter muscles. The anorectal junction, which can be easily appreciated on digital rectal examination, is the point where the rectum angulates posteriorly from the axis of the anal canal. The internal anal sphincter, which is responsible for about 70% of the resting anal tone, is an extension of the inner circular smooth muscle layer of the rectum. The external sphincter muscle comprises skeletal muscle and is under voluntary control. The dentate line is located about 2 cm proximal to the anal verge (anal opening). Hemorrhoids are classified as internal versus external according to their relative location proximal or distal to the dentate line.

The mucosal lining changes histologically along the course of the anal canal. Superiorly, the anal canal consists of columnar epithelium that mirrors the rectum. Approximately 1 to 2 cm above the level of the dentate line is a transitional zone, where columnar, cuboidal, transitional, and squamous epithelia cells are found. This admixture of cells constitutes the derivation of the term "basaloid" as it relates to anal canal cancers and marks the proximal boundary for anal cancer surveillance. Distal to this line, the squamous epithelium extends to the anal verge and perianal skin, eventually adding glandular and hair follicles that resemble skin elsewhere on the body. Infected anal glands are a frequent cause of perianal abscess and fistula. Below the dentate line, lymphatic drainage generally goes to the inguinal nodes. The external anal sphincter is innervated by fibers from S4 and the internal pudendal nerve. Somatic sensation of the anal canal comes from the inferior rectal nerve via the pudendal nerve. This somatic sensation ceases 1 to 2 cm above the dentate line, which explains why some procedures such as hemorrhoid ligation can be performed in the office without anesthesia.

SPECIFIC ANORECTAL CONDITIONS

Hemorrhoids

EPIDEMIOLOGY AND PATHOBIOLOGY

An estimated 15 million or more individuals, about 5 to 12% of adults, in the United States experience symptoms related to hemorrhoids each year, and these individuals generate over 4 million annual office visits. However, the true incidence and prevalence of hemorrhoids are unknown because several anorectal conditions that are commonly attributed to "hemorrhoids" are actually caused by other conditions.

Despite a commonly held notion that hemorrhoids are always abnormal, they actually are normal structures that are identifiable even in the fetus. Hemorrhoids are vascular cushions that consist of connective tissue, smooth muscle, and both arterioles and veins. Functionally, they likely aid with overall fecal continence by serving as a malleable gasket that improves the seal of the anal canal.

Hemorrhoids are *not* rectal varices, which are distinct vascular entities that can develop in the setting of portal hypertension. *Hemorrhoidal disease* is a more appropriate term to describe the pathologic state with hemorrhoids that generates symptoms. The hemorrhoidal arteriolar component explains why hemorrhoidal bleeding is typically bright red in color and can be copious in quantity. Causative factors that can provoke hemorrhoidal symptoms include constipation, diarrhea, older age, pregnancy, and prolonged straining with defecation. Over time, repeated stretching of the anal canal damages the supporting tissue and results in downward displacement of the vascular cushions. Although none of these precipitating factors has been established rigorously, each can cause either increased abdominal pressure or obstruction of venous return, thereby leading to engorgement and enlargement of the vascular cushions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptom of internal hemorrhoids is bright red bleeding. This bleeding is typically painless and is most often seen on the toilet tissue or in the toilet bowl. The quantity of blood is variable, but patients may occasionally describe blood dripping or squirting into the toilet bowl. Passage of dark blood or blood mixed in the stool suggests a more proximal source. Internal hemorrhoids are classified based on the symptoms they cause. As internal hemorrhoids enlarge, they are also associated with redundant rectal mucosa that protrudes from the anus with defecation. Early hemorrhoids bleed but do not prolapse (grade 1). Initial protrusion reduces spontaneously (grade 2); more advanced protrusion requires digital reduction (grade 3) and, at its most advanced form, becomes irreducible (grade 4) (Fig. 131-1). Internal hemorrhoids are insensate and do not themselves result in pruritus, but they can cause itching owing to associated perianal soiling or mucus deposition caused by mucosal prolapse. Additionally, patients may complain of anal discomfort or pressure, mucus discharge, extra tissue at the verge (i.e., mucosal prolapse), or a sensation of incomplete evacuation.

ABSTRACT

Diseases of the anus and rectum can range from benign to serious conditions. A good understanding of anorectal anatomy, a thorough history, and a careful examination of the anorectum are highly valuable in assessing most anorectal complaints and differentiating among the various entities that patients will often call "hemorrhoids." Recent advances have substantially improved the treatment of several more serious anorectal issues, including rectal prolapse and fecal incontinence. Human papillomavirus vaccine plays a pivotal role in prevention of sexually transmitted anal dysplasia and cancer.

FIGURE 131-1. Grade 4 nonreducible internal and external hemorrhoids.

FIGURE 131-2. Thrombosed external hemorrhoid.

Individuals with anorectal symptoms frequently present complaining of "hemorrhoids" or are even referred from other physicians with a diagnosis of hemorrhoids. Although hemorrhoids may be present, they are often not the source of the underlying complaint. Therefore, it is always incorrect—and sometimes dangerous—for the physician to apply this diagnosis without completing an adequate evaluation. Fortunately, the initial evaluation is simple, and the correct diagnosis is often suspected based on history alone and confirmed by a limited visual and endoscopic examination. Internal hemorrhoids are best visualized with a slotted anoscope.

Rectal bleeding should never be attributed to hemorrhoids alone, even if hemorrhoids are visible; at a minimum, flexible sigmoidoscopy is required to exclude more proximal pathology. For more concerning symptoms or high-risk patients (e.g., personal or family history of colorectal cancer, persistent bleeding despite adequate treatment, unscreened individuals over age 45 years), a full evaluation of the large intestine should be performed by colonoscopy. The rising incidence of colon and rectal cancers (Chapter 179) in individuals under age 45 years serves to emphasize the point that unexplained rectal symptoms require thorough evaluation at all ages and should not simply be attributed to "hemorrhoids."

External hemorrhoids are usually asymptomatic and should be differentiated from perianal skin tags, which may cause difficulties with perianal hygiene, particularly when they are large or elongated. External hemorrhoids become symptomatic when they thrombose, thereby causing acute-onset pain and swelling (Fig. 131-2). Thrombosed external hemorrhoids, which are usually diagnosed by simple inspection of the anus, appear as an external lump, covered by anoderm and skin, with the underlying thrombosis giving it a purple appearance. Occasional patients who present with extensive, circumferential thrombosis require urgent surgical consultation.

TABLE 131-1 INTERNAL HEMORRHOIDS: GRADING AND MANAGEMENT

GRADE	SYMPTOMS AND SIGNS	MANAGEMENT
1	Bleeding No prolapse	Dietary modifications* Rubber band ligation Infrared coagulation Injection sclerotherapy
2	Prolapse with spontaneous reduction Bleeding, seepage	Rubber band ligation Infrared coagulation Dietary modifications* Injection sclerotherapy Doppler hemorrhoidal artery ligation
3	Prolapse requiring digital reduction Bleeding, seepage	Surgical hemorrhoidectomy Rubber band ligation Dietary modifications* Doppler hemorrhoidal artery ligation
4	Prolapsed, cannot be reduced Strangulated	Surgical hemorrhoidectomy Urgent hemorrhoidectomy

*Dietary modifications include increasing the consumption of fiber, bran, or psyllium and water. Dietary modifications are always appropriate for the management of hemorrhoids and to prevent recurrence after banding or surgery (or both).

TREATMENT

Grade 1 hemorrhoids often respond to dietary manipulation alone: increased dietary fiber, addition of a fiber supplement, and increased water intake (Table 131-1).[1,2] The goal, which may not be readily achievable, is approximately 25 to 30 g of fiber and 8 glasses of water daily. Patients often require a dietary fiber supplement to reach the recommended fiber intake. Patient education should also include maintaining proper bowel habits, including limiting time on the commode and avoiding straining with defecation.

More advanced hemorrhoids require specific therapy, which is almost always office-based. The most popular and simplest technique is rubber band ligation, whereby a tiny rubber band (internal diameter approximately 1 mm) is placed around some of the redundant rectal mucosa and prolapsing hemorrhoid well above the dentate line. The banded tissue sloughs in 7 to 14 days, an event occasionally heralded by rectal bleeding, which can be significant in rare cases. The result of surgery is a pexy effect for the prolapsing hemorrhoid and ligation of part of the blood flow to the hemorrhoid pile. Recovery is relatively straightforward for most patients. Banding can be repeated at 3- to 4-week intervals until bleeding and protrusion are controlled. Bands placed too close to the dentate line cause immediate severe pain and must be removed promptly. Patients who are at high risk of bleeding because of intrinsic coagulopathies or treatment with anticoagulant agents should not undergo rubber band ligation, unless these agents can be discontinued prior to the procedure, owing to the increased risk of postprocedure bleeding. Alternative office therapies for moderate internal hemorrhoids include injection sclerotherapy and infrared coagulation. Thrombosed external hemorrhoids that are early in their course (up to 72 hours since onset), have not responded to conservative therapy, or have thrombosed repeatedly also can be treated by excision in the office under local anesthesia or, if required because of size and location, may require excision in the operating room.

Operative hemorrhoidectomy is needed in only a minority of patients with advanced disease. Indications for hemorrhoidectomy include irreducible prolapse, a substantial external component, and failure of more conservative therapies. The most common approach is an excisional hemorrhoidectomy, which is generally performed on an outpatient basis. Excisional hemorrhoidectomy can also be performed using a coagulation device that seals the tissue, with comparable results and potentially less recurrence (weak evidence).[A1] An alternative approach is Doppler-guided hemorrhoidal artery ligation, after which recurrence rates of 3 to 60% have been reported. Recurrent hemorrhoids are less frequent after hemorrhoidal artery ligation than after a single rubber band ligation,[A2] but hemorrhoidal artery ligation typically must be performed in the operating room and is associated with more pain. Stapled hemorrhoidopexy, which entails resecting a ring of rectal mucosa proximal to the internal hemorrhoids using a circular stapling device, has mostly fallen out of favor because of its higher recurrence rate and a small but worrisome risk of significant complications, such as chronic pain, rectovaginal fistula, and staple line bleeding.

PERIANAL ABSCESS

EPIDEMIOLOGY AND PATHOBIOLOGY

Several superficial and deep spaces around the rectum and anal canal normally contain loose areolar tissue that can serve as potential spaces for perianal infections. Perianal abscess is a common condition, but its incidence is not

well documented. Approximately 80% of perianal abscesses are caused by infection of the anal glands that track toward the skin, whereas other causes include simple skin infections, trauma, inflammatory bowel disease, anorectal surgery, malignancy, and immunosuppression.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients most commonly present with complaints of perianal pain and swelling with or without antecedent events such as trauma. In most cases, a local area of erythema, tenderness, and fluctuance can be appreciated on physical examination. However, these findings are often absent in abscesses in certain locations, including intersphincteric abscesses in the plane between the internal and external sphincter muscles, as well as in supralevator and deep ischiorectal locations. These abscesses should still be suspected based on a history of increasing pain and fever, as well as focal perianal tenderness on the physical examination.

As with all acutely painful anal conditions, digital examination should generally be avoided. Likewise, office instrumentation with an anoscope or proctoscope is contraindicated because these examinations cause substantial pain and typically yield little, if any, diagnostic information. When the cause of the acute pain cannot be determined in the office, prompt examination under anesthesia should be performed. Adjunctive computed tomographic (CT) scanning, magnetic resonance imaging (MRI), or endorectal ultrasound can provide valuable information, particularly in settings of occult, recurrent, or complex disease.

TREATMENT

Treatment for perianal abscess is prompt incision and drainage, which usually can be performed in the office.[3] Large or deep (e.g., postanal or horseshoe) abscesses are best evaluated in the operating room with proper sedation. Antibiotics do not adequately penetrate abscess cavities, and extension of a local infection can lead to sepsis and complex long-term problems. Therefore, antibiotic therapy is inadequate and should never be given in an attempt to avoid or delay incision and drainage. After incision and drainage, antibiotics (e.g., 7 days of oral metronidazole 500 mg every 8 hours and ciprofloxacin 500 mg every 12 hours in addition to standard care) may reduce the rate of subsequent fistula formation.[A3] Antibiotics are especially recommended in immunocompromised patients (e.g., patients with poorly controlled HIV or diabetes mellitus, transplant recipients, and patients undergoing chemotherapy), patients with extensive cellulitis or severe systemic symptoms, and patients at high risk for endovascular infection (e.g., patients with cardiac shunts or prosthetic valves). In patients who fail to improve following incision and drainage, prompt surgical reevaluation is warranted because the problem is likely to be a residual abscess that requires further drainage.

ANAL FISTULA

EPIDEMIOLOGY

An anal fistula, which represents the chronic form of a perianal abscess in which the tract from the infected anal gland to the abscess cavity does not adequately heal, can occur in 30 to 50% of patients following a perianal abscess.[4] This usually manifests as one or more chronic tracts from the anal canal to the perianal skin. The incidence of anal fistula is about 8.6 per 100,000. Fistulae are two to three times more common in men than in women.

PATHOBIOLOGY

After a perianal abscess is drained, the internal opening—the site at the dentate line where the infected gland originated—can remain patent, thereby leaving a source for recurrent infection as well as a tract from the internal anal gland to the abscess cavity and its drainage site. Multiple or atypical anal fistulae should always raise the diagnostic suspicion of Crohn disease, which can occasionally be isolated to the perianal area.

Anal fistulae are characterized by their relationship to the sphincter complex. The simplest and most common (approximately 70%) fistula is intersphincteric—located in the plane between the internal and external sphincter muscles. Transsphincteric fistulas (about 20 to 25%), which traverse both the internal and external sphincter muscles, are classified either as low fistulae, which traverse only the distal external sphincter, or high fistulae, which traverse the more proximal portions of the external sphincter. Suprasphincteric fistulae originate at the dentate line and loop over the entire sphincter complex. Extrasphincteric fistulae have internal openings remote from the dentate line; most originate from a pelvic abscess caused by a ruptured appendix (Chapter 128), diverticulitis (Chapter 128), or Crohn disease (Chapter 127).[5] A horseshoe fistula, which has external openings with associated tracts on both sides of the midsagittal plane, most commonly has a single internal opening in the posterior midline.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Anal fistulae sometimes present as recurrent abscesses in the same location as the original one or as persistent and sometimes intermittent purulent drainage from an abscess site that has failed to heal completely. Patients may often think the area has healed for several weeks or longer prior to experiencing the same feeling of a "boil" forming in the identical area, spontaneously rupturing, and relieving their symptoms.

The diagnosis of an anal fistula is established by history and by visualization of an external opening in the perianal skin. A fibrous fistula tract can sometimes be palpated along the course of the fistula from the skin toward the anal canal. An internal opening is occasionally visible on anoscopy, but a visible internal opening is not necessary to identify a fistula and to make a presumptive diagnosis.

TREATMENT

Treatment of anal fistulae is surgical. Most fistulae are cured by being laid open via a fistulotomy to eliminate the original source of infection at the internal opening. The fistula tract can then heal by secondary intention. However, this approach divides sphincter muscle and puts the patient at risk for impaired fecal continence in proportion to the quantity of muscle involved. In general, intersphincteric and low transsphincteric fistulae can be safely laid open if the patient has normal baseline continence and no underlying predisposing factors for diarrhea (e.g., colitis) or recurrent fistulae (e.g., Crohn disease). Because the anterior sphincter mechanism is relatively short and subject to injury following vaginal delivery, fistulotomy for anterior fistulae in women must be undertaken only after careful consideration.

When a high or complex fistula is identified, the first step is often placement of a seton, a suture, or other material (now commonly a Silastic vessel loop) that is passed though the fistula tract, out the anus, and secured to itself. The seton guarantees that the external fistula opening will not heal over, so a recurrent abscess is much less likely to supervene. After being left in for several weeks, the tract often scars around the seton and becomes fibrotic. Treatment options to eliminate the internal opening include endorectal advancement flap repair and ligation of the intersphincteric fistula tract. Because Crohn disease–associated fistulae tend to be multiple and recurrent, fistulotomy is avoided, except for the most superficial fistulae. In general, patients with Crohn disease are best served by placement of long-term draining setons and medical therapy for their underlying disease (Fig. 131-3).

PROGNOSIS

After appropriate surgery, about 85% of anal fistules are healed at 6 years.

ANAL FISSURE

EPIDEMIOLOGY

Anal fissures can occur at any age but most frequently affect young adults. Men and women are equally affected.

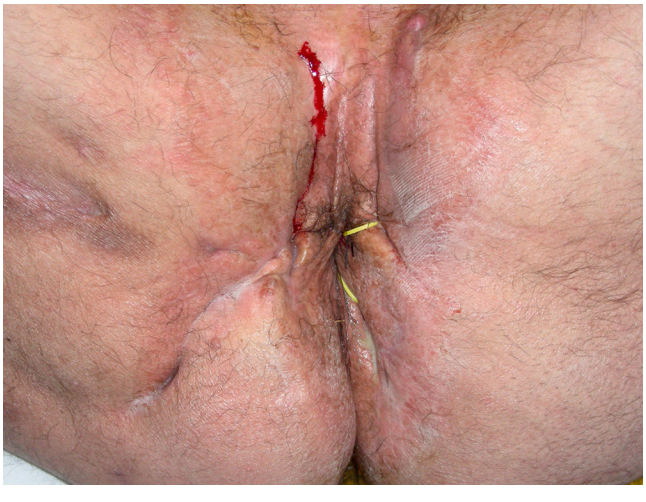

FIGURE 131-3. Crohn disease fistulae. Silastic setons in place with several additional draining tracts and evidence of prior surgery.

FIGURE 131-4. Anal fissure. This longitudinal tear occurs just inside the anal margin.

PATHOBIOLOGY

An anal fissure, which is a longitudinal tear typically with ulceration in the anoderm, occurs just inside the anal margin (Fig. 131-4). The underlying pathophysiology of anal fissures is hypertonia of the internal anal sphincter. Typical anal fissures occur at the midline; most commonly they occur posteriorly, but about 15% are found anteriorly or both anteriorly and posteriorly. "Off-the-midline" fissures may represent a routine fissure, but they generally require examination under anesthesia with culture, biopsy, and pathologic evaluation to exclude other causes such as anal cancer, Crohn disease, syphilis, HIV, leukemia, or tuberculosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with anal fissures generally present with pain during and after bowel movements. Fissures are sometimes precipitated by a bout of constipation or a period of excessive diarrhea, but no specific precipitating event is usually noted. Patients typically describe severe anal pain that may persist for hours or even continue until exacerbation by the next bowel movement. There is sometimes an association with minor bright red bleeding, most commonly seen in small quantities that streak the stool or the toilet tissue. Whereas an acute anal fissure appears as a superficial split in the perianal skin and anoderm, chronic anal fissures, defined by their presence for at least 6 to 8 weeks, are often associated with a "sentinel" skin tag (so-called because its presence should suggest the presence of an underlying fissure) or a hypertrophied anal papilla located just proximal to the fissure at the dentate line, as well as more extensive tearing and ulceration. Well-established fissures may have fibrotic margins with "rolled edges" of the anoderm and visible internal anal sphincter fibers at their base.

Most fissures can be readily observed on physical examination by applying opposing traction to the buttocks. In general, no further examination is performed at that time when a classic anal fissure is identified. Digital and endoscopic examination typically should be delayed until the patient has healed to avoid causing pain. However, patients should be advised that they will require subsequent examination, which may include anoscopy or colonoscopy to exclude other anorectal or more proximal pathology.

TREATMENT

In addition to treating any instigating bowel abnormalities (e.g., constipation or diarrhea), most therapies for anal fissures are directed at the underlying hypertonia of the internal anal sphincter.[6] Approximately 40% of fissures heal with fiber supplementation and increased fluid intake alone, including the great majority of acute fissures. Patients are also advised to take warm sitz baths for symptomatic relief, especially following bowel movements.

Two pharmacologic approaches can augment diet and sitz baths: topical sphincter relaxants and botulinum toxin injection. Topical nitroglycerine (0.2 to 0.8%) or a topical calcium-channel blocker such as diltiazem gel (2%) applied externally around the anal orifice two to four times daily reduces sphincter tone and often leads to healing. Both drugs have similar efficacy, but nitroglycerine has the disadvantage of causing headaches, lightheadedness, or syncope owing to systemic vasodilation in approximately 25% of patients. Botulinum toxin injection into the internal anal sphincter appears to promote healing with recurrence rates similar to topical treatments. Overall, these more conservative approaches unfortunately are only marginally better than placebo for healing chronic fissures, and recurrent fissures occur in approximately 50% of patients.

For patients who fail medical therapy or who are simply too subjectively miserable to pursue pharmacologic treatment, lateral internal sphincterotomy is an appropriate and generally safe approach that is easily performed under monitored local anesthesia in an outpatient setting.[A4] Recovery after lateral internal sphincterotomy is rapid, and fissure healing is expected in more than 90% of cases. Sphincterotomy as first-line therapy provides higher healing rates, fewer relapses, and fewer side effects than topical nitroglycerine, with fewer symptoms, greater satisfaction, and no difference in continence at long-term follow-up. However, a small percentage of patients who undergo sphincterotomy develop minor seepage or even actual incontinence. Therefore, the sphincterotomy should be "tailored" to adjust the amount of internal anal sphincter according to the size of the fissure and the patient's overall amount of internal anal sphincter to maintain sufficient sphincter muscle. When such patients have refractory fissures, a trial of botulinum toxin injection, potentially in conjunction with a topical sphincter relaxant, is often a good alternative. A new experimental treatment is the injection of recently collected autologous adipose tissue, which has been reported to heal up to 55% of perianal fistulas in patients with Crohn disease.[7]

PRURITUS ANI

EPIDEMIOLOGY

The reported incidence of pruritus ani ranges from 1 to 5% in the general population, though it is likely much higher. Men are more commonly affected than women (4 : 1), and this condition is most common in the fourth through the sixth decades of life. Primary or idiopathic pruritus is responsible for 50 to 90% of all cases of pruritus ani.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pruritus ani, or perianal itching, is a very common symptom but is not a disease in and of itself. The most common cause is likely inadequate perianal hygiene, often exacerbated by scratching, which leads to excoriation of the skin, further inflammation, and worsening pruritus.[8] Secondary causes include dermatologic, infectious, systemic, and lower gastrointestinal disease, as well as local irritants. Some of these sources include prolapsing hemorrhoids, anal fistulas, and anal incontinence, as well as specific dermatologic conditions such as contact dermatitis, psoriasis, lichen sclerosis, squamous intraepithelial neoplasia (formerly called Bowen disease), and perianal Paget disease (intraepidermal adenocarcinoma).

Diagnosis is typically based on a history of intractable itching despite trials of several over-the-counter medications and physical examination to exclude an obvious inciting source. The severity of the condition can be classified as stage 0—normal skin; stage 1—red and inflamed skin; stage 2—lichenified skin; and stage 3—lichenified skin as well as coarse ridges and often ulcerations.

TREATMENT

A therapeutic trial of symptomatic empiric management is effective in more than 90% of patients. Options include improved hygiene, avoidance of potential contact allergens (e.g., soaps and over-the-counter topical treatments), and use of either talc to absorb excess moisture or a barrier cream such as zinc oxide.[9] Mechanical scratching will perpetuate the cycle of inflammation and must be strictly avoided. Some patients benefit from the avoidance of certain foods, including caffeinated beverages, alcohol, milk, chocolate, and tomatoes. Mild topical steroids such as 1% hydrocortisone are sometimes helpful, but stronger steroid preparations are frequently counterproductive and should be avoided when they are not indicated for a specific dermatologic diagnosis. The placement of a small fluff of absorbent cotton at the anal verge can help to wick away moisture and collect any drainage before it can be in prolonged contact with the skin. Other adjuncts include drying the perianal skin with a hairdryer after bathing and replacing toilet paper with nondetergent, nondeodorant, nonalcoholic hypoallergenic wipes. Skin biopsies and dermatologic consultation should be obtained when a primary dermatologic condition is suspected or when the perianal irritation fails to heal with conservative therapy.

FECAL INCONTINENCE

EPIDEMIOLOGY AND PATHOBIOLOGY

Involuntary loss of stool or flatus is a relatively common problem that, when severe, can be socially isolating and debilitating. About 2% of individuals in the United States report incontinence symptoms, but the prevalence is more common in women and the elderly, and it also is substantially higher in patients who visit primary care providers and gastroenterologists. Almost half of U.S. nursing home patients suffer from fecal incontinence. Factors such as embarrassment, denial, and the degree of symptoms hinder a determination of true prevalence. Patients presenting with fecal incontinence often have concomitant urinary incontinence (Chapter 115), and up to 25% of women with fecal incontinence have at least one associated pelvic floor disorder.

Normal continence involves the coordinated interaction between multiple different neuronal pathways and the pelvic and perineal structures. In addition, several factors including bowel motility, stool consistency, evacuation efficiency, mental status, and sphincter integrity all play a role in normal regulation.[10] Sphincter disruption related to vaginal delivery is a common cause that often affects young women; many incontinent women who present later in life have an underlying sphincter injury for which they can no longer compensate. Other causes of incontinence include fecal impaction, surgical or traumatic sphincter injury, rectal prolapse, neurologic disorders (e.g., diabetic neuropathy, stroke, multiple sclerosis, brain or spinal cord injury), chronic diarrheal states, dementia, impaired mobility, and poor access to toilet facilities.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Because fecal incontinence is a symptom and not a disease, the diagnosis is based on history alone. Specific evaluation of the incontinent patient can include anal manometry, anal ultrasound, pudendal nerve testing, and defecography. Anal endoscopic ultrasonography, which is generally a helpful test, accurately depicts sphincter anatomy and reliably identifies sphincter defects. Some patients with fecal incontinence may have concomitant disorders such as impaired evacuation, pelvic prolapse, or urinary incontinence; urogynecologic evaluation should be performed when appropriate.

TREATMENT

Mild incontinence is often treated successfully by the addition of a fiber supplement to make stools less liquid and the use of an antimotility agent, such as loperamide 2 to 4 mg up to four times daily, to treat diarrhea. Biofeedback also is sometimes successful.

For individuals with significant sphincter disruptions, surgical repair (sphincteroplasty) usually leads to substantial improvement (Fig. 131-5). Unfortunately, this improvement tends to wane over time, so sacral nerve modulation, which requires placement of an electrical lead into the S3 sacral foramen and implantation of an electrical stimulator, is usually a better option. Sacral nerve modulation is highly effective for fecal incontinence,[11] with about 40% of patients regaining continence and another 45% noting improvement at 36 months.

For patients without a sphincter defect, sacral nerve modulation is one option, but another option is transanal submucosal injection of dextranomer in stabilized hyaluronic acid. These injections add bulk to the perianal tissues, thereby allowing the perianal tissues to coapt together. As a result, injection therapy is most effective in patients who have a small amount of leakage and not loss of full bowel movements. After two treatments of four injections each, reported fecal incontinence decreases by about 50%, but many patients require repeat injections. This treatment should not be used in patients who are immunosuppressed or who have had prior radiation therapy, rectal prolapse, or inflammatory bowel disease.

For patients with severe refractory incontinence, creation of a colostomy should be strongly considered. Initial reluctance notwithstanding, most patients regain control of their bowel function and report a substantially improved quality of life.

RECTAL PROLAPSE

EPIDEMIOLOGY AND PATHOBIOLOGY

Rectal prolapse is a full-thickness protrusion of the rectum beyond the anal sphincter. It occurs in about 1% of adults over age 65 years, and about 90% of cases are in women. Prolapse is caused by an internal rectal intussusception that eventually becomes more severe and then progresses so that the full thickness of the rectal wall protrudes externally. Risk factors include multiparity, a history of pelvic surgery, higher body mass index, chronic diarrhea or constipation with significant straining, connective tissue disorders, and neurologic diseases. Uncorrected prolapse also frequently leads to fecal incontinence by mechanically stretching the sphincter complex and causing a stretch injury to the pudendal nerves, with frank loss of fecal material when the rectal mucosa prolapses externally.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The main clinical manifestation of rectal prolapse is the protruding rectal mass (Fig. 131-6). The protrusion most commonly occurs with bowel movements, but with time it may occur with coughing or sneezing, and eventually it can occur spontaneously. Approximately 75% of patients have at least minor complaints of fecal incontinence, whereas complaints of "constipation,"

FIGURE 131-6. Rectal mucosal prolapse. The main clinical manifestation of rectal prolapse is the protruding rectal mass.

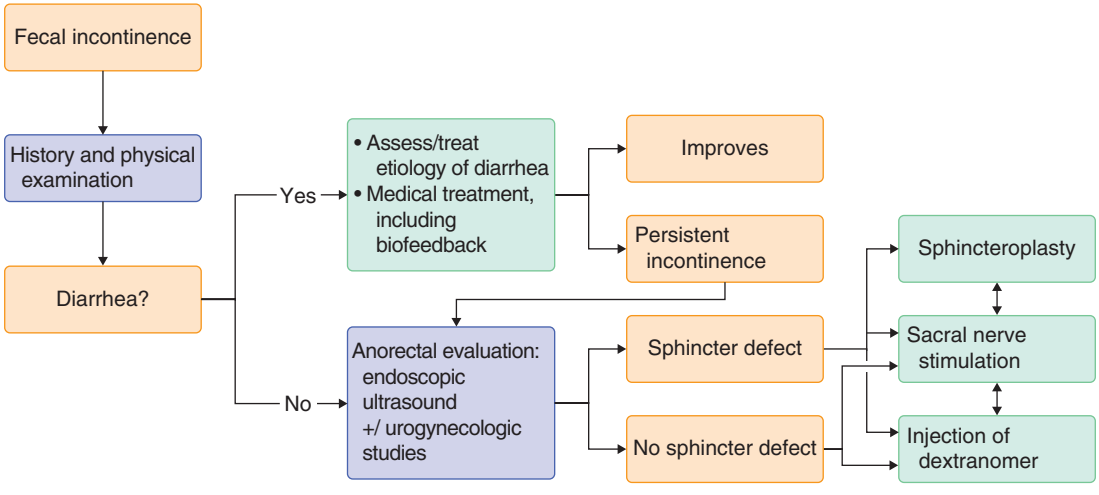

FIGURE 131-5. Algorithm for fecal incontinence. (Adapted from Madoff RD, Parker SC, Varma MG, et al. Fecal incontinence in adults. *Lancet*. 2004;364:621-632.)

which are often caused by unsuccessful attempts to evacuate the intussusceptingrectum, occur in 15 to 65%. Other associated symptoms include chronic mucus discharge, pelvic discomfort, and minor bleeding. Patients can also rarely present with an incarcerated or strangulated prolapse that mandates urgent intervention.

The diagnosis of rectal prolapse is confirmed on physical examination. Full-thickness prolapse, which is characterized by concentric mucosal folds of the rectum, must be differentiated from circumferential mucosal prolapse, which is characterized by radial folds alone. The prolapse is often best demonstrated by having the patient strain on a commode. Ancillary studies do not routinely alter management, but colonoscopy should be performed to help exclude other pathology. Defecography is also helpful to diagnose internal rectal intussusception and associated pelvic floor abnormalities, such as rectocele and enterocele.

TREATMENT

Nonoperative measures will not correct rectal prolapse, so conservative measures should be considered only in patients who have very minor and minimally symptomatic prolapse or who are poor surgical candidates. A ventral rectopexy with mesh (either biologic or nonabsorbable), which involves mobilizing the rectum anteriorly, suturing the mesh to the anterior rectal wall, and then fixing the mesh to the sacrum, is the procedure of choice. This operation, which can be performed laparoscopically or robotically, can help to correct rectoceles and is associated with less postoperative constipation and recurrence than prior surgical alternatives.[A5]

HUMAN PAPILLOMAVIRUS

EPIDEMIOLOGY AND PATHOBIOLOGY

Human papillomavirus (HPV), which is the most common sexually transmitted infection, is a cause of anal dysplasia and cancer. The approximately 40 HPV subtypes that can cause anogenital infections are divided into low-risk types (e.g., types 6 and 11) that cause anal warts (condyloma acuminata) and high-risk types (e.g., types 16, 18, and 33) that can cause anal dysplasia and cancer. HPV infection is associated with cervical, vulvar, vaginal, and penile cancers, and some patients have HPV-related dysplasia or cancer in multiple sites. Over 90% of anal cancers are attributable to HPV infection.

The incidence of anal cancer has been steadily increasing, from 0.6 per 100,000 in 1973 to 1.0 per 100,000 in 2001 and 2.0 per 100,000 in 2018. In the United States alone, an estimated 9090 individuals develop anal cancer annually, and approximately 1400 will die from it.[12] These epidemiologic trends have been attributed to a particularly rapid increase in anal cancers among men who have sex with men, especially men infected with HIV. Anal HPV, including the high-risk serotypes, is highly prevalent in at-risk populations (sex workers, intravenous drug users, transplant recipients, men who have sex with men, and HIV-positive men and women). Furthermore, anal dysplasia is common in at-risk populations, as evidenced by the 30 to 50% prevalence of high-grade anal dysplasia among HIV-positive men who have sex with men seen in specialty clinics in New York and San Francisco. Other associated risk factors for both dysplasia and anal cancer include a history of other HPV-related genital dysplasia or malignancy (cervical, vaginal, or vulvar), prior sexually acquired diseases, anoreceptive intercourse, multiple sexual partners, and cigarette smoking.

ANAL WARTS

CLINICAL MANIFESTATION AND DIAGNOSIS

Anal warts can occur in the perianal skin and within the anal canal. The lesions are raised, epithelialized (when external), and narrow based. Their spectrum of appearances can range from scattered individual warts to a confluent mass of warts (Fig. 131-7).

TREATMENT

External warts can be treated with topical podophyllin or imiquimod, but extensive warts usually require surgical excision or fulguration. Untreated warts can rarely progress to form Bushke-Löwenstein tumors—giant, locally invasive condyloma acuminata that frequently contain in situ or invasive cancer. Anal warts, especially in high-risk patients, have a high risk of recurrence, can progress to dysplasia and anal cancer,[13] and often require multiple local treatments and ongoing surveillance to prevent cancer.

FIGURE 131-7. Anal condyloma. These can occur as individual warts or as a confluent mass.

ANAL CANCER

Anal cancer is almost always a manifestation of HPV infection (Chapter 344), especially HPV 16 and 18.[14] Other significant but less common anal cancers include adenocarcinoma, melanoma, and Paget disease.

Anal cancer is a common problem in the HIV-positive population, especially in men who have sex with men. In the United States, anal cancer is nearly 20 times more common in HIV-positive individuals than in the uninfected population. However, the incidence has been declining by 7% per year since 2008, presumably because of more effective antiretroviral therapy. Other independent risk factors include low nadir CD4 counts, alcohol use, and smoking.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptoms of anal cancer are bleeding, pain, and a palpable mass. The cancer may be seen externally as an ulcerated mass or may be palpated within the anal canal. Anal dysplastic lesions may appear as anal warts or as flat, pigmented lesions, or they may be invisible to the naked eye. They are best visualized using anal microscopy after topical application of 3 to 5% acetic acid (see later). Biopsy is necessary to make the diagnosis.[15]

Thorough palpation of the inguinal lymph nodes is important to detect the presence of any clinically relevant adenopathy, but proper staging for anal canal malignancies requires a chest, abdominal, and pelvic CT scan. Pelvic MRI is useful to assess the size and depth of the lesion as well as the presence and location of any involved regional lymph nodes.

The great majority of anal cancers are variants of squamous cell carcinoma. The terms *anal dysplasia, anal intraepithelial neoplasia*, and *squamous intraepithelial lesion* differ slightly but have often been used interchangeably. Squamous intraepithelial lesions are divided into low-grade (LSIL) and high-grade (HSIL) groups; the former may be transient, but the latter are generally considered to be premalignant even though they may clear spontaneously in about 20% of patients, especially patients below age 45 years without persistent HPV16.[16] Anal intraepithelial neoplasia (AIN), an older term that is being supplanted by the squamous intraepithelial terminology, is divided into grades 1, 2, and 3, with grades 2 and 3 being classified as high-grade lesions. Squamous cell carcinoma in situ corresponds to high-grade squamous intraepithelial lesion and grade 3 anal intraepithelial neoplasia.

Squamous cell carcinoma of the anus is divided into two groups based on tumor location: cancers of the anal margin (extending from the anal orifice for a distance up to 5 cm) and cancers of the anal canal. Tumors visible externally but extending into the anal canal are considered anal canal lesions.

TREATMENT

Management of the patient with anal dysplasia is controversial. Many authorities advocate a screening and treatment approach based on that used for cervical cancer (Chapter 184), which is another HPV-associated disease. High-risk individuals are screened with anal Papanicolaou smears, and high-definition anal microscopy (analogous to colposcopy of the cervix) is performed when abnormal cytology is detected. Using this technique, dysplastic lesions can be identified and focally ablated[A6] or treated with topical imiquimod or 5-fluorouracil. Reported complete response rates vary significantly (≈30 to 80%), and side effects (pain, irritation, and ulceration) may require withdrawal of therapy. More extensive dysplasia requires microscopy-directed targeted ablation in the operating room.

Chemoradiotherapy is standard first-line treatment for squamous cell cancer of the anal canal. Current radiation protocols most frequently use 45-Gy external beam radiation therapy in 25 fractions, with a boost to the primary tumor and involved inguinal nodes to a total dose of 54 to 59 Gy. Standard chemotherapy utilizes 5-fluorouracil (1000 mg/m^2 per 24 hours, continuous infusion for 96 hours, starting on days 1 and 29) in combination with mitomycin C (most commonly 10 mg/m^2 intravenous bolus on days 1 and 29). Abdominoperineal resection with permanent colostomy is reserved for tumors that fail to respond to chemoradiation and those that recur. Similarly, groin dissection is performed only when involved inguinal nodes fail chemoradiation.

Early squamous cell cancers of the anal margin can be locally excised if a satisfactory margin can be obtained without injuring the anal sphincter and if there is no evidence of nodal spread. More advanced anal margin tumors are treated with chemoradiotherapy as described for anal canal tumors. Combined chemoradiation therapy is the primary treatment for most squamous cell carcinomas of the anal canal.

PREVENTION

In addition to its proven efficacy in the prevention of cervical neoplasia in women, HPV vaccination appears to be effective in preventing external genital lesions and intraepithelial neoplasm in HIV-uninfected men. The use of an HPV vaccine may reduce anal intraepithelial neoplasm in men who have sex with men, but it does not appear to benefit HIV-infected men.[A7]

Routine HPV vaccination is recommended at age 11 to 12 years, but it can be administered starting at age 9 years in both males and females (Chapter 15).[17] A catch-up vaccination is recommended in previously unvaccinated females between ages 13 and 26 years and in males between ages 13 and 21 years and in individuals who did not complete the vaccine series. For males 22 to 26 years, catch-up HPV vaccination is recommended in men who have sex with men and in immunocompromised men (including HIV-infected males).

OTHER SEXUALLY TRANSMITTED ANORECTAL DISEASES

A number of sexually transmitted diseases (Chapter 264) of the anorectum occur most frequently in individuals who practice anoreceptive intercourse. Common causative agents include *Treponema pallidum* (Chapter 295), *Neisseria gonorrhoeae* (Chapter 275), *Chlamydia trachomatis* (Chapter 294), herpes simplex (Chapter 345), and HIV (Chapter 353). Other sexually transmitted pathogens are *Shigella* (Chapter 285), *Campylobacter jejuni* (Chapter 279), *Haemophilus ducreyi* (Chapter 276), *Calymmatobacterium granulomatis* (Chapter 292), *Entamoeba histolytica* (Chapter 323), *Giardia lamblia* (Chapter 322), and *Isospora belli* (Chapter 324).

The widely variable presentations range from asymptomatic to anal pain, pruritus, discharge, fever, cramps, and bloody diarrhea. Clinical suspicion followed by appropriate and specific testing is necessary to make the correct diagnosis, and clinicians should consider the possibility of simultaneous infections. Treatment addresses the specific infection.

132 APPROACH TO THE PATIENT WITH LIVER DISEASE

PAUL MARTIN

The liver serves multiple key functions, including metabolism of the products of ingested food, production of amino acids to form proteins, detoxification of ingested drugs, conversion of nitrogenous substances from the gut into urea, formation of clotting factors, metabolism of bilirubin, processing of lipids absorbed from the intestine, and excretion of its products as bile. The liver also stores glycogen, which is a source of glucose, and helps contain infections by removing bacteria from the blood stream. These diverse functions reflect the activities of hepatocytes, bile duct cells called cholangiocytes, Kupffer cells, endothelial cells, and portal fibroblasts.

The liver has a dual blood supply: 70% is delivered by the portal vein, which drains the intestine, and the remainder is delivered by the hepatic artery. After arrival in the liver, nutrient-rich portal blood passes along the hepatic sinusoids in close contact with lining hepatocytes before draining into the hepatic vein. The hepatocytes detoxify, metabolize, and synthesize the products of digestion. Bilirubin, which is produced by breakdown of red cells and other hemoproteins by reticuloendothelial cells predominantly in the liver and spleen, is transported to the hepatocytes, bound to albumin, and solubilized by them for biliary excretion.

Liver disease causes loss of hepatocellular capacity, with diminished detoxification, excretory, and synthetic functions. Hepatocyte dysfunction results in impaired production of clotting factors, albumin, and other proteins, as well as reduced endogenous formation of lipids. Hepatocyte injury from a variety of causes, including viruses, alcohol, autoimmune disorders, and drug hepatotoxicity, is accompanied by leakage of cellular enzymes into the systemic circulation (Chapter 133). Coagulopathy, decreased serum albumin, and hyperbilirubinemia are observed with more profound hepatocellular injury. Portal hypertension occurs because of disruption of the low-pressure intrahepatic blood flow from the portal to the systemic venous circulation owing to hepatic fibrosis. Consequences of portal hypertension include accumulation of abdominal ascites and the development of portal-systemic venous collaterals with portal-systemic shunting, with formation of varices and development of hepatic encephalopathy. Vascular disorders, including portal vein thrombosis, can result in portal hypertension in the absence of parenchymal liver disease.

The diversity of the liver's functions, its complicated blood supply, and its intimate relationship with the biliary tree contribute to the divergent manifestations of liver disease. The initial complaint often reflects whether the cause is diffuse, such as acute viral hepatitis with widespread hepatocyte injury that manifests as malaise or fatigue, or whether the cause is discrete, such as when biliary obstruction from a gallstone in the common bile duct manifests as severe abdominal pain. Patients may present with multiple complaints, such as nausea and anorexia owing to hepatocellular disease accompanied by right upper quadrant discomfort due to stretching of the hepatic capsule by parenchymal cell edema and inflammation. Patients with more advanced liver disease, such as decompensated cirrhosis (Chapter 139), may have substantial hepatocellular dysfunction with jaundice and coagulopathy in addition to portal hypertension with ascites and bleeding esophageal varices. Many patients who present with hepatic symptoms or signs may have extrahepatic disease; for example, a tender, enlarged liver may be caused by a systemic disorder, such as heart failure with hepatic congestion, rather than a primary hepatic disorder. In patients with cirrhosis, the initial presentation of previously unrecognized liver disease may be a major complication such as variceal hemorrhage, which in turn can precipitate hepatic encephalopathy and other features of frank hepatic decompensation.

HISTORY

Patients with liver disorders come to medical attention for a variety of reasons,[1] ranging from the incidental discovery of abnormal liver chemistries[2] to decompensated cirrhosis. Many complaints related to liver disease, such as fatigue, are nonspecific; unless liver disease is considered in the differential diagnosis, recognition of the hepatic origin of these complaints may be delayed.

In clinical practice, a frequent manifestation of asymptomatic liver disease is discovery of abnormal liver biochemistries during a life insurance application, annual physical examination, or attempt to donate blood. It is important to inquire about occasions when liver biochemistries may have been obtained to determine whether hepatic dysfunction is long-standing or more recent. In a patient with hepatic dysfunction, inquiry should be made about the presence of malaise, anorexia, fatigue, and weight change. Jaundice (Chapter 133) is a dramatic manifestation of possible liver disease. A patient may first notice lighter-colored stools or dark urine rather than scleral icterus. The absence of these latter changes suggests that unconjugated hyperbilirubinemia is due to hemolysis rather than intrinsic liver disease. Not infrequently, a patient may be unaware of jaundice until it is noted by others.

Abdominal pain (Chapter 118) related to liver disease can have a variety of explanations. Symptomatic gallstones (Chapter 141) can present with the abrupt onset of severe epigastric or right upper quadrant discomfort, often after a large meal and frequently associated with nausea and vomiting. The pain is often steady rather than colicky and can radiate widely, including to the chest and back. A patient may not be able to achieve a position that lessens the pain, which may last several hours. More persistent pain, particularly if associated with weight loss and jaundice, raises concern about malignant bile duct obstruction. Pain is also common in parenchymal liver disease in the absence of biliary tract disease. Many patients with chronic hepatocellular disorders, such as chronic hepatitis C (Chapter 135) or nonalcoholic fatty liver disease (NAFLD) (Chapter 138), complain of vague right upper quadrant discomfort that has no particular relieving or aggravating factors. Abdominal pain, which can be severe, is also frequent in acute viral hepatitis (Chapter 134), as well as with the hepatic congestion that results from back pressure in heart failure or hepatic vein occlusion, as in Budd-Chiari syndrome (Chapter 129).

Fatigue, anorexia, and malaise can be present in both acute and chronic liver disease. In acute liver disorders such as acute viral hepatitis (Chapter 134), drug-induced liver disease (Chapter 136), or an acute manifestation of autoimmune hepatitis (Chapter 135), patients may report profound fatigue, nausea, and malaise with decreased appetite and substantial associated weight loss. Distaste for cigarettes is said to be characteristic of acute viral hepatitis. Fatigue is also prominent in chronic liver disease such as chronic hepatitis C (Chapter 135). Pruritus is a prominent feature of cholestatic disorders, such as primary biliary cirrhosis, sclerosing cholangitis, or cholestatic drug reactions, particularly when patients are frankly icteric; however, pruritus also occurs in chronic parenchymal liver disease, most notably chronic hepatitis C, and in acute viral hepatitis. Easy bruising in patients with liver disease reflects coagulopathy and/or thrombocytopenia.

Fever in a patient with hepatic dysfunction is experienced in the prodrome of acute hepatitis A, as well as in alcoholic hepatitis and drug-induced liver disease. In a patient with suspected biliary obstruction, fever suggests complicating bacterial cholangitis or acute cholecystitis. Ascites is most frequently a manifestation of cirrhosis and portal hypertension in a patient with liver disease. Patients note increasing abdominal girth, which may be preceded by ankle edema. Weight gain owing to fluid retention may be masked by concomitant loss of muscle mass. The onset of ascites in the absence of a history of liver disease suggests a vascular event, such as hepatic vein occlusion (Chapter 129), or a nonhepatic cause of ascites, such as nephrotic syndrome or heart failure. Accumulation of ascites in a patient with liver disease may be subtle, with a slowly increasing waist circumference, or it may be more rapid, such as in a cirrhotic patient who receives fluid resuscitation after gastrointestinal bleeding. Although ascites in a patient with liver disease implies the presence of cirrhosis, ascites also can complicate severe acute liver disease, including alcoholic hepatitis and viral hepatitis, in which it suggests a poor prognosis.

Hepatic encephalopathy (Chapter 139), which is a neuropsychiatric disorder in patients with liver disease, can range from subtle cognitive impairment to deep coma.[3] Early symptoms include a disturbed sleep pattern with nocturnal insomnia and daytime somnolence. More advanced encephalopathy can result in impairment of memory, confusion, and difficulty completing routine tasks. However, new-onset confusion or coma in a patient with liver disease should not be presumed to reflect hepatic encephalopathy unless other explanations, such as sedative overdose or subdural hematoma, have been excluded. Important precipitants of hepatic encephalopathy in a cirrhotic patient include gastrointestinal bleeding, bacterial infection (e.g., spontaneous bacterial peritonitis), electrolyte imbalance, and renal insufficiency, all of which need to be excluded during the initial clinical evaluation. In a patient with acute liver failure, coma as a consequence of cerebral edema may be impossible to distinguish from advanced hepatic encephalopathy unless the increased intracranial pressure results in papilledema.

Gastrointestinal hemorrhage resulting from bleeding varices is usually profuse and often abrupt in onset. It typically presents with hematemesis or

ABSTRACT

The liver has a variety of important roles, including metabolism of food products from the gut, synthesis of proteins and clotting factors, detoxification of drugs, processing of lipids and bilirubin, and formation of bile. It also stores glycogen for conversion into glucose and helps contain infection by removing bacteria from the blood stream. Liver disease can result from a diffuse insult such as acute viral hepatitis or a more discrete process such as obstruction of the common bile duct by a gallstone. The pattern of the biochemical abnormality can provide important clues to the possible cause. Physical examination can elicit signs of chronic liver disease and portal hypertension, as well as more acute presentations such as a tender gallbladder in acute cholecystitis. An asymptomatic liver mass is a common clinical scenario, and its nature can often be determined by imaging. A number of hereditary disorders have prominent hepatic features, including Wilson disease, hemochromatosis, and alpha-1-antitrypsin deficiency.

jaundice
ascites
liver mass

melena (Chapter 121), and frequently coexisting postural hypotension or presyncope indicates major blood loss. The increased protein load in the gut can precipitate hepatic encephalopathy. Nonvariceal causes of gastrointestinal bleeding in a patient with liver disease include portal gastropathy (Chapter 121).

RISK FACTORS FOR LIVER DISEASE

An important aspect of the history is identification of possible risk factors for liver disease. The history should include directed questioning about alcohol consumption, including frequency and pattern (Chapter 364). The age of initial alcohol use and whether consumption has increased with age should be ascertained. Family members also should be asked about their perception of the patient's alcohol use and whether it has resulted in difficulties in personal relationships or work performance. Other clues to alcohol abuse are a history of convictions for driving under the influence of alcohol, motor vehicle accidents, and physical symptoms of alcohol dependence (Chapter 364). More circumspect questioning may be required to elicit a history of recreational drug use. Not infrequently, a patient with suspected viral hepatitis admits to smoking marijuana or snorting cocaine but does not acknowledge intravenous drug use. With the increasing frequency of nonalcoholic fatty liver disease as a cause of hepatic dysfunction (Chapter 138), comorbid conditions such as diabetes mellitus, hyperlipidemia, sleep apnea, and weight gain should be noted.

Medication use, whether prescription or over-the-counter, must be assessed because drug-induced liver disease is an important cause of apparently cryptogenic hepatic dysfunction and is not limited to therapeutic drugs (Chapter 136).[1] Increasingly, herbal and "natural" products (Chapter 30) are ingested for a variety of maladies, and patients may fail to disclose their use because they do not perceive these agents to have side effects or may sense that the physician does not endorse their use. As with alcohol, it is important to quantify the amount of medication ingested and over what period. The social history should include details about recent travel and contact with individuals with viral hepatitis through intimate, household, or occupational contact. It is also important to ask about vigorous physical activity that can result in elevated aminotransferase levels of nonhepatic origin.

ASSESSING DURATION OF LIVER DISEASE

The differential diagnosis in a patient with liver disease is determined to a large extent by the presentation, such as jaundice or ascites. In many patients, however, the timing of more subtle findings such as elevated aminotransferases is difficult to determine. Prior blood test results should be retrieved to determine whether hepatic dysfunction is long-standing or more recent. Hepatic dysfunction of less than 6 months' duration is regarded as acute and is frequently self-limited, whereas abnormalities that persist for more than 6 months are unlikely to resolve spontaneously. If the patient has had a cholecystectomy, it is important to determine the indication. Incidental gallstones are sometimes assumed to be the cause of abnormal liver chemistries in a patient with parenchymal liver disease and can lead to an unnecessary cholecystectomy. Thrombocytopenia owing to portal hypertension in a patient with unrecognized cirrhosis may have been investigated in the past without a firm conclusion being reached.

REVIEW OF OTHER ORGAN SYSTEMS

While focusing on liver-related symptoms, it is important not to overlook other diagnostic clues, associated disorders, and complications. Sicca symptoms, including dry eyes and mouth, are common in primary biliary cholangitis (Chapter 141); florid features of scleroderma and CREST syndrome (Chapter 246) are other associations. Dyspnea in a patient with hepatic dysfunction may reflect cardiac failure with hepatic congestion (Chapter 45). Other explanations include hepatopulmonary syndrome (Chapter 139), with the characteristic complaint of platypnea-dyspnea (often with chest tightness) that is worse in the upright position owing to aggravation of the ventilation-perfusion mismatch because of intrapulmonary shunting. A hydrothorax in decompensated cirrhosis can cause dyspnea, as can emphysema in patients with liver disease caused by α_1-antitrypsin deficiency. A history of premature menopause is common in middle-aged women with cirrhosis, as is decreased libido and sexual potency in cirrhotic men. Arthralgias are often reported in viral hepatitis, and hemochromatosis (Chapter 196) may manifest with involvement of the proximal interphalangeal joints or chondrocalcinosis of the knees; increased skin pigmentation and diabetes mellitus are other features of this disorder. Accelerated osteopenia occurs in many liver diseases, including primary cirrhosis, primary sclerosing cholangitis, and alcoholic cirrhosis; osteopenia may be aggravated by corticosteroid use in autoimmune hepatitis. Alcoholic peripheral neuropathy (Chapter 384) can manifest with pain and paresthesias. Tremor and inattentiveness in a younger patient with hepatic dysfunction suggest Wilson disease (Chapter 195). Diarrhea and rectal bleeding in a patient with cholestatic liver disease suggest associated inflammatory bowel disease (Chapter 127).

FAMILY HISTORY

The family history should include an inquiry not only about relatives with liver disease but also associated extrahepatic conditions. Hereditary hepatic conditions (see later), such as Wilson disease and hemochromatosis, may occur in several members of a sibship. In α_1-antitrypsin deficiency, some family members may experience predominantly emphysema rather than cirrhosis. Similarly, renal failure in a family member of a patient with hepatic cysts suggests adult polycystic disease (Chapter 112). A family history of inflammatory bowel disease may be a clue to primary sclerosing cholangitis in a patient with cholestatic liver chemistries. The history in patients with suspected alcoholic liver disease may reveal other family members with alcoholism.

PHYSICAL EXAMINATION

GENERAL CONDITION

In a patient with suspected liver disease, it is crucial to resist the temptation to palpate the abdomen immediately, thus potentially ignoring other important diagnostic clues. Apart from seeking icterus, the initial observation should note whether muscle wasting, cutaneous stigmata of liver disease, abdominal distention, and peripheral edema are present. The vital signs may reflect the hyperdynamic circulation characteristic of cirrhosis, with a resting tachycardia, wide pulse pressure, and low blood pressure resulting from peripheral vasodilation. Fetor hepaticus, which is described as a musty smell, may be detected when a cirrhotic patient exhales and must be distinguished from more frequent halitosis caused by poor dental hygiene.

MUCOCUTANEOUS FINDINGS

Icterus (Fig. 132-1) is best confirmed by examination of the sclera or, if necessary, under the tongue, where elastin tissue retains bilirubin. Grayish skin discoloration in hemochromatosis may be most evident in the skin folds in the groin or axilla. Acanthosis nigricans can be observed in nonalcoholic fatty liver disease (Chapter 138). A Kayser-Fleischer ring (see Fig. 195-2), caused by the deposition of copper in the Descemet membrane, is a brownish circle around the periphery of the iris and may require slit lamp examination to detect; it always should be sought in a patient with suspected Wilson disease (Chapter 195). Poor dentition is characteristic in alcoholic or drug-abusing individuals, and excessive dental caries may result from decreased saliva production in sicca syndrome. Parotid gland swelling is occasionally observed in alcoholic patients. Central cyanosis and clubbing are found in the hepatopulmonary syndrome. Temporal muscle wasting and "paper money" facial skin, owing to atrophy with telangiectasia, are signs of advanced liver disease. Xanthelasma from lipid deposits may be observed on the eyelids and skin around the orbits in patients with cholestatic liver disease. Spider nevi on the face and thorax are not pathognomonic of liver disease, especially in women, but they are suggestive if more than a few are present. Palmar erythema (Fig. 132-2) may be normal in women but suggests liver disease in men. Dupuytren contracture (see Fig. 138-1), the retraction of the palmar fascia with subsequent contracture of the palms and fingers, can be a sign of alcoholic liver disease, although it

FIGURE 132-1. Scleral icterus.

FIGURE 132-2. Palmar erythema.

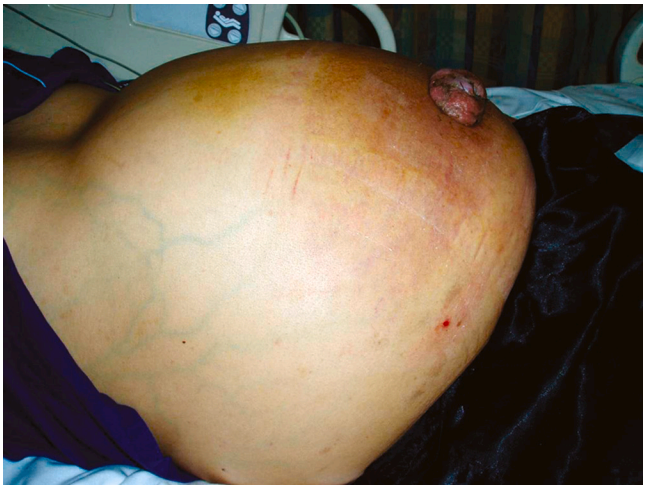

FIGURE 132-4. Ascites.

FIGURE 132-3. Caput medusae. Photograph shows caput medusae accentuated by a large amount of ascites in a patient being prepared for liver transplantation. An extensive plexus of veins is seen emanating from the umbilical region and radiating across the anterior abdominal wall. Note the large vein coursing inferiorly along the right flank (*arrows*). This is the superficial epigastric vein, which drains into the external iliac vein. (From Henseler KP, Pozniak MA, Le FT, et al. Three-dimensional CT angiography of spontaneous portosystemic shunts. *Radiographics*. 2001;21:691-704.)

is also described in patients with epilepsy or diabetes mellitus, as well as in individuals who have work-related contractures. Petechiae and ecchymoses reflect impaired production of clotting factors and hypersplenism in advanced liver disease. Patches of white discoloration on the nails may be present in advanced liver disease. Scratch marks from pruritus may be observed on the trunk and extremities of patients with cholestatic liver disease. Sparing of the center of the back can lead to a less pigmented butterfly-shaped area because patients cannot reach that area with their fingernails.

EXAMINATION OF THE ABDOMEN

Abdominal distention with ascites and dilation of collateral veins owing to portal hypertension represent florid signs of advanced liver disease. Caput medusae (Fig. 132-3) in the periumbilical area implies recanalization of the umbilical vein with portal hypertension.

Abdominal percussion may confirm the presence of ascites (Fig. 132-4). Shifting dullness results from movement of ascites to the most dependent portion of the abdomen. The subject should be examined in the supine position, with percussion of the abdomen from the midline toward the right or left flank. A change from a tympanic sound to a dull sound signifies a change from air to fluid, and the location of that change identifies the surface of the fluid pool. Next, the examiner should percuss below the point at which dullness is elicited and ask the subject to turn toward the examiner. With the subject on his or her side, the examiner percusses again at the same point where tympany converted to dullness. If that spot is now tympanic, shifting dullness has been detected as a result of movement of the air-fluid boundary; this finding supports the presence of ascites. This maneuver should be performed sequentially on each side for confirmation. A fluid wave can be felt by placing the medial border of one hand on the abdomen and tapping the right or left lateral abdominal walls; the resulting wave is felt by the first hand. Scrotal edema and abdominal wall hernias are often present in patients with long-standing ascites. Abdominal tenderness in a patient with ascites suggests peritonitis (e.g., spontaneous bacterial peritonitis or the result of a perforated viscus). However, it is important to note that abdominal tenderness is frequently absent in spontaneous bacterial peritonitis.

The liver is dull to percussion. Percussion of the right upper quadrant can determine the liver span, normally 6 to 12 cm in the midclavicular line. The liver span may be diminished in a patient with cirrhosis, whereas hepatomegaly (Fig. 132-5) is detected in hepatic congestion resulting from heart failure, nonalcoholic fatty liver disease, and cholestatic forms of cirrhosis. The liver is best examined with the patient in the supine position, arms parallel to the side of the body and knees bent to relax the abdominal muscles. Palpation should begin in the right lower quadrant of the abdomen and move upward toward the rib cage so that the liver edge is felt on the way up. A normal liver edge is smooth and sometimes slightly tender when palpated. In general, a liver edge that is felt up to 2 cm below the right costal margin is considered normal, but a normal-sized liver can be displaced downward by other abnormalities, such as emphysema. In thin subjects, the liver edge may be felt on deep inspiration, even if it is normal in size.

The liver can feel hard and irregular, as in cirrhosis, or slightly tender, enlarged, and smooth, as in acute viral hepatitis, alcoholic hepatitis, or hepatic congestion, as occurs with right heart failure. The liver can extend across the midline, and the left lobe can be felt in the epigastrium. When the location of the edge of the liver is unclear, the scratch test may be more accurate than palpation.[A1] The bell of the stethoscope is placed on the right upper quadrant over the rib cage while scratching the surface of the abdominal wall from the mid-abdomen toward the liver; the sound of the scratch is amplified in an area under which the liver lies. In the presence of ascites, the liver edge may be detected by exerting quick pressure with the fingertips below the rib cage.

A palpable gallbladder suggests obstruction of the biliary system, whereas tenderness elicited by palpation during inspiration (the Murphy sign) suggests acute cholecystitis. Marked hepatic tenderness with hepatomegaly is observed in patients with a hepatic abscess (Chapter 137).

Splenomegaly (Chapter 154) is suggested by dullness to percussion between the 9th and 11th ribs in the left midaxillary line. A palpable spleen tip implies portal hypertension in a patient with chronic liver disease, although an enlarged spleen also can be detected in acute viral hepatitis and infiltrative disorders that involve both the liver and the spleen (see Table 154-5). Rectal examination is obligatory if gastrointestinal bleeding is suspected because of melena, anemia, or unexplained hepatic encephalopathy.

COMPLETE PHYSICAL EXAMINATION

The presence of rales and elevation of the jugular venous pressure suggest heart failure or pericardial disease as a cause of hepatic congestion.[5] Loss of secondary sexual characteristics in liver disease is reflected by a loss of axillary and

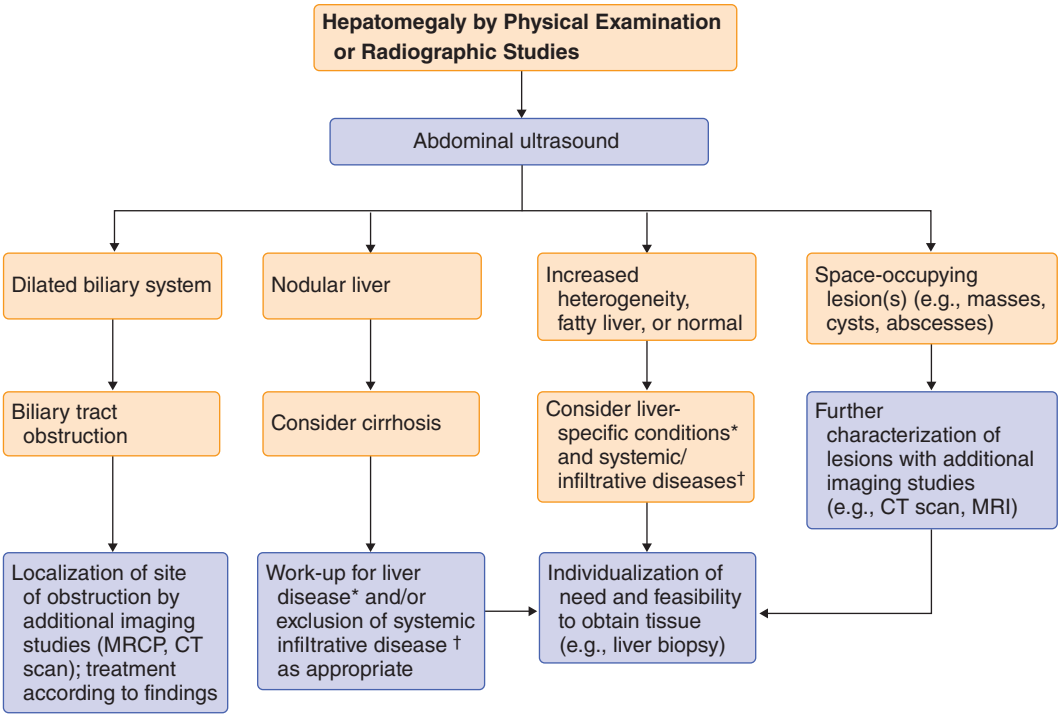

FIGURE 132-5. Diagnostic approach to hepatomegaly. *Conditions to be excluded include viral hepatitis, alcohol- and drug-induced liver disease, steatohepatitis, autoimmune liver diseases, and metabolic disorders, including hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency. †Systemic and infiltrative diseases include amyloidosis, lymphoma, sarcoidosis, and infectious processes such as disseminated tuberculosis and fungemia. CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging.

TABLE 132-1 APPROACH TO COMMON HEPATIC COMPLAINTS

PRESENTATION	COMMON SYMPTOMS	COMMON PHYSICAL SIGNS	DIAGNOSTIC STUDIES	COMMON DIAGNOSES
Ascites	Abdominal distention and pain, ankle edema	Flank dullness Shifting dullness Fluid wave	Ultrasound with Doppler Diagnostic paracentesis Urinalysis	Cirrhosis Budd-Chiari syndrome Heart failure Nephrotic syndrome
Hepatic encephalopathy	Sleep disorientation, confusion, coma	Asterixis Altered mentation Fetor hepaticus	Serum ammonia Blood cultures Stool Hemoccult Serum creatinine and electrolytes	Decompensated cirrhosis Acute liver failure Other metabolic encephalopathies (renal, respiratory)
Hepatic mass	None or abdominal pain	Hepatic bruit or rub	α-Fetoprotein Ultrasound CT scan MRI Biopsy	Benign lesions: Hemangioma, adenoma, focal nodular hyperplasia Malignant lesions: Hepatocellular carcinoma, cholangiocarcinoma, metastases
Abdominal pain	Nausea, vomiting, fever	Right upper quadrant tenderness Palpable gallbladder Murphy sign	Ultrasound HIDA scan Paracentesis for ascites if present	Biliary colic Acute cholecystitis Hepatic congestion Hepatic metastases

CT = computed tomography; HIDA = hepatobiliary iminodiacetic acid; MRI = magnetic resonance imaging.

pubic hair, as well as feminization of body habitus in a male patient. Testicular atrophy also may be present. Peripheral edema is common in decompensated cirrhosis and may occur before ascites is obvious.

Neuropsychiatric alterations can include subtle changes in personality or more overt hepatic encephalopathy. Constructional apraxia (e.g., inability to draw a five-pointed star or to write legibly) in a fully conscious patient is a typical finding in hepatic encephalopathy. Asterixis, which is characterized by a series of extensor and flexor wrist movements, can be elicited by having the patient extend the arms, with dorsiflexion of the wrists, while separating the fingers for at least 15 seconds. Tremors (Chapter 379) are nonspecific but are also common in advanced cirrhosis.

DIAGNOSTIC STUDIES (TABLE 132-1)

LABORATORY STUDIES

The initial evaluation of liver disease involves a battery of blood tests, which can assess hepatic necroinflammation (serum aminotransferases), cholestatic biliary tract dysfunction (alkaline phosphatase, γ-glutamyl transpeptidase), excretory function (bilirubin), and synthetic function (coagulation factors, albumin) (Chapter 133). In hepatocellular dysfunction caused by viral hepatitis (Chapter 134), aminotransferase levels are elevated, with the serum alanine aminotransferase (ALT) level higher than the aspartate aminotransferase (AST) level. In alcoholic hepatitis (Chapter 138), AST elevation exceeds that of ALT. In patients with biliary obstruction or cholestatic liver diseases (Chapter 141), such as primary biliary cirrhosis or a cholestatic drug reaction, bilirubin and generally alkaline phosphatase levels are elevated. Impairment of synthetic function leads to a decreased serum albumin level over days to weeks. The prothrombin time, expressed as the international normalized ratio (INR), is a more sensitive test of hepatic synthetic function and becomes prolonged within several hours after a major hepatic insult. Portal hypertension owing to advanced hepatic fibrosis or cirrhosis results in a decreased platelet count resulting from hypersplenism. Although these general patterns of liver dysfunction are helpful in the initial evaluation of liver disease, they are nonspecific. For

example, a patient with a predominantly hepatocellular process and elevated aminotransferase levels may also have elevated bilirubin and alkaline phosphatase levels as well as a low serum albumin level if liver injury is severe. Nevertheless, initial blood tests should identify the predominant pattern of abnormality and direct further diagnostic evaluation with serologic studies and abdominal imaging, which should be carefully selected and focused based upon the initial clinical evaluation.

ABDOMINAL IMAGING

Plain abdominal radiographs generally do not have a major role in the evaluation of suspected liver disease. An exception is a patient with severe abdominal pain, in whom it is important to exclude a perforated viscus suggested by free air under the diaphragm.

Ultrasonography should be the initial investigation in patients with obstructive jaundice. It can confirm dilated bile ducts in patients with biliary obstruction and often can identify the cause, such as a pancreatic mass or a gallstone lodged in the common bile duct. Ultrasonography also can determine whether the hepatic parenchyma is diffusely abnormal, such as in acute viral hepatitis; it can identify bright hepatic echo texture in nonalcoholic fatty liver disease or a coarsened echo texture in cirrhosis. In addition to confirming the presence of ascites, ultrasonography can identify other signs of portal hypertension, such as splenomegaly or intra-abdominal varices. A Doppler flow study can evaluate blood flow through the portal and hepatic vessels. An ultrasound study can identify hepatic masses and distinguish a cystic mass from a solid lesion (see later). Computed tomography (CT) and magnetic resonance imaging (MRI) add greater detail to the assessment of the hepatic vasculature, hepatic masses, and hepatic vascular structures. For the evaluation of focal liver lesions, the sensitivities of ultrasonography, contrast, CT, and MRI are similar. MRI can obtain a detailed cholangiogram, thereby avoiding a more invasive endoscopic retrograde cholangiopancreatography in many patients with suspected bile duct obstruction or disease (Chapters 119 and 120).

Transient elastography assesses hepatic fibrosis by measuring liver stiffness based on the propagation of shear waves in liver tissue, and it has largely replaced liver biopsy for this purpose.[6] In addition to measuring liver stiffness, transient elastography, often combined with standard ultrasonography, can assess the degree of attenuation by fat and thereby can also estimate hepatic steatosis. Magnetic resonance–based elastography may be preferred in the presence of ascites or obesity.[7] A low stiffness score and a normal platelet count can identify patients who are at low risk for variceal bleeding.[8]

MEASUREMENT OF TRANSJUGULAR PRESSURE

Transjugular pressure measurements are indicated in patients who have atypical presentations of portal hypertension (e.g., when it is unclear whether liver disease is the cause) or occasionally to assess whether portal hypertension is severe enough to warrant prophylaxis against variceal hemorrhage (Chapter 139). A catheter is advanced under fluoroscopy into the hepatic vein, and the free hepatic venous pressure is measured. The catheter is then advanced further until it becomes "wedged" in a small hepatic vein venule. A small balloon occludes the venule, and the wedged hepatic vein pressure, which reflects hepatic sinusoidal pressure, is obtained. The portal pressure gradient, which is derived by subtracting the free pressure measurement from the wedged pressure measurement, is normally less than 5 mm Hg. Varices form at a gradient greater than 10 mm Hg, whereas ascites and variceal hemorrhage occur only when the gradient is greater than 12 mm Hg. A transjugular approach also increases the safety of liver biopsy in the presence of ascites, coagulopathy, or thrombocytopenia when standard percutaneous liver biopsy is hazardous.

LIVER BIOPSY

Although liver biopsy had been the definitive test to assess the severity of hepatic inflammation and fibrosis in diffuse hepatocellular disease, its use has diminished in large part due to the availability of transient elastography. Nevertheless, it retains an important role in the diagnosis of autoimmune hepatitis (Chapter 135), drug hepatotoxicity (Chapter 136), and small duct primary sclerosing cholangitis (Chapter 141).[9] However, because of its potential complications, such as intra-abdominal bleeding, biopsy is recommended only when less invasive testing does not yield a definitive diagnosis or prognosis or when additional information,[10] such as quantitative determination of hepatic copper in Wilson disease or hepatic iron in hemochromatosis, is necessary for definitive diagnosis (see later). Liver biopsy under radiographic guidance is also indicated if a hepatic mass cannot be characterized as benign or malignant by noninvasive means.[11]

APPROACH TO NEW-ONSET ASCITES

The three leading causes of ascites in the United States are cirrhosis (85%; Chapter 139), peritoneal malignancy (7%), and heart failure (3%; Chapter 46), with nephrotic syndrome (Chapter 107) and tuberculosis (Chapter 299) accounting for the remainder. Diagnostic paracentesis, which is the appropriate initial test, has a low complication rate, including ascitic fluid leak (in about 5% of patients with cirrhosis) and bleeding or infection (less than 2% of patients). A serum-ascites albumin gradient (defined as serum albumin concentration minus ascitic albumin concentration) level of 1.1 g/dL or greater indicates portal hypertension, with a sensitivity of 97% and specificity of 90%. If the ascitic fluid protein level is less than 2.5 g/dL, cirrhosis is the most likely cause of the portal hypertension. If the ascitic fluid protein level is more than 2.5 g/dL, heart failure is the likely cause of the portal hypertension (see Table 139-3), and the diagnosis can be confirmed by an elevated brain natriuretic protein level (Chapter 45). If the gradient is less than 1.1 g/dL and the ascitic fluid protein is low, malignancy is most likely. Malignant ascites also is usually associated with an ascitic white blood cell count greater than 500/μL. Spontaneous bacterial peritonitis (Chapter 128) is diagnosed based on an ascitic neutrophil count above 250 cells/μL or more if secondary causes of peritonitis can be excluded.

APPROACH TO A HEPATIC MASS

A hepatic mass may be discovered under a number of different circumstances and is often an incidental finding on abdominal imaging performed for another indication. The initial evaluation depends upon whether the mass is cystic or solid (Fig. 132-6).[12]

HEPATIC CYSTS

Most hepatic cysts are benign and incidental. Simple hepatic cysts are typically solitary and asymptomatic, although larger cysts may cause abdominal discomfort. Ultrasonography, which is usually diagnostic, shows an anechoic fluid-filled space, an imperceptible wall, and posterior acoustic enhancement (Fig. 132-7A and B). Worrisome features, including the presence of symptoms or increasing size, require exclusion of a cystadenoma. On ultrasound a cystadenoma is hypoechoic with irregular walls and septations. Hepatic resection is indicated because malignant transformation can occur.

Multiple hepatic cysts may suggest the presence of autosomal dominant adult polycystic disease.[13] Polycystic liver disease can occur in conjunction with polycystic kidney disease (Chapter 112) or without it. Isolated polycystic liver disease is associated with mutations in the *PRCKSCH* gene, which encodes the glucosidase 2 subunit β enzyme, and in Sec63, which is part of a large protein complex involved in protein translocation in the endoplasmic reticulum, but many other genetic mutations have also been described.[14] Adult polycystic liver disease typically is asymptomatic, although some patients note dull right upper quadrant pain, fullness, sense of a mass, and increasing abdominal girth. Rupture of a cyst, hemorrhage into a cyst, infection of a cyst, or torsion of a cyst may cause severe pain. Physical examination may include hepatomegaly, cachexia due to weight loss, and ascites. As cysts increase in number and size with age, they may become palpable. On ultrasound, multiple fluid-filled cysts are present without internal echoes unless bleeding or infection has occurred. Treatment with long-acting somatostatin analogues (e.g., lanreotide 120 mg subcutaneously every 4 weeks) can modestly reduce the volumes of liver cysts.[A2] Interventions indicated for symptoms include aspiration or resection. Polycystic liver disease usually does not result in clinical hepatic impairment, and prognosis depends on the severity of any concurrent polycystic renal disease. In some cases, however, large, symptomatic, or bleeding cysts may raise the consideration of liver transplantation,[15] often with combined kidney transplantation (Chapter 117) for associated renal cysts and kidney failure.

Caroli disease, which is a rare congenital abnormality with cystic dilation of the intrahepatic biliary tree, can be associated with cholangitis and biliary stones.[16] Many patients ultimately develop cholangiocarcinoma (Chapter 141). Magnetic resonance cholangiopancreatography demonstrates intrahepatic dilations with normal ducts in between and a normal common bile duct. Endoscopic treatment is indicated for cholangitis, although resection or liver transplantation may ultimately be required.

SOLID HEPATIC MASS

Most solid hepatic masses are asymptomatic, but some patients may have vague right upper quadrant discomfort. The abrupt onset of more severe pain suggests a complication, such as hemorrhage or rupture. The approach to a solid hepatic mass (Fig. 132-8) is influenced by the presence or absence of underlying chronic liver disease, such as chronic viral hepatitis, as well as

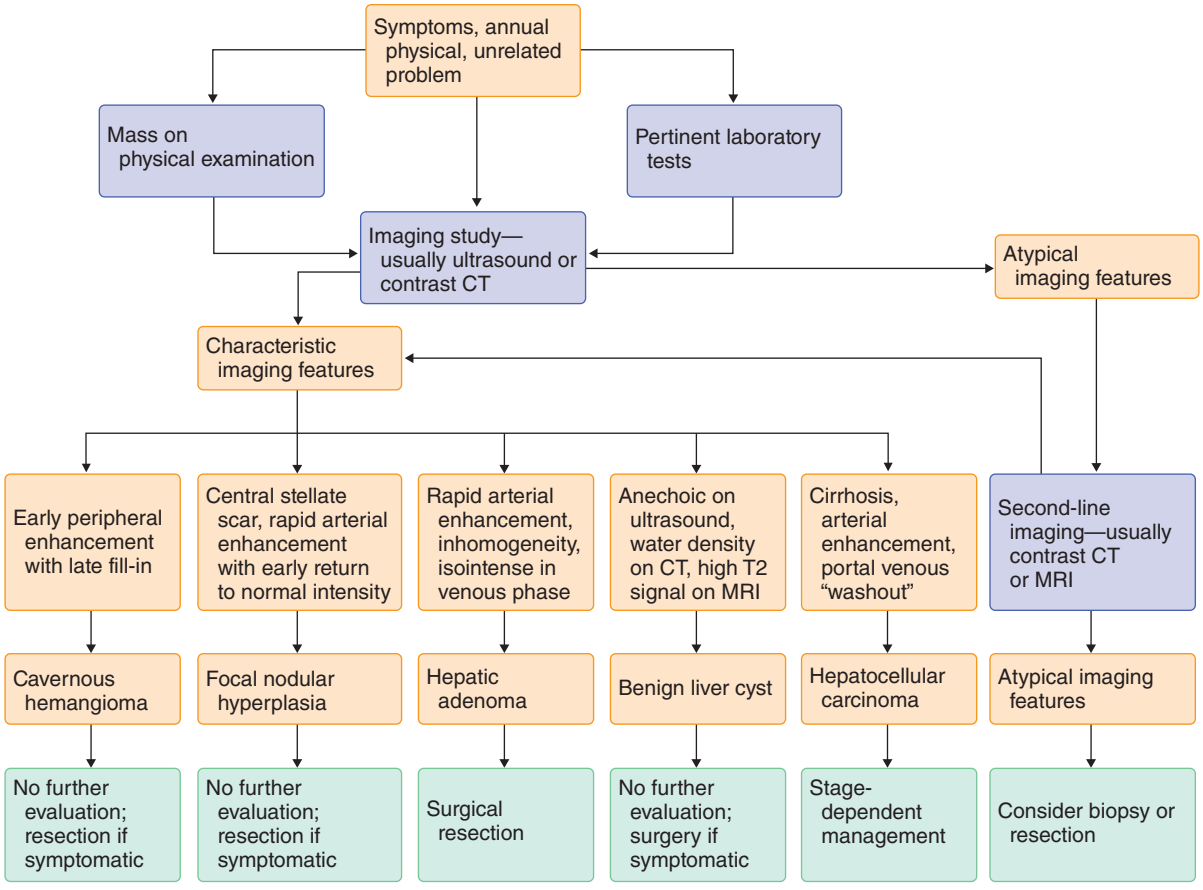

FIGURE 132-6. Approach to evaluating the patient with a mass lesion in the liver. This flowchart shows an algorithm for evaluating and managing common liver mass lesions. CT = computed tomography; MRI = magnetic resonance imaging. (From Roberts LR. Liver and biliary tract tumors. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

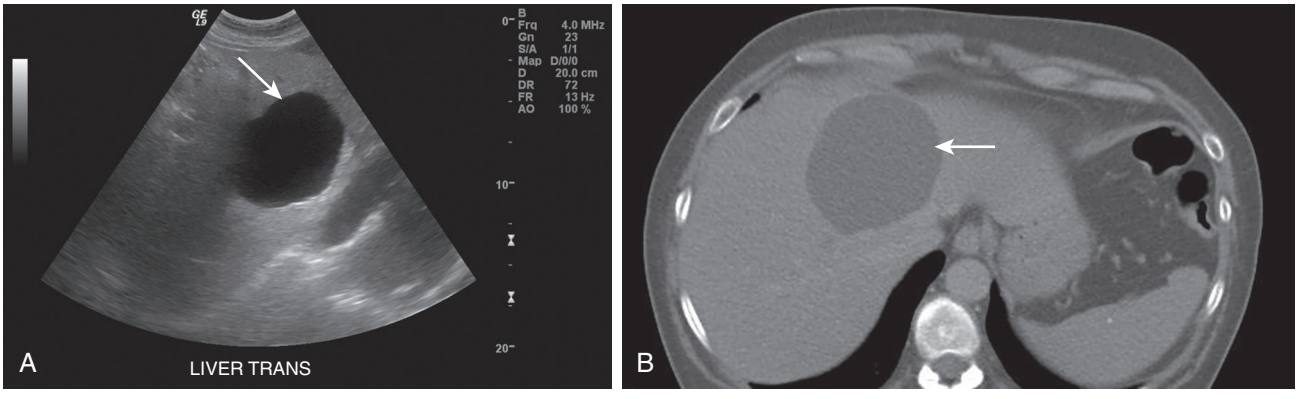

FIGURE 132-7. Simple hepatic cyst. A, Ultrasound demonstrates clear contents and an imperceptible wall (*arrow*). **B,** On a computed tomographic scan, a simple hepatic cyst is characterized by the lack of septation and an imperceptible wall (*arrow*). (Courtesy of Dr. B. Madrazo.)

whether an extrahepatic malignancy with hepatic metastases is a consideration. If chronic liver disease is present, a solid mass must be assumed to represent primary hepatocellular carcinoma (Chapter 181) until proven otherwise. By comparison, a solid lesion in the absence of underlying liver disease is more likely to be benign and incidental. Benign hepatic adenomas are commonly discovered in young to middle-aged women and are not associated with hepatic dysfunction. With modern contrast studies, it is usually possible to make a confident radiologic diagnosis about the nature of a solid hepatic mass. Important examples include the initial peripheral filling and retention of contrast dye by a hemangioma (see Fig. 132-8A, B, and C), the rapid arterial filling of a hepatocellular carcinoma with subsequent "washout" of contrast during the portal venous phase (see Fig. 181-4), or the central scar typical of focal nodular hyperplasia (see Fig. 132-8D). If a benign etiology cannot be adequately determined noninvasively, then biopsy may be necessary.

Hepatic hemangiomas are the most common benign solid hepatic mass. On ultrasound, the lesion is hyperechoic, with a typical hypervascular appearance on contrast-enhanced abdominal CT or MRI. Generally, no intervention is required unless there is a clear association with abdominal symptoms, increasing size, or a complication such as rupture.

Hepatic adenomas (Chapter 181) are benign epithelial hepatic tumors associated with the use of oral contraceptives with a higher estrogen content. On ultrasound, adenomas are hyperechoic, reflective of their fat content, but become anechoic if hemorrhage has occurred. Contrast CT and MRI show arterial enhancement and varying signal intensity reflecting steatosis and hemorrhage, if present. Biopsy may be needed for diagnosis. Potential complications of adenomas, especially if greater than 5 cm, include spontaneous hemorrhage and rupture. Malignant transformation is more common in men and in adenomas with a β-catenin exon 3 mutation. Such patients and patients

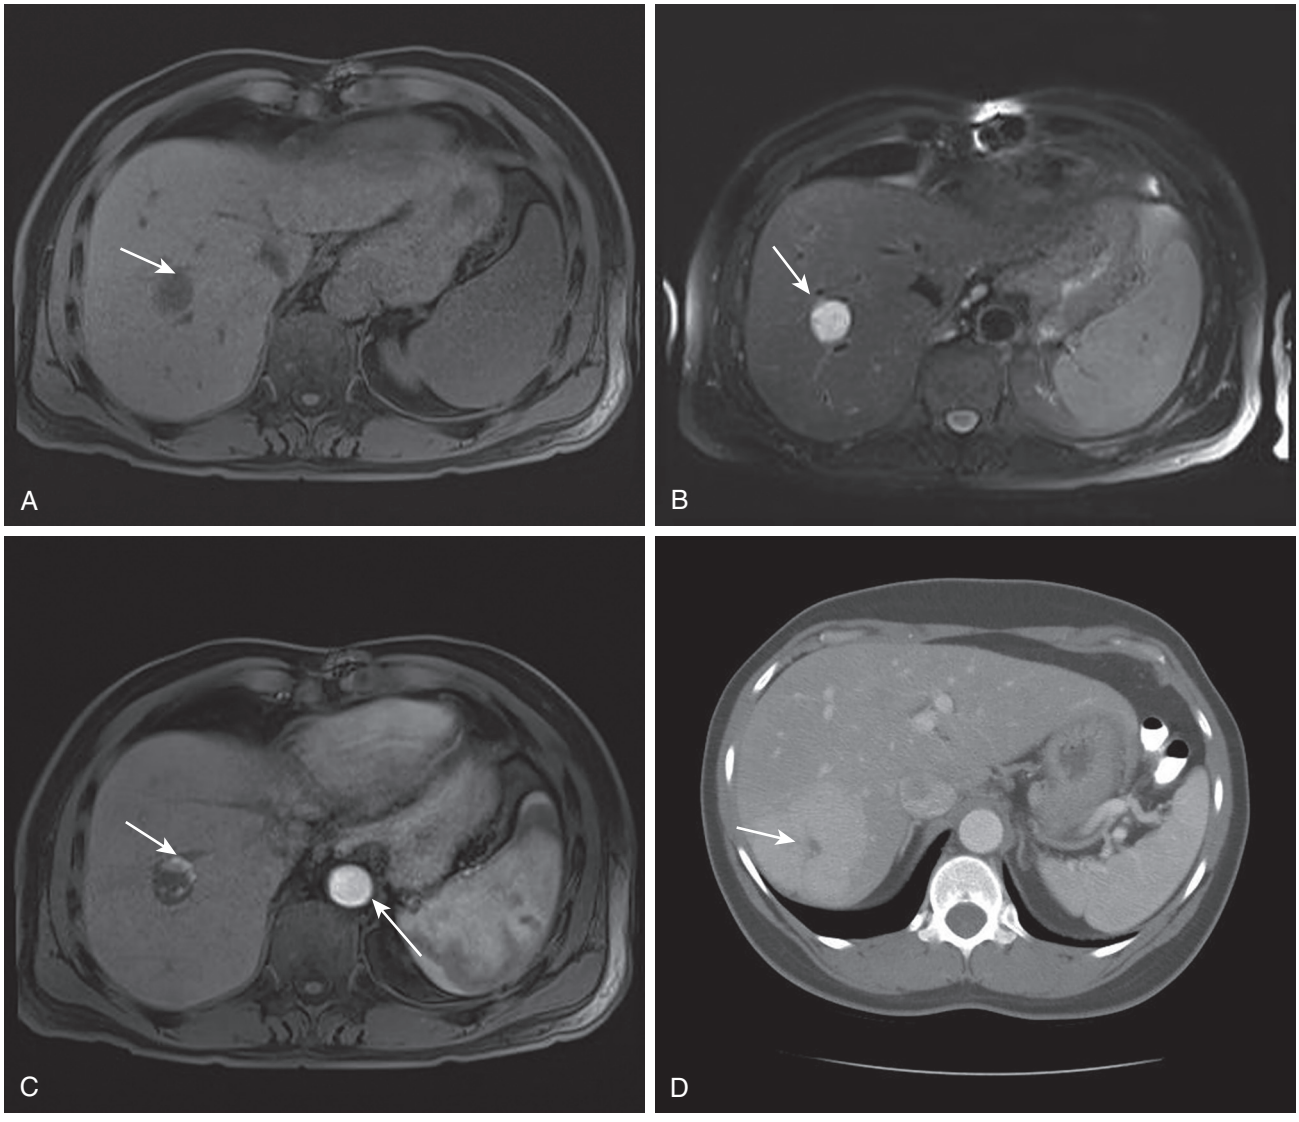

FIGURE 132-8. **Solid hepatic mass. A**, Hemangioma seen as a solid mass (*arrow*) on the T1 phase of a magnetic resonance (MR) imaging scan. **B**, Hemangioma on MR T2 image is characterized by a high signal density (*arrow*). **C**, A hemangioma fills slowly (*shorter arrow*) from the periphery after intravenous contrast is administered (*longer arrow*). **D**, Focal nodular hyperplasia is characterized by a central scar (*arrow*) in the late venous phase of a contrast computed tomographic scan. (Courtesy of Dr. B. Madrazo.)

with adenomas greater than 5 cm should undergo prophylactic hepatic resection.[17] Discontinuation of oral contraceptives may lead to a decrease in size.

Focal nodular hyperplasia, which is a benign lesion characterized by a central scar, is thought to represent a hyperplastic response due to a vascular malformation. Identification of the scar by ultrasound, CT, or MRI is diagnostic (see Fig. 132-8D). Observation in the absence of symptoms is advised.

Multiple regenerative 1- to 3-mm nodules clustered around the portal triads characterize nodular regenerative hyperplasia. It is associated with a variety of systemic disorders, predominantly autoimmune, including rheumatoid arthritis, systemic lupus erythematosus, and polymyalgia rheumatica; neoplastic such as myeloproliferative syndromes; and medications, including thiopurines. Symptoms, if present, reflect associated portal hypertension. Diagnosis is by biopsy, which shows hypertrophied hepatocytes clustered around the center of the nodules with peripheral atrophy. Management is directed to the associated portal hypertension (Chapter 139).

Hepatocellular carcinoma (Chapter 181) is a frequent complication of cirrhosis of any cause as well as chronic hepatitis B infection even in the absence of cirrhosis. Patients usually will have evidence of cirrhosis with hepatic dysfunction. Because surveillance for hepatocellular carcinoma is now recommended in individuals at risk, this tumor is increasingly identified when asymptomatic and potentially curable. On ultrasound, hepatocellular carcinoma appears solid. Owing to its predominantly arterial blood supply compared with that of normal hepatic parenchyma, intravenous contrast is rapidly taken up by a hepatic cellular carcinoma and then "washes out" on CT scan or MR imaging (see Fig. 181-4). Serum α-fetoprotein is elevated in approximately 60% of cases. Therapeutic options depend on the tumor's size and severity of associated liver disease.

APPROACH TO THE PATIENT WITH INHERITED LIVER DISEASE

The major inherited liver diseases in adults are hemochromatosis, Wilson disease, cystic fibrosis, and α_1-antitrypsin deficiency. These disorders may be suspected by their extrahepatic manifestations or may be detected during evaluation of unexplained hepatic dysfunction.

Hereditary hemochromatosis (Chapter 196), which is the most common inherited liver disorder, is most frequently due to mutations in the *HFE* gene (located on chromosome 6p22.2), typically at C282Y and H63D. Approximately 1 in 250 individuals of Northern European descent are homozygous for C282Y, the major *HFE* mutation, although only a minority develop phenotypic manifestations.[18] Liver blood test abnormalities, if present, are nonspecific. Definitive diagnosis is confirmed by detection of C282Y homozygote or compound heterozygote (C282Y/H63D). MRI or CT scan can confirm excessive hepatic iron. Liver biopsy is unnecessary for diagnosis but is advised for a serum ferritin greater than 1000 μg/L because the patient is likely to be cirrhotic. Iron accumulates in hepatocytes, but not in Kupffer cells, in a periportal to pericentral gradient (Fig. 132-9). By comparison, secondary iron overload accumulates in Kupffer cells in conditions such as ineffective erythropoiesis. Quantitative iron measurement in liver tissue, calculated as the μmol of iron/g dry weight liver/age, can confirm the diagnosis. Treatment of hemochromatosis is by phlebotomy (Chapter 196).

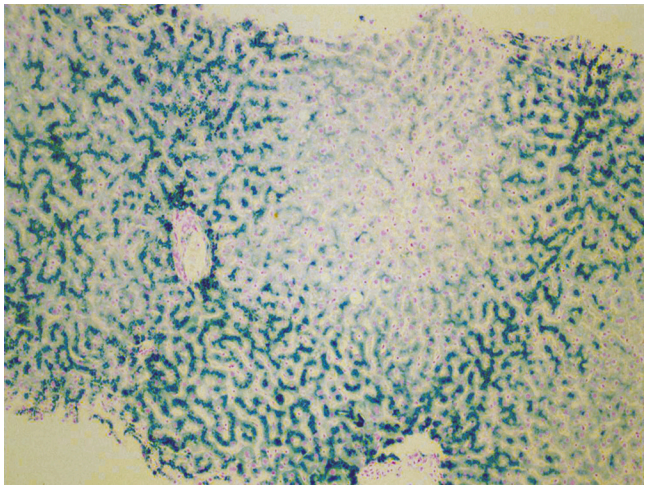

FIGURE 132-9. Liver biopsy in hemochromatosis (Prussian blue stain for iron). Iron deposition is found in a periportal distribution, predominantly in parenchymal cells (hepatocytes). (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

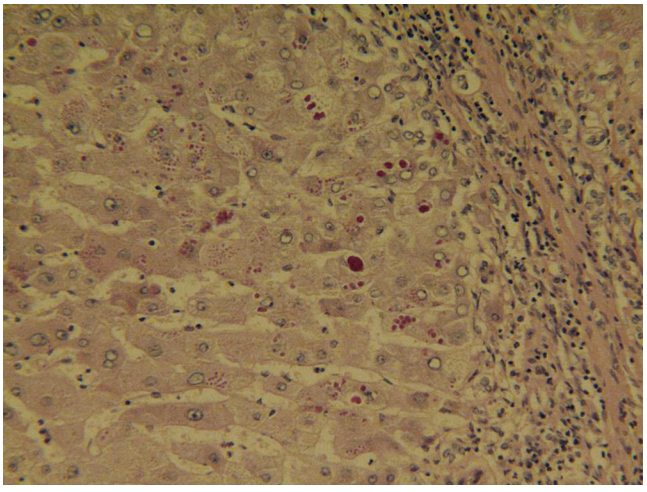

FIGURE 132-10. Liver biopsy in α_1-antitrypsin deficiency. On a periodic acid–Schiff, diastase-resistant stain, α_1-antitrypsin globules, with a characteristic magenta color, are found at the periphery of the lobule. (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

α_1-Antitrypsin deficiency, which results from inherited mutations in this serine protease inhibitor, prevents its export from hepatocytes, where its accumulation causes liver inflammation, fibrosis, and cirrhosis.[19] Deficiency of circulating α_1-antitrypsin results in panlobular emphysema (Chapter 76) even in nonsmokers. The disease is most frequent in persons of European ancestry. Inheritance is autosomal recessive with codominant inheritance because each allele provides 50% of circulating α_1-antitrypsin. A large number of alleles have been identified in the proteinase inhibitor (Pi) gene, with MM associated with normal circulating α_1-antitrypsin levels and the most common abnormal alleles, S and Z, associated with reduced levels. PiZZ homozygotes, who have the most severe α_1-antitrypsin deficiency, have only 15% of normal circulating levels and are prone to liver and lung disease. Liver disease has a bimodal distribution, with neonatal hepatitis and cholestatic jaundice manifesting in early life and cirrhosis in adulthood. Only approximately one third of adults with the PiZZ phenotype develop cirrhosis, thereby implying that other cofactors are involved in disease progression. For example, Pi*Z heterozygosity, found in 2.4% of Whites, increases the risk of cirrhosis secondary to either alcoholic or nonalcoholic fatty liver disease (Chapter 139) by about six-fold.[20] Other phenotypes with α_1-antitrypsin deficiency (e.g., PiMZ or PiSZ) increase the risk for liver disease, whereas null variants have lung but not liver disease. The condition may be suspected as the result of a low α_1-1 globulin level on protein electrophoresis, and the diagnosis can be confirmed by demonstration of a low serum α_1-antitrypsin level followed by Pi testing to determine the phenotype. Liver function test abnormalities are generally nonspecific, although the albumin level can be low and the INR prolonged if cirrhosis is present. Liver biopsy, which shows the extent of fibrosis, is characterized by periodic acid–Schiff (PAS)-positive, diastase-resistant globules in the periphery of the lobule (Fig. 132-10). Weekly intravenous α_1-antitrypsin protein concentrate infusions, which are approved by the U.S. Food and Drug Administration, might prevent progression of lung disease by restoring serum and alveolar α_1-antitrypsin levels. Fazirsiran, which is an RNA interference therapeutic, is an experimental approach to improving liver enzyme abnormalities.[21]

Wilson disease (Chapter 195) is excessive copper accumulation in liver and extrahepatic tissues owing to an inherited disorder in copper transport from hepatocytes to bile. Hepatic manifestations include chronic hepatitis and cirrhosis, most typically appearing by the fourth decade of life, although they can manifest later. A characteristic finding in a fulminant manifestation of Wilson disease is hemolysis with an abnormally low alkaline phosphatase level, jaundice, and coagulopathy. More typically, patients have elevated aminotransferase levels without hemolysis at presentation. Diagnosis usually is based on an elevated 24-hour urinary copper level and low serum ceruloplasmin levels, but in unclear cases the quantification of increased hepatic copper content by biopsy is definitive.[22] Copper chelation prevents disease progression.

Cystic fibrosis (Chapter 77) is usually dominated by pulmonary complications, but liver disease is an important cause of morbidity and mortality in adults.[23] In patients with elevated alkaline phosphatase and bilirubin levels, biliary cirrhosis (Chapter 141) can develop owing to abnormal bile viscosity. Whether new therapies for cystic fibrosis lung disease will improve liver disease is unknown. Ursodeoxycholic acid may improve biochemical test results but has no clear benefit on outcome. Liver transplantation (Chapter 140) may be necessary for decompensated cirrhosis.

133 APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

KEVIN M. KORENBLAT

JAUNDICE AND HYPERBILIRUBINEMIA

DEFINITION

Jaundice, from the French *jaune* ("yellow"), is the yellow-orange discoloration of the skin, conjunctivae, and mucous membranes that results from an elevated plasma bilirubin level. Mild hyperbilirubinemia may be clinically undetectable, but jaundice becomes evident at plasma bilirubin greater than 3 to 4 mg/dL, depending on the patient's skin pigmentation, the conditions of observation, and the bilirubin fraction that is elevated. Hyperbilirubinemia may result from increased bilirubin production or inherited or acquired defects in the metabolism of hepatic bilirubin.

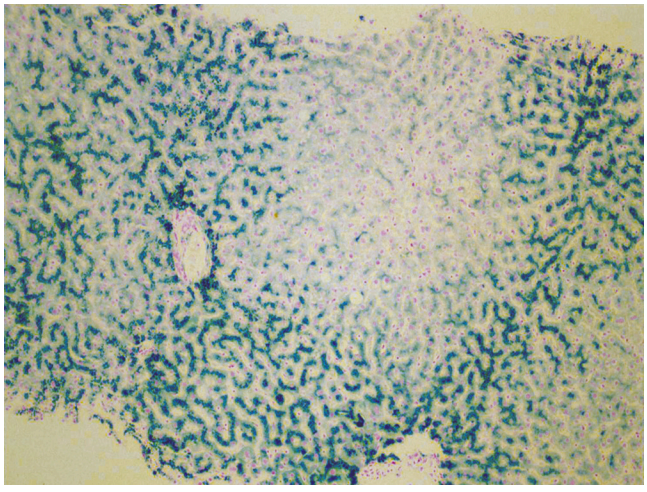

FIGURE 132-9. Liver biopsy in hemochromatosis (Prussian blue stain for iron). Iron deposition is found in a periportal distribution, predominantly in parenchymal cells (hepatocytes). (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

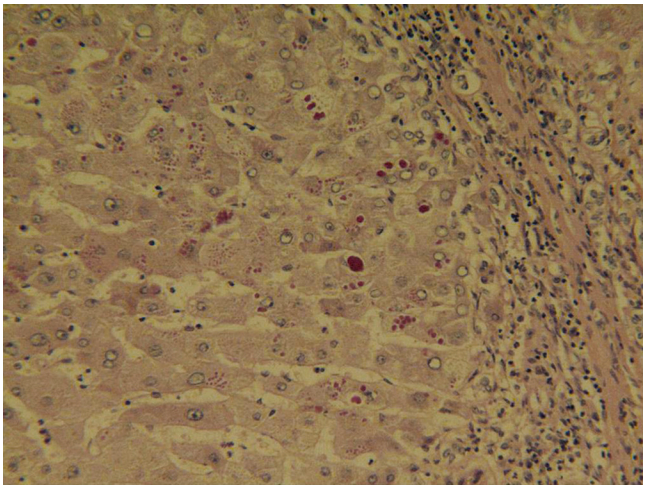

FIGURE 132-10. Liver biopsy in α_1-antitrypsin deficiency. On a periodic acid–Schiff, diastase-resistant stain, α_1-antitrypsin globules, with a characteristic magenta color, are found at the periphery of the lobule. (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

α_1-Antitrypsin deficiency, which results from inherited mutations in this serine protease inhibitor, prevents its export from hepatocytes, where its accumulation causes liver inflammation, fibrosis, and cirrhosis.[19] Deficiency of circulating α_1-antitrypsin results in panlobular emphysema (Chapter 76) even in nonsmokers. The disease is most frequent in persons of European ancestry. Inheritance is autosomal recessive with codominant inheritance because each allele provides 50% of circulating α_1-antitrypsin. A large number of alleles have been identified in the proteinase inhibitor (Pi) gene, with MM associated with normal circulating α_1-antitrypsin levels and the most common abnormal alleles, S and Z, associated with reduced levels. PiZZ homozygotes, who have the most severe α_1-antitrypsin deficiency, have only 15% of normal circulating levels and are prone to liver and lung disease. Liver disease has a bimodal distribution, with neonatal hepatitis and cholestatic jaundice manifesting in early life and cirrhosis in adulthood. Only approximately one third of adults with the PiZZ phenotype develop cirrhosis, thereby implying that other cofactors are involved in disease progression. For example, Pi*Z heterozygosity, found in 2.4% of Whites, increases the risk of cirrhosis secondary to either alcoholic or nonalcoholic fatty liver disease (Chapter 139) by about six-fold.[20] Other phenotypes with α_1-antitrypsin deficiency (e.g., PiMZ or PiSZ) increase the risk for liver disease, whereas null variants have lung but not liver disease. The condition may be suspected as the result of a low α_1-1 globulin level on protein electrophoresis, and the diagnosis can be confirmed by demonstration of a low serum α_1-antitrypsin level followed by Pi testing to determine the phenotype. Liver function test abnormalities are generally nonspecific, although the albumin level can be low and the INR prolonged if cirrhosis is present. Liver biopsy, which shows the extent of fibrosis, is characterized by periodic acid–Schiff (PAS)-positive, diastase-resistant globules in the periphery of the lobule (Fig. 132-10). Weekly intravenous α_1-antitrypsin protein concentrate infusions, which are approved by the U.S. Food and Drug Administration, might prevent progression of lung disease by restoring serum and alveolar α_1-antitrypsin levels. Fazirsiran, which is an RNA interference therapeutic, is an experimental approach to improving liver enzyme abnormalities.[21]

Wilson disease (Chapter 195) is excessive copper accumulation in liver and extrahepatic tissues owing to an inherited disorder in copper transport from hepatocytes to bile. Hepatic manifestations include chronic hepatitis and cirrhosis, most typically appearing by the fourth decade of life, although they can manifest later. A characteristic finding in a fulminant manifestation of Wilson disease is hemolysis with an abnormally low alkaline phosphatase level, jaundice, and coagulopathy. More typically, patients have elevated aminotransferase levels without hemolysis at presentation. Diagnosis usually is based on an elevated 24-hour urinary copper level and low serum ceruloplasmin levels, but in unclear cases the quantification of increased hepatic copper content by biopsy is definitive.[22] Copper chelation prevents disease progression.

Cystic fibrosis (Chapter 77) is usually dominated by pulmonary complications, but liver disease is an important cause of morbidity and mortality in adults.[23] In patients with elevated alkaline phosphatase and bilirubin levels, biliary cirrhosis (Chapter 141) can develop owing to abnormal bile viscosity. Whether new therapies for cystic fibrosis lung disease will improve liver disease is unknown. Ursodeoxycholic acid may improve biochemical test results but has no clear benefit on outcome. Liver transplantation (Chapter 140) may be necessary for decompensated cirrhosis.

133 APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

KEVIN M. KORENBLAT

JAUNDICE AND HYPERBILIRUBINEMIA

DEFINITION

Jaundice, from the French *jaune* ("yellow"), is the yellow-orange discoloration of the skin, conjunctivae, and mucous membranes that results from an elevated plasma bilirubin level. Mild hyperbilirubinemia may be clinically undetectable, but jaundice becomes evident at plasma bilirubin greater than 3 to 4 mg/dL, depending on the patient's skin pigmentation, the conditions of observation, and the bilirubin fraction that is elevated. Hyperbilirubinemia may result from increased bilirubin production or inherited or acquired defects in the metabolism of hepatic bilirubin.

ABSTRACT

Bilirubin metabolism reflects the balance between bilirubin production and clearance. Jaundice is the clinical manifestation of hyperbilirubinemia and the result of bilirubin overproduction, decreased bilirubin clearance, or a combination of both processes. Bilirubin is commonly categorized as either indirect or direct. Indirect hyperbilirubinemia arises from increased bilirubin production from the increased turnover of heme-containing protein or decreased bilirubin conjugation with compounds that aid its clearance. Gilbert syndrome, which is the most frequent disorder of indirect hyperbilirubinemia, is associated with a UDG-glucuronosyltransferases 1A1 gene polymorphism that results in its decreased transcription. Direct or mixed hyperbilirubinemia often reflects disorders of bilirubin clearance at all stages of bilirubin removal, including inherited and acquired disruption of canalicular bile transport, liver diseases that impair organ function, mechanical obstruction of bile flow, or disruption of enterohepatic circulation. The cause of the bilirubin elevation can be deduced by the bilirubin fraction that is elevated, the presence of forms of bilirubin in urine, the clinical history, and other laboratory findings, particularly hepatic enzymes and protein products. Similar to the approach to bilirubin, the evaluation of abnormal liver biochemistries relies on an appreciation of the origin and pattern of the biochemical abnormalities, as well as the clinical context in which they occur. Biochemical abnormalities can be described as hepatocellular, cholestatic (affecting bile flow), or mixed. The diagnosis of the cause of biochemical abnormalities often requires serologic studies, liver imaging, and liver biopsy.

PATHOBIOLOGY

Bilirubin Metabolism

Bilirubin Production

Bilirubin is the degradation product of the heme moiety of hemoproteins, a class of proteins involved in the transport or metabolism of oxygen (E-Fig. 133-1). Normal adults produce approximately 4 mg of bilirubin per kilogram of body weight per day. Between 70 and 90% of bilirubin is derived from the hemoglobin in erythrocytes, which are sequestered and destroyed by the mononuclear phagocytic cells of the reticuloendothelial system, principally in the spleen, liver, and bone marrow. The remainder is from the turnover of nonhemoglobin hemoproteins, such as myoglobin, the P-450 cytochromes, catalase, and peroxidase, principally in the liver. Ineffective erythropoiesis, which is the premature destruction of newly formed erythrocytes in the bone marrow, contributes a minor fraction. Bilirubin is more than just a byproduct of a degradatory pathway; it has antioxidant and immune modulating properties, and it is a ligand for cellular receptors.[1]

The two-step conversion of heme to bilirubin begins with the opening of the heme molecule at its α bridge carbon by the microsomal enzyme *heme oxygenase*, a process that results in the formation of equimolar quantities of carbon monoxide and the green tetrapyrrole biliverdin. This nontoxic, water-soluble pigment is the main excretory product of heme in birds, reptiles, and amphibians. However, biliverdin cannot cross the placenta. Accordingly, its reduction to bilirubin in mammals by a second enzyme, *biliverdin reductase*, allows its transplacental removal from the fetus into the maternal circulation, from which it can be excreted by the maternal liver. The unconjugated bilirubin produced in the periphery is transported in plasma to the liver. Because of its insolubility in aqueous media, it is kept in solution by tight but reversible binding to albumin. A number of compounds, including salicylates, sulfonamides, furosemide, and radiographic contrast agents, can competitively displace bilirubin from its binding sites on albumin, a phenomenon that is of little clinical significance except in neonates, in whom the resulting increased concentration of unbound bilirubin raises the risk for kernicterus.

Disposition of Bilirubin by the Liver

Excretion of bilirubin from the body is a major function of the liver (see E-Fig. 133-1), where the specialized microanatomy enhances the extraction of protein-bound compounds from the circulation. Hepatic translocation of bilirubin from blood to bile involves four distinct steps: (1) uptake of unconjugated bilirubin, principally by facilitated transport and, to a lesser extent, diffusion; (2) intracellular binding, mainly to various cytosolic proteins of the glutathione-*S*-transferase family; (3) conversion in the endoplasmic reticulum of unconjugated bilirubin to bilirubin monoglucuronides and diglucuronides by a specific uridine 5′-diphospho-glucuronosyltransferase (UDP-glucuronosyltransferase) isoform designated UGT1A1, encoded by the *UGT1* gene complex; and (4) transfer of bilirubin monoglucuronides and diglucuronides into bile by a canalicular membrane adenosine triphosphate (ATP)–dependent transporter designated multidrug resistance–associated protein 2 (MRP2) and also known as canalicular multispecific organic anion transporter (cMOAT) or ATP-binding cassette sub-family C member 2 (ABCC2). MRP2 is encoded by the gene *ABCC2*, a member of the ATP-binding cassette (ABC) transporter superfamily of genes. Conjugated bilirubin is secreted also across the hepatocyte sinusoidal membrane by multidrug resistance–associated protein 3 (MRP3), particularly when the transport capacity of MRP2 is exceeded. MRP2 and MRP3 share a 48% amino acid identity.

Conjugation of unconjugated bilirubin to bilirubin monoglucuronides and diglucuronides is a critical process that greatly increases the aqueous solubility of bilirubin, thereby enhancing its elimination from the body while simultaneously reducing its ability to diffuse across biologic membranes, including the blood-brain barrier. In newborn infants, a decreased capacity to conjugate bilirubin leads to unconjugated hyperbilirubinemia (physiologic jaundice of the newborn). If severe, this hyperbilirubinemia may then lead to kernicterus. Phototherapy by exposure to light in the blue spectrum (390 to 470 nm) converts bilirubin to water-soluble photoisomers that are readily excreted in bile, thereby protecting the central nervous system from bilirubin toxicity. Gilbert syndrome and Crigler-Najjar syndrome types 1 and 2, which result from genetic defects in bilirubin conjugation, are characterized by unconjugated hyperbilirubinemia; by contrast, Dubin-Johnson syndrome, which results from inheritable defects in MRP2, is characterized by conjugated or mixed hyperbilirubinemia. Loss of function of the membrane organic ion transport proteins OATP1B1 and OATP1B3 causes Rotor syndrome, also a conjugated or mixed hyperbilirubinemia.

Enterohepatic Circulation and Excretion of Bilirubin

Normal human bile contains an average of less than 5% unconjugated bilirubin, 7% bilirubin monoconjugates, and 90% bilirubin diconjugates. Following canalicular secretion, conjugated bilirubin passes down the gastrointestinal tract without reabsorption by either the gallbladder or intestinal mucosa. Although some bilirubin reaches the feces, most is converted to urobilinogen and to related compounds by bacteria within the ileum and colon. Urobilinogen is reabsorbed and returns to the liver through the portal circulation, where it is re-excreted into bile. This process of enterohepatic recirculation occurs with urobilinogen, bile salts, and some medications. Any urobilinogen not taken up by the liver reaches the systemic circulation, from which it is cleared by the kidneys. Normal urine urobilinogen excretion is 4 mg/day or less. Hemolysis increases the load of bilirubin entering the gut and therefore the amount of urobilinogen formed and reabsorbed. Liver disease decreases hepatic extraction of bilirubin; as a result, plasma urobilinogen levels rise and more urobilinogen is excreted in the urine. Cholestasis, bile duct obstruction, or antibiotics that reduce or eliminate the bacterial conversion of bilirubin to urobilinogen decrease the formation and urinary excretion of urobilinogen.

Unconjugated bilirubin ordinarily does not reach the gut except in neonates or, by ill-defined alternative pathways, in the presence of severe unconjugated hyperbilirubinemia (e.g., Crigler-Najjar type 1). In these circumstances, unconjugated bilirubin is reabsorbed from the gut, thereby amplifying the hyperbilirubinemia.

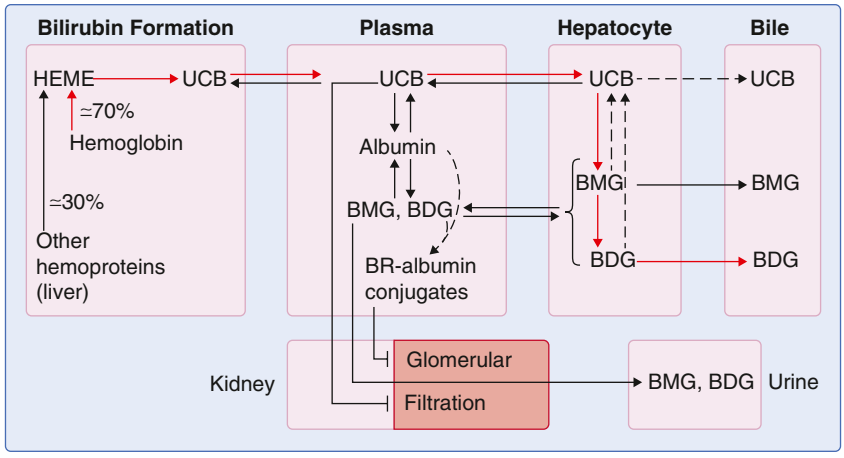
Measurement of Bilirubin in Plasma

The total plasma bilirubin concentration in normal adults is less than 1 to 1.5 mg/dL. Modern analytic techniques show that normal plasma contains principally unconjugated bilirubin, with only a trace of conjugated bilirubin. Clinical laboratories quantify plasma bilirubin by a reaction in which bilirubin is cleaved by a diazo reagent under acidic conditions to form azobilirubin that is quantitated spectrophotometrically. Bilirubin conjugates react rapidly ("prompt" or "direct"-reacting bilirubin). Unconjugated bilirubin reacts slowly because the site of attack by the diazo reagent is protected by internal hydrogen bonding. Measurement of the total plasma bilirubin concentration requires addition of an agent, such as a detergent, to solubilize the unconjugated bilirubin.

The "indirect"-reacting bilirubin is calculated by subtracting the direct-reacting bilirubin from the total. Although physicians traditionally equate the direct-reacting fraction of bilirubin in plasma with conjugated bilirubin and the indirect fraction with unconjugated bilirubin, this approach is, at best, an approximation. The unqualified interpretation of direct and indirect fractions as reflecting conjugated and unconjugated bilirubin, respectively, may lead to diagnostic errors, particularly in the diagnosis of hereditary hyperbilirubinemias. In common practice, 10 to 20% of the bilirubin in normal plasma gives a prompt (direct) diazo reaction even though more than 95% of total bilirubin in normal plasma is unconjugated. Thus, at virtually any total bilirubin concentration, a direct-reacting fraction of less than 15% of the total bilirubin can be considered as essentially all unconjugated.

When the direct-reacting fraction is greater than 15%, a simple dipstick test for bilirubinuria may clarify the situation. Unconjugated bilirubin is not excreted in urine regardless of the height of its plasma concentration because its binding to albumin is too tight for effective glomerular filtration and it is not secreted by the tubules. In comparison, conjugated bilirubin in the blood under conditions of parenchymal liver disease or bile duct obstruction is loosely bound to albumin and readily filtered at the level of the glomerulus. Even modest degrees of conjugated hyperbilirubinemia result in bilirubinuria, which is *always* a pathologic finding. With prolonged conjugated hyperbilirubinemia, some of the conjugated bilirubin binds *covalently* to albumin and produces what is designated the delta (δ)-bilirubin fraction. Although δ-bilirubin gives a direct diazo reaction, it is not filterable by the glomerulus and does not appear in the urine; it disappears slowly from the plasma, with the 14- to 21-day half-life of the albumin to which it is bound. δ-Bilirubin can account for the slow rate at which a mixed or predominantly conjugated (direct) hyperbilirubinemia resolves as hepatitis improves or biliary obstruction is relieved. Although δ-bilirubin is not easily measured, its presence can be inferred when an elevated direct-reacting bilirubin persists after bilirubinuria resolves.

Transcutaneous bilirubinometry is an alternative method for measuring bilirubin in infants with neonatal jaundice. The method is based on the measurement of the light reflected from the percutaneous transmission of visible light and can be used to screen newborns.



E-FIGURE 133-1. Overview of bilirubin metabolism. Unconjugated bilirubin (UCB) formed from the breakdown of heme from hemoglobin and other hemoproteins is transported in plasma reversibly bound to albumin and is converted in the liver to bilirubin monoglucuronide (BMG) and diglucuronide (BDG), the latter being the predominant form secreted in bile. BMG and BDG together normally account for less than 5% of normal serum bilirubin. In patients with hepatobiliary disease, BMG and BDG accumulate in plasma and appear in urine. Bilirubin glucuronides in plasma also react nonenzymatically with albumin and possibly other serum proteins to form protein conjugates, which do not appear in urine and have a plasma half-life similar to that of albumin. BR = bilirubin.

Bilirubin Kinetics

The plasma unconjugated bilirubin concentration ([UCB]) is determined by a balance between the bilirubin production rate (BRP) and hepatic bilirubin clearance (C_{BR}) according to the relationship:

$$[UCB] \approx BRP/C_{BR}$$

C_{BR} is analogous to the creatinine clearance test of kidney function; it is a measure of the rate at which bilirubin is extracted from plasma, and it is a true quantitative test of liver function. This equation indicates that [UCB] is directly proportional with increases in BRP and inversely proportional with C_{BR}, thereby providing a basis for classifying unconjugated hyperbilirubinemias according to their pathogenesis.

Increased Bilirubin Production

An increased production of bilirubin can be caused by hemolysis, an accelerated destruction of transfused erythrocytes, resorption of hematomas, or ineffective erythropoiesis owing to lead poisoning, megaloblastic anemia related to deficiency of either folic acid or vitamin B_{12}, sideroblastic anemia, congenital erythropoietic porphyria, or myeloproliferative or myelodysplastic diseases. In these settings, other liver tests are typically normal and the hyperbilirubinemia is modest, rarely exceeding 4 mg/dL; higher values imply concomitant hepatic dysfunction. However, after brisk blood transfusion or resorption of massive hematomas caused by trauma, the increased bilirubin load may be transiently sufficient to lead to observable jaundice. The causes of hemolysis are numerous (Chapters 146 and 147). Besides specific blood disorders, mild hemolysis accompanies many acquired diseases. In the setting of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration. Prolonged hemolysis may lead to the formation of pigmented gallstones that contain calcium salts of bilirubin.

Decreased Hepatic Bilirubin Clearance

Decreased Bilirubin Uptake

Bilirubin uptake by hepatocytes involves both facilitated transport and passive diffusion. Decreased bilirubin uptake is believed to explain the initial increase in unconjugated bilirubin associated with rifampin use.

Impaired Bilirubin Conjugation

The most frequent cause of decreased bilirubin clearance is a decrease in bilirubin conjugating activity. Bilirubin conjugation with glucuronic acid is catalyzed principally by a UDP-glucuronosyltransferase, which is designated UGT1A1 and encoded by the *UGT1* gene complex. The *UGT1A1* gene is assembled by alternative splicing of a bilirubin-specific variant of exon 1, designated exon A_1, with four common exons (exons 2 to 5) that encode the shared carboxyl terminal end of all *UGT1*-encoded proteins. Its promoter region normally contains an $A(TA)_6TAA$ TATA box–like construct.

APPROACH TO THE PATIENT WITH HYPERBILIRUBINEMIA

Hyperbilirubinemia and jaundice may result from isolated disorders of bilirubin metabolism, liver disease, or obstruction of the biliary tract. Jaundice represents the most visible sign of hepatobiliary disease of many causes (Table 133-1).

GENETIC DISORDERS OF BILIRUBIN CONJUGATION

The hereditary hyperbilirubinemias (Table 133-2) are a group of five syndromes in which hyperbilirubinemia occurs as an isolated biochemical abnormality, without evidence of liver disease.

CRIGLER-NAJJAR AND GILBERT SYNDROMES

Crigler-Najjar syndrome types 1 and 2 and Gilbert syndrome are hereditary forms of unconjugated hyperbilirubinemia that have been known for more than two decades to result principally from mutations in *UGT1A1*. In Crigler-Najjar type 1, essentially no functional enzyme activity is present; in Crigler-Najjar type 2, enzymatic activity can be as much as 10% of normal; and in Gilbert syndrome, the enzymatic activity is 10 to 33% of normal levels. The resulting bilirubin concentrations are 18 to 45, 6 to 25, and 1.5 to 4 mg/dL, respectively (Table 133-2). Because total UGT1A1 enzymatic activity must be less than 50% of normal to produce unconjugated hyperbilirubinemia, phenotypic expression of mutations in this enzyme requires either homozygosity or double heterozygosity, and each of these disorders is inherited in an autosomal recessive pattern. Individuals of Black or White ancestry with Gilbert syndrome are typically homozygous for an $A(TA)_7TAA$ promoter mutation; this polymorphism is designated *UGT1A1*28*. Structural mutations in exon 1 of *UGT1A1* causing modest reductions in enzymatic activity have been reported in some Japanese patients with Gilbert syndrome. To date, at least 130 different mutations in *UGT1A1* associated with hereditary hyperbilirubinemia have been identified, including ones linked to Crigler-Najjar type 1 and type 2. Other studies in patients with unconjugated hyperbilirubinemia have also identified mutations and polymorphism in multiple additional regions of *UGT1A*, including its promoter region, in the solute carrier protein SCLO1B1, and in the enzymes heme oxygenase and biliverdin reductase A that influence serum bilirubin concentrations.

Crigler-Najjar Syndrome Type 1

Crigler-Najjar type 1 is characterized by a striking unconjugated hyperbilirubinemia that appears in the neonatal period, persists for life, and is unresponsive to phenobarbital.[2] Most patients (type 1A) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin as the result of homozygous or compound heterozygous mutations in one of the common exons (2 to 5) of the *UGT1* complex. In a smaller subset (type 1B), a mutation in the bilirubin-specific exon A1 limits the defect to bilirubin conjugation. Fifty-nine structurally diverse *UGT1A1* mutations can cause Crigler-Najjar type 1; their common feature is that they all encode proteins with absent or, at most, traces of enzymatic activity.

Before the availability of phototherapy, most patients with Crigler-Najjar type 1 died of bilirubin encephalopathy (kernicterus) in infancy or early childhood. Optimal treatment for a neurologically intact patient includes approximately 12 hours/day of phototherapy from birth throughout childhood, perhaps supplemented by exchange transfusion in the neonatal period; use of oral calcium phosphates to bind bilirubin isomers generated by phototherapy and, thereby, disrupt enterohepatic circulation; and early liver transplantation, before the onset of brain damage. Plasmapheresis can temporarily control abrupt increases in bilirubin.

Crigler-Najjar Syndrome Type 2

Bilirubin concentrations are typically lower in Crigler-Najjar type 2, and plasma bilirubin levels can be reduced to 3 to 5 mg/dL by phenobarbital. At least 48 different mutations of *UGT1A1* have been associated with Crigler-Najjar type 2; all encode a bilirubin-UDP-glucuronosyltransferase with markedly reduced but detectable enzymatic activity. Although much less common in Crigler-Najjar type 2, kernicterus has occurred at all ages, typically associated with factors that temporarily raise the plasma bilirubin concentration above baseline (e.g., fasting, intercurrent illness). For this reason, phenobarbital therapy is often recommended; a single bedtime dose usually maintains clinically safe plasma bilirubin concentrations.

Gilbert Syndrome

Gilbert syndrome is the most common form of the hereditary hyperbilirubinemias.[3] The most common polymorphism is the homozygous $A(TA)_7TAA$ promoter polymorphism designated as the UGT1A1*28 allele. Approximate allelic frequencies are 42%, 30%, and 10% in Black, White, and Asian populations, respectively. In Asian populations, polymorphisms in coding regions are more common than the *28 allele. The high prevalence of Gilbert syndrome often explains the frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients and why population-level studies of bilirubin levels tend to skew toward higher levels. Plasma bilirubin concentrations are most often less than 3 mg/dL, although both higher and lower values are frequent, with increases of two-fold to three-fold commonly occurring with fasting and intercurrent illness. The phenotypic distinction between mild Gilbert syndrome and a normal state is often blurred. Phenobarbital's ability to induce hepatic enzyme activity normalizes both the bilirubin concentration and C_{BR}. Oxidative drug metabolism and the disposition of many, but not all, xenobiotics that are metabolized by glucuronidation appear to be normal in Gilbert syndrome. A critical exception is the antitumor agent irinotecan (CPT-11), whose active metabolite (SN-38) is glucuronidated specifically by UGT1A1. In patients with Gilbert syndrome, irinotecan can cause intractable diarrhea, myelosuppression, and other serious toxicities. The estrogen modulator raloxifene is also a substrate for UGT1A1, and the presence of the homozygous *28 allele results in a two-fold higher exposure to the medication and a greater increase

TABLE 133-1 DIFFERENTIAL DIAGNOSIS OF HYPERBILIRUBINEMIA AND JAUNDICE

DISORDERS OF BILIRUBIN METABOLISM WITHOUT LIVER DISEASE
Unconjugated Hyperbilirubinemia
Increased bilirubin production
Examples: Hemolysis, ineffective erythropoiesis, blood transfusion, resorption of hematomas
Decreased hepatocellular uptake
Examples: Drugs (e.g., rifampin)
Decreased conjugation
Examples: Gilbert and Crigler-Najjar syndromes, physiologic jaundice of the newborn, breast milk jaundice, HIV protease inhibitors
Conjugated or Mixed Hyperbilirubinemia
Decreased canalicular transport: Dubin-Johnson syndrome
Decreased reuptake of bilirubin conjugates: Rotor syndrome
LIVER DISEASE
Acute or Chronic Hepatocellular Dysfunction
Acute or subacute hepatocellular injury
Examples: Viral hepatitis A, B, C, E; hepatotoxins (e.g., ethanol, acetaminophen, mushroom *[Amanita phalloides]* poisoning); drugs (e.g., isoniazid, diclofenac); metabolic diseases (e.g., Wilson disease, Reye syndrome); pregnancy-related (e.g., acute fatty liver of pregnancy, HELLP); hepatic ischemia (e.g., shock)
Chronic hepatocellular disease
Examples: Hepatitis B, B and D, C, and E; hepatotoxins (e.g., organic solvents, vitamin A); nonalcoholic and alcoholic fatty liver disease; autoimmune hepatitis; metabolic disease (Wilson disease, hemochromatosis, α_1-antitrypsin deficiency)
Hepatic Disorders with Cholestasis
Familial cholestatic disorders
Single gene disorders
Examples: Benign recurrent intrahepatic cholestasis; progressive familial intrahepatic cholestasis; Navajo neurohepatopathy syndrome; North American Indian cholestasis
Diffuse infiltrative disorders
Familial cholestatic disorders of unknown pathogenesis
Examples: Aagenaes syndrome
Examples: Granulomatous diseases (e.g., bacterial, mycobacterial, fungal, rickettsial, and trepenomal infections, sarcoidosis, lymphoma), medications (e.g., phenytoin, carbamazepine), amyloidosis, infiltrative malignancies, extramedullary hematopoiesis
Inflammation of intrahepatic bile ductules and/or portal tracts
Examples: Primary biliary cholangitis, liver allograft rejection, graft-versus-host disease
Miscellaneous conditions
Examples: Uncommon presentations of viral or alcoholic hepatitis, intrahepatic cholestasis of pregnancy, contraceptive jaundice, estrogens, anabolic steroids, postoperative cholestasis, cholestasis of sepsis, total parenteral nutrition, drug-induced liver injury (amoxicillin-clavulanate)
BILE DUCT OBSTRUCTION
Choledocholithiasis
Diseases of the Bile Ducts
Inflammation, infection
Examples: Primary sclerosing cholangitis, AIDS cholangiopathy, hepatic artery thrombosis, hepatic arterial infusion pump chemotherapy, postsurgical biliary strictures
Neoplasms (e.g., cholangiocarcinoma)
Extrinsic Compression of the Biliary Tree
Neoplasms
Examples: Pancreatic carcinoma, metastatic lymphadenopathy, hepatoma
Pancreatitis with or without pseudocyst formation
Vascular enlargement (e.g., aneurysm, cavernous transformation of portal vein)

AIDS = acquired immunodeficiency syndrome; HELLP = hemolysis, elevated liver enzymes, and low platelets; HIV = human immunodeficiency syndrome.

in bone density. Although Gilbert syndrome has no association with disease, occasional reports have suggested an association of the UGT1A1*28 allele with a decreased risk for cardiovascular and inflammatory diseases, an association that has been attributed to the vasodilatory and antioxidant effects of bilirubin and heme oxygenase.[4]

UNCONJUGATED HYPERBILIRUBIN IN THE NEWBORN PERIOD

Most neonates develop mild, physiologic jaundice from unconjugated hyperbilirubinemia between days 2 and 5 after birth because of hepatic immaturity and low UGT1A1 levels. Neonates can also experience early and late-onset jaundice from breast milk from two processes. Early onset jaundice occurs within 1 to 3 days of life and is attributed to the reduced calorie intake associated with breastfeeding. Late-onset jaundice occurs within 4 to 5 days of birth and can arise from the inhibition of bilirubin conjugation by the progestational steroid 3α,20β-pregnanediol and certain fatty acids present in breast milk. Peak bilirubin levels are typically less than 5 to 10 mg/dL, and levels return to normal within 2 weeks as mechanisms fostering bilirubin disposition mature. Prematurity, with or without hemolysis, is associated with higher bilirubin levels that may require phototherapy.

CONJUGATED OR MIXED HYPERBILIRUBINEMIA

Two phenotypically similar but mechanistically distinct inherited disorders, Dubin-Johnson syndrome and Rotor syndrome, are characterized by conjugated or mixed hyperbilirubinemia with normal values for other standard liver tests (see Table 133-2). Dubin-Johnson syndrome results from any of several mutations in the *ABCC2* gene that encodes MRP2, and Rotor syndrome is associated with mutations in *SLCO1B1* and *SLCO1B3*. Serum bilirubin levels tend to be modestly elevated (2 to 5 mg/dL), and aminotransferase levels tend to be normal.

In both Dubin-Johnson and Rotor syndromes, liver function is normal. The syndromes can be distinguished from other conditions and from one another by analysis of urine porphyrin excretion. In Dubin-Johnson syndrome, total urine coproporphyrin levels are normal, but coproporphyrin I constitutes 80% of the total; typically coproporphyrin III is 75% of the total.[5] In Rotor syndrome, total coproporphyrin levels are elevated two- to five-fold.

LIVER AND BILIARY TRACT DISEASE

Jaundice is a common sign of generalized hepatobiliary dysfunction, both acute and chronic. Icteric hepatobiliary disease is readily distinguished from the isolated disorders of bilirubin metabolism because the increase in plasma bilirubin concentration occurs in association with other markers of hepatobiliary disease (Fig. 133-1).

Liver diseases can be categorized as those in which the primary injury results from inflammation and hepatocellular necrosis, inhibition of bile flow (cholestasis), or a combination of the two. The cholestatic disorders can be further subdivided into those resulting from mechanical obstruction of the bile duct flow and those from intrahepatic cholestasis, from a multitude of conditions that include several familial cholestatic syndromes; infiltrative disorders, inflammatory or neoplastic conditions; and drug-induced liver injury (see Table 133-1).

TABLE 133-2 PRINCIPAL FEATURES OF THE HEREDITARY DISORDERS OF BILIRUBIN METABOLISM

FEATURE	CRIGLER-NAJJAR SYNDROME TYPE 1	CRIGLER-NAJJAR SYNDROME TYPE 2	GILBERT SYNDROME	DUBIN-JOHNSON SYNDROME	ROTOR SYNDROME
Incidence	Very rare	Rare	Up to 12% of population	Rare	Rare
Total serum bilirubin (mg/dL)	18-45 (usually >20), unconjugated	6-25 (usually ≤20), unconjugated	Typically ≤4 in absence of fasting or overt hemolysis; mostly unconjugated	Typically 2-5, less often ≤25; approximately 60% direct reacting	Usually 3-7, occasionally ≤20; approximately 60% direct reacting
Defect(s) in bilirubin metabolism*	Bilirubin UGT1A1 conjugating activity markedly reduced: trace to absent	Bilirubin UGT1A1 conjugating activity reduced: ≤10% of normal	Complex haplotype Bilirubin UGT1A1 conjugating activity typically reduced to 10-33% of normal; reduced bilirubin uptake in some cases; mild hemolysis in up to 50% of patients	Impaired canalicular secretion of conjugated bilirubin owing to MRP2 mutation	Impaired hepatic secretion or storage of conjugated bilirubin owing to impaired reuptake of bilirubin conjugates resulting from simultaneous OATP1B1 and OATP1B3 mutations
Routine liver tests	Normal	Normal	Normal	Normal	Normal
Serum bile acids	Normal	Normal	Normal	Usually normal	Normal
Pharmacologic responses/ special features	No response to phenobarbital	Phenobarbital reduces bilirubin by ≤75%	Phenobarbital reduces bilirubin, often to normal	Increased bilirubin concentration with estrogens; diagnostic urine coproporphyrin isomer pattern (total is normal, with isomer I increased to ≥80% of total)	Characteristic urine coproporphyrin excretion pattern (total is increased ≤2.5-fold in ≈65% of cases but isomer I always <80% of total)
Major clinical features	Kernicterus in infancy if untreated; may occur later despite therapy	Rare late-onset kernicterus with fasting	None	Occasional hepatosplenomegaly	None
Hepatic morphology/ histology	Normal	Normal	Normal; occasionally increased lipofuscin pigment	Liver grossly black; coarse, dark centrilobular pigment	Normal
Bile bilirubin fractions†	>90% unconjugated	Largest fraction (mean 57%) monoconjugates	Mainly diconjugates but monoconjugates are increased (mean 23%)	Mixed conjugates, reported increase in diconjugates	Increased conjugates
Inheritance (all autosomal)	Recessive	Recessive	Promoter mutation is recessive; missense mutation often dominant	Recessive; rare kindred appears dominant	Recessive
Diagnosis	Clinical and laboratory findings, lack of response to phenobarbital	Clinical and laboratory findings, response to phenobarbital	Clinical and laboratory findings; promoter genotyping; liver biopsy rarely necessary	Clinical and laboratory findings; liver biopsy unnecessary if coproporphyrin studies available	Clinical and laboratory findings; urine coproporphyrin analysis
Treatment	Phototherapy or tin protoporphyrin as short-term therapy; liver transplantation definitive	Consider phenobarbital if baseline bilirubin ≥8 mg/dL	None necessary	Avoid estrogens; no other therapy necessary	No treatment necessary

*UGT1A1 = bilirubin specific isoform of the UGT1 family of uridine diphosphate glucuronosyltransferases.
†Bilirubin in normal bile: <5% unconjugated bilirubin, with an average of 7% bilirubin monoconjugates and 90% bilirubin diconjugates.

FAMILIAL CHOLESTASIS SYNDROMES

Bile secretion, which is essential both for the elimination of metabolic wastes and for the solubilization and subsequent absorption of specific nutrients, is a complex, energy-dependent process in which three genes encoding ABC (ATP binding cassette) transporters (*ATP8B1*, *ABCB11*, and *ABCB4*) play critical roles. Cholestatic disorders of childhood (E-Table 133-1) can be caused by a wide range of developmental, heritable, and acquired conditions. Congenital disorders of bile duct development include extrahepatic biliary atresia, progressive familial intrahepatic cholestasis,[6] and Alagille syndrome.[7]

Signs and symptoms associated with progressive familial intrahepatic cholestasis 1 include stunted growth, diarrhea, jaundice, and pruritus.[8] The pruritus from cholestatic disorders can be treated by interruption of the enterohepatic circulation by blockade of the apical bile salt transporter in the ileum.[9] Odevixibat (40 mcg/kg orally once daily) is indicated for the treatment of pruritus in patients 3 months of age and older with progressive familial intrahepatic cholestasis, and maralixibat (190 mcg/kg orally daily for 7 days, then 380 mcg/kg daily, as tolerated) is indicated for treatment of cholestatic pruritus in patients 1 year of age or older with Alagille syndrome.[A1] Treatment can also include reduction of bile acids by partial biliary external diversion, in which bile from the gallbladder is drained by a jejunal conduit externally.

Benign recurrent intrahepatic cholestasis is a rare, autosomal recessive disorder characterized by recurrent attacks of sometimes disabling malaise, pruritus, and jaundice, beginning in childhood or adulthood and varying in duration from weeks to months. Intervals between attacks may vary from months to years, and care is directed at managing the symptoms of fatigue and pruritus. Some cases are associated with progressive hepatic fibrosis.

ACQUIRED CONJUGATION DEFECTS

A modest reduction in bilirubin conjugating capacity occurs in advanced hepatitis or cirrhosis (Chapter 139). In these settings, however, conjugation is better preserved than canalicular excretion. Pharmacologic and

E-TABLE 133-1 CHOLESTATIC DISORDERS ASSOCIATED WITH SINGLE GENE DISORDERS

DISORDER	GENE	CHROMOSOME	PROTEIN	CLINICAL PHENOTYPE
Progressive familial intrahepatic cholestasis type 1	*ATP8B1*	18q21-22	Phosphatidylserine flippase	Cholestasis, mild; lobular fibrosis
Progressive familial intrahepatic cholestasis type 2	*ABCB11*	2q24	Canalicular bile salt translocase	Canalicular cholestasis
Progressive familial intrahepatic cholestasis type 3	*ABCB4*	7q21	Phosphatidylcholine (lecithin) floppase	Cholestasis
Progressive familial intrahepatic cholestasis type 4	*TJP2*	9q21.11	Tight proteins; organization of intercellular junctions	Cholestasis; progressive liver disease in early childhood
Progressive familial intrahepatic cholestasis type 5	*NR1H4*	12q23.1	Nuclear bile acid receptor FXR	Neonatal-onset cholestasis; severe vitamin K–independent coagulopathy
Progressive familial intrahepatic cholestasis type 6	*MYO5B*	18q21.1	Maintenance hepatocyte polarity	Cholestasis
Benign recurrent intrahepatic cholestasis	*ATP8B1; ABCB11*	18q21-22; 2q24	Phosphatidylserine flippase; canalicular bile salt translocase	Cholestasis
Alagille syndrome	*JAG1*	20p12.2	Ligand for NOTCH	Bile duct paucity; congenital heart disease; ophthalmologic and vertebral abnormalities
Navajo neurohepatopathy	*MPV17*	2p23.3	Inner mitochondrial membrane protein	Cirrhosis; sensorimotor neuropathy; metabolic acidosis; failure to thrive
North American Indian cholestasis	*CIRH1A*	16q22	Nucleolar protein	Neonatal jaundice; progressive hepatic fibrosis; also reports of individuals with homozygous mutations without disease phenotype

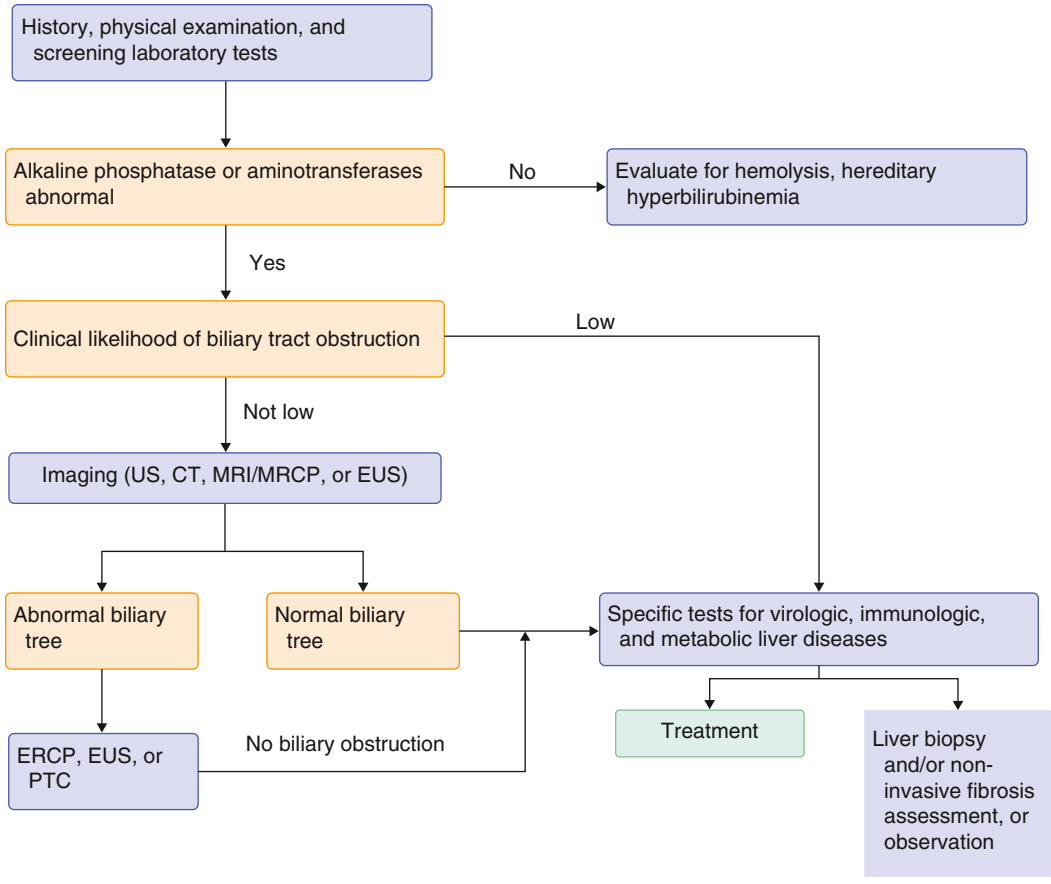


FIGURE 133-1. Diagnostic algorithm for the evaluation of hyperbilirubinemia and other liver test abnormalities and signs and symptoms suggestive of liver disease. CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; PTC = percutaneous transhepatic cholangiogram; US = ultrasound. (Modified from Lidofsky SD, Scharschmidt BF. Jaundice. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Gastrointestinal and Liver Disease*. 6th ed. Philadelphia: WB Saunders; 1998:227.)

metabolic perturbations may lead to acquired reductions in bilirubin conjugation. Medications known to inhibit UGT1A1 function include the human immunodeficiency virus (HIV) protease inhibitors (indinavir and atazanavir) and sorafenib, which is a multikinase inhibitor. Various other drugs (e.g., pregnanediol and the antibiotics chloramphenicol and gentamicin) also may cause unconjugated hyperbilirubinemia by inhibiting UGT1A1. In all settings in which UGT1A1 inhibitors cause unconjugated hyperbilirubinemia, the presence of Gilbert syndrome amplifies the hyperbilirubinemia.

JAUNDICE IN PREGNANCY

Jaundice in pregnancy (Chapter 221) includes any liver disease that occurs during pregnancy.[10] Conditions unique to pregnancy include elevation of aminotransferase and bilirubin levels during the first trimester with hyperemesis gravidarum. Intrahepatic cholestasis of pregnancy, which occurs during the second and third trimesters, is associated with intrauterine demise and resolves spontaneously after delivery. Mutations and sequence variations in genes encoding biliary transporters, especially *ABCB4* and *ABCB11*, have been reported in some but not all cases. Acute fatty liver or HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome occurs in association with preeclampsia in the third trimester. Acute fatty liver may resemble fulminant hepatic failure, with early delivery a prerequisite to maternal recovery.

POSTOPERATIVE JAUNDICE

This multifactorial syndrome can be caused by increased bilirubin production (e.g., breakdown of transfused erythrocytes, resorption of hematomas), decreased hepatic bilirubin clearance (e.g., bacteremia, endotoxemia, parenteral nutrition, perioperative hypoxia), or both. Postoperative hyperbilirubinemia (Chapter 401) is often accompanied by a several-fold increase in levels of alkaline phosphatase, GGT, or both. Aminotransferase levels are, at most, minimally elevated, and synthetic function is typically normal. The differential diagnosis includes biliary obstruction (Chapter 141) or hepatocellular injury related to shock, medication-induced liver injury (Chapter 136), or viral hepatitis (Chapters 134 and 135). The resolution of postoperative jaundice tends to parallel the overall postoperative course.

DIAGNOSIS

Accurate diagnosis and the distinction between acute and chronic disease often depend on appropriate selection and interpretation of laboratory and imaging studies. Tests used in initial evaluation of liver disease fall into two categories: tests that indicate injury, most commonly the aminotransferase levels, and tests that measure, or at least reflect, actual function. The results of laboratory testing can be informative for the magnitude of their deviation from the reference range, or as binary data to distinguish normal from abnormal. Serial determinations often can be helpful to assess the course of disease or the outcome of an intervention.

Serum Enzyme Tests

The levels of hepatic enzymes found in plasma are a measure of hepatocyte turnover or injury. Enzymes released during normal hepatocyte turnover are believed to be the basis for normal circulating levels. Cell injury and cell death activate phospholipases that create holes in the plasma membrane, thereby increasing the release of intracellular contents.

Aminotransferases

The aminotransferases catalyze transfer of the α-amino group of aspartate (aspartate aminotransferase [AST]) or alanine (alanine aminotransferase [ALT]) to the α-keto group of α-ketoglutarate, with pyridoxal phosphate (vitamin B_6) as a cofactor. Laboratory methods that assay aminotransferase activity require supplementation with vitamin B_6 to avoid falsely decreased activity in subjects who are vitamin B_6 deficient.

Normal serum levels, which are established locally from samples obtained from normal populations, may vary appreciably in different populations but are typically 40 IU/L or less (see Appendix). Deviations from the reference ranges should be expressed as multiples of the upper limits of the reference range.

Values >20 times the upper limit of normal can occur with acute hepatocyte injury from shock, viral infection, or immune- or medication-induced injury. ALT is a purely cytosolic enzyme. Distinct isoforms of AST are present in cytosol and mitochondria, and AST is also found on the plasma membrane. Expression of the mitochondrial isoform and its physiologic export from the hepatocyte are upregulated by ethanol.

Circulating levels of AST and ALT are elevated in most hepatic diseases,[11] and the degree of aminotransferase activity found in plasma roughly reflects the current activity of the disease process. There are, however, exceptions, and aminotransferases can both underestimate and overestimate the degree of hepatic injury. In alcohol-related hepatitis (Chapter 138), aminotransferase levels greater than 10 times the upper limit of normal are uncommon, and levels exceeding this threshold may suggest an additional cause of organ injury. In nonalcoholic fatty liver disease (Chapter 138), normal values for ALT may be found in an appreciable fraction of patients with steatohepatitis, fibrosis, or even cirrhosis. By contrast, conditions as diverse as papillary stenosis, transient choledocholithiasis (Chapter 141), and some forms of acute viral hepatitis (Chapter 134) manifest minimal histologic changes despite aminotransferase levels in excess of 10 times the upper limit of normal. Conversely, aminotransferase levels may decline during the course of massive hepatic necrosis because liver injury is so extensive that little enzyme activity remains. In rare circumstances, antibodies to AST result in an antibody-enzyme complex called a macroenzyme that has a delayed clearance from the circulation.

Aminotransferase levels are useful in several distinct ways. First, they provide a relatively specific screening test for hepatobiliary disease, including the diagnosis of previously unsuspected chronic hepatitis B or C. Although AST levels may be increased with diseases of other organs (notably myocardial and skeletal muscle), the source of increased aminotransferase activity can often be elucidated by consideration of the clinical context in which it arises. Aminotransferase levels are also used to monitor the activity of an acute or chronic parenchymal liver disease and its response to therapy.

Aminotransferase levels also can be elevated in patients with severe systemic disease. For example, aminotransferase levels may be elevated in over 90% of patients hospitalized with coronavirus 2019 (COVID-2019; Chapter 336) infection,[12] in whom they appear to indicate hepatic injury.

Aminotransferase levels may provide diagnostic clues. In most liver diseases, the ratio of AST to ALT is usually 1 or less; however, ratios are typically 2 or higher in alcoholic fatty liver and alcoholic hepatitis (Chapter 138) as a reflection of increased synthesis and secretion of mitochondrial AST into plasma and selective loss of ALT activity because of the pyridoxine deficiency commonly seen in alcoholism. An elevated AST/ALT ratio also occurs in acute liver failure from Wilson disease (Chapter 195).

Alkaline Phosphatases

Alkaline phosphatases are widely distributed enzymes (e.g., liver, bile ducts, intestine, bone, kidney, placenta, and leukocytes) that catalyze the release of orthophosphate from ester substrates at an alkaline pH. The normal activity level in adult serum is dependent on the patient's age and sex, as well as the method of measurement.[13] Two widely used current methods have upper limits of normal in adults of 85 and 110 IU/L (see Appendix). Serum levels higher than the reference range are normal in children and in pregnancy. Bone alkaline phosphatase participates in the deposition of hydroxyapatite in osteoid. In other sites, including the liver, its phosphatase activity may facilitate movement of molecules across cell membranes. Serum alkaline phosphatase activity principally reflects the contribution of hepatic and bone isoforms; the intestinal form may account for 20 to 60% of the total after a fatty meal, and blood groups B and O are associated with sustained increases. There is a substantial placental contribution to the alkaline phosphatase level late in pregnancy; the Regan isozyme, a variant that appears identical to the placental form, is associated with hepatocellular cancer (Chapter 181), lung cancer (Chapter 177), and other neoplasms.

Elevations in the serum alkaline phosphatase in cholestatic hepatobiliary disease result from two distinct mechanisms: increased synthesis and secretion of the enzyme and solubilization from the apical (canalicular) surface of hepatocytes and the luminal surface of biliary epithelial cells by the increased local concentrations of bile acids that occur with cholestasis. The first step in the evaluation of alkaline phosphatase is to elucidate the source of the elevation. The placenta, bone, and intestine are non-hepatobiliary sources, and increases in activity can be seen in pregnancy and disorders of increased bone turnover, including Paget disease (Chapter 228), osteomalacia (Chapter 226), and osseous metastatic disease. When the source of the alkaline phosphatase is inapparent from the clinical history, elevation of the gamma-glutamyl transferase (GGT) or 5'-nucleotidase (5'-NT) make a hepatobiliary source likely. The interpretation of a normal GGT is more complicated; although the GGT can be normal in non-hepatobiliary disorders, it is also typically normal in intrahepatic cholestasis of pregnancy, and in some familial cholestatic disorders. With a serum half-life of approximately 1 week, serum alkaline phosphatase levels may remain elevated for days to weeks after resolution of biliary obstruction. This delay may be especially misleading when accompanied by prolonged direct-reacting hyperbilirubinemia owing to delayed clearance of delta bilirubin.

Modest increases in serum alkaline phosphatase (<3 times the upper limit of normal) occur in many hepatic parenchymal disorders, including hepatitis and cirrhosis. Greater increases (3 to 10 times the upper limit of normal) usually indicate obstruction of bile flow. Although the highest levels usually reflect obstruction of the common bile duct, elevations also can occur with obstruction of intrahepatic bile ducts from infiltrative conditions that arise from granulomatous processes (sarcoidosis [Chapter 83], mycobacterial infection [Chapters 299 and 300]), malignancy (lymphoma, cholangiocarcinoma, or metastatic cancer), or amyloidosis (Chapter 174).

Other Hepatic Enzymes

5′-nucleotidase (5′-NT) is a plasma membrane enzyme that cleaves orthophosphate from the 5′ position on the pentose sugar of adenosine or inosine phosphate. Leucine aminopeptidase (LAP) is a ubiquitous cellular peptidase. The serum levels of both usually increase in cholestasis. Accordingly, their major use is to confirm whether an elevated alkaline phosphatase is of hepatobiliary origin. Both enzymes may be increased in the later stages of a healthy pregnancy.

Gamma-glutamyl transpeptidase (GGT) is present in many tissues. Its serum activity increases in hepatobiliary disease but also in neuromuscular diseases, pancreatic disease (even in the absence of biliary obstruction), pulmonary disease, and during the ingestion of ethanol and other inducers of microsomal enzymes. Nevertheless, because serum GGT levels are usually normal in bone disease, the enzyme may be helpful in confirming the hepatic origin of alkaline phosphatase. Lactate dehydrogenase levels are often elevated in hepatic ischemia and other conditions that result in hepatic necrosis.

Tests Based on Clearance of Metabolites and Drugs

A major function of the liver is to remove various metabolites and toxins from the blood. In liver disease, clearance of such molecules may be impaired because of loss of parenchymal cells, diminished bile secretion, biliary obstruction, decreased cellular uptake or metabolism, or reduced or heterogeneous hepatic blood flow. Serum levels of metabolites produced at a relatively constant rate (e.g., bilirubin) can be particularly useful indicators of liver function.

Bilirubin

The differential diagnosis of hyperbilirubinemia (see earlier) includes generalized liver disease, inherited disorders of bilirubin metabolism (e.g., Gilbert, Crigler-Najjar, Dubin-Johnson, and Rotor syndromes), and nonhepatic conditions (e.g., hemolysis). Higher bilirubin levels correlate with a poorer prognosis in most forms of chronic liver disease.

Ammonia

Ammonia, a byproduct of amino acid metabolism, is removed from blood by the liver, converted to urea in the Krebs-Henseleit cycle, and excreted by the kidneys. In the setting of portosystemic shunting or severe hepatic dysfunction, ammonia levels rise. Measurements of blood ammonia are typically used to confirm a diagnosis of hepatic encephalopathy (Chapter 139); however, they do not strongly correlate with the severity of the encephalopathy (Chapter 139). The correlations may be improved if the measurement is made rapidly on an iced arterial blood sample. Elevated ammonia levels also occur when ammonia production is increased by intestinal flora, by the kidney (in response to metabolic alkalosis or hypokalemia), or in rare genetic diseases that affect the pathway of urea synthesis.[14]

Tests Reflecting Hepatic Synthetic Function

Coagulation Tests

Prothrombin Time

The prothrombin time (PT) reflects the plasma concentrations of both extrinsic and common pathway factors, that is, factors VII, X, and V; prothrombin; and fibrinogen. A prolonged PT most often results from vitamin

K deficiency, liver disease, or the therapeutic use of warfarin-like anticoagulants. Vitamin K, a fat-soluble vitamin, is found in many foods and is also synthesized by gut bacteria (Chapter 161). Vitamin K deficiency can be caused by poor dietary intake and malabsorptive states, including the fat malabsorption that results from cholestasis, and with antibiotic suppression of gut flora, particularly in patients who receive inadequate vitamin K replacement.

The half-lives of clotting factors are typically less than 1 day. Factor VII, which has the shortest half-life, is usually the earliest and most severely depressed during periods of defective hepatic synthesis. Because the PT is dependent on factor VII, it responds rapidly with changes in hepatic synthetic function; it is useful for following the course of acute liver diseases, in which a significant or growing prolongation of the PT may indicate a poor prognosis (Chapters 139 and 140). An abnormal PT that is due solely to vitamin K deficiency usually becomes normal within 24 to 48 hours after parenteral repletion; however, if decreased synthesis of clotting factors reflects hepatocyte dysfunction, there may be little or no response to vitamin K.

Although the prolongation of PT with liver disease is generally accepted as indicative of defective clotting factor synthesis, the synthesis of both procoagulant and anticoagulant proteins is disturbed in liver disease. The physiologic consequences of this rebalancing of coagulation may preserve the coagulation response. Prolongation of the PT may also reflect an acquired dysfibrinogenemia or spur cell hemolytic anemia, both of which can occur in decompensated cirrhosis (Chapter 139).

Albumin

Albumin is produced solely by the liver. Its plasma concentration reflects a balance between its synthetic rate of approximately 100 to 200 mg/kg/day and plasma half-life of approximately 21 days. The synthetic rate is affected by the patient's nutritional state, thyroid and glucocorticoid hormone levels, plasma colloid osmotic pressure, exposure to hepatotoxins (e.g., alcohol), and presence of systemic disorders, liver disease, or both. Many conditions increase albumin losses and shorten its plasma half-life, including nephrotic syndrome (Chapter 107), protein-losing enteropathy (Chapter 126), severe burns (Chapter 97), exfoliative dermatitis, and major gastrointestinal bleeding (Chapter 121). Hypoalbuminemia in cirrhosis indicates diminished hepatic synthetic function.

Hematologic Tests in Liver Disease

In moderate to severe acute liver diseases, varying degrees of cytopenias can be seen with all three cell lineages. The most common finding is thrombocytopenia from hypersplenism, which can be a surrogate marker of portal hypertension. Anemia may reflect low-grade hemolysis or marrow depression. Bone marrow suppression may be caused by ethanol or drugs, and aplastic anemia has an uncommon but recognized association with acute viral hepatitis. Zieve syndrome (spur cell hemolytic anemia and hypertriglyceridemia) is a rare but well-characterized complication of severe alcoholic liver disease (Chapter 138). Modest leukopenia, often with atypical lymphocytes, also may be present. Chronic liver disease, especially if cholestatic, may be accompanied by target cells, erythrocytes with an expanded cell membrane that reflects abnormalities in serum lipids.

APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

History, Physical Examination, and Initial Laboratory Studies

Patients with liver disease may present with jaundice or other signs or symptoms, or the disease may be detected in the asymptomatic patient by the finding of abnormal liver tests during a routine evaluation. Regardless of how the patient comes to medical attention, the diagnostic approach (see Fig. 133-1) begins with a careful history, physical examination, and screening laboratory studies (measurement of total and direct bilirubin, ALT, AST, alkaline phosphatase levels, and PT) to formulate an initial differential diagnosis.[15,16] The ability to distinguish between liver disease and biliary tract obstruction is the major goal of the initial evaluation (Table 133-3).

Historic details relevant to the assessment of liver disease include quantification of alcohol consumption, use of medications including complementary and alternative supplements, injection drug use, prior hepatobiliary surgery, and a family history of liver disease. Physical evidence of cirrhosis (e.g., spider angiomas, gynecomastia, ascites, splenomegaly) supports the diagnosis of chronic parenchymal disease. Laboratory testing should help to distinguish primary hepatocellular injury from a cholestatic or mixed pattern. Hepatic synthetic function and signs of portal hypertension (thrombocytopenia) should be assessed. Serologic testing can further elucidate the causes of liver disease. It is also important to recognize that laboratory patterns alone commonly are not sufficient to make or exclude a diagnosis.

TABLE 133-3 OBSTRUCTIVE JAUNDICE VERSUS CHOLESTATIC LIVER DISEASE

FEATURE	SUGGESTS OBSTRUCTIVE JAUNDICE	SUGGESTS PARENCHYMAL LIVER DISEASE
History	Abdominal pain Fever, rigors Prior biliary surgery Acholic stools	Anorexia, malaise, myalgias, suggestive of viral prodrome Known infectious exposure Use of injection drugs or intranasal cocaine Exposure to known hepatotoxin Family history of jaundice
Physical examination	High fever Abdominal tenderness Palpable abdominal mass	Ascites Other stigmata of liver disease (e.g., prominent abdominal veins, gynecomastia, spider angiomata, asterixis, encephalopathy, Kayser-Fleischer rings)
Laboratory studies	Elevated alkaline phosphatase level with varying degrees of hyperbilirubinemia Prothrombin time that is normal or normalizes with vitamin K administration	Elevated aminotransferase levels Prolonged prothrombin time that does not correct with vitamin K administration Blood tests indicative of specific liver disease

Imaging Studies

If extrahepatic obstruction is suspected, its site and nature can be determined in virtually all patients. A reasonable initial step is the use of a noninvasive imaging study such as ultrasonography or magnetic resonance cholangiopancreatography (MRCP) to determine whether the intrahepatic or extrahepatic biliary system, or both, are dilated, thereby implying mechanical obstruction. Because of its lesser expense, portability, and convenience, ultrasound is often the procedure of choice for the diagnosis of cholelithiasis (Chapters 132 and 141). Biliary obstruction may be less apparent in cirrhosis, and mild biliary dilation without obstruction is common after cholecystectomy.

The biliary tree can be examined by endoscopic retrograde cholangiopancreatography (ERCP; Chapter 120) or percutaneous transhepatic cholangiography. Endoscopic ultrasound (EUS) (Chapter 120) is a complementary approach that permits internal ultrasonographic analysis of the pancreas, extrahepatic bile ducts, and regional lymph nodes and blood vessels. EUS combined with fine needle aspiration permits tissue sampling of abnormalities in areas such as the bile ducts and pancreas that typically have been difficult to sample percutaneously.

Selection of Imaging Tests

Liver ultrasound is an ideal screening test to evaluate the liver architecture, assess for surface nodularity and parenchymal mass lesions, and exclude biliary obstruction. Ultrasound is relatively inexpensive in comparison to other imaging modalities, is widely available, and avoids ionizing radiation. The identification of mass lesions on ultrasound will commonly prompt further cross-sectional imaging with either computed tomography or magnetic resonance imaging. If imaging reveals evidence of biliary obstruction or if obstruction is still considered likely despite imaging findings, cholangiography by ERCP or PTC, both of which offer therapeutic and diagnostic capabilities, may be an appropriate choice. In patients with an intermediate probability of obstruction, MRCP is a reasonable study. Individual radiology units have different levels of expertise for these procedures, and the local radiology staff may be quite helpful in recommending the best procedure for a given patient.

ALKM = anti–liver/kidney microsomal antibody; ANA = antinuclear antibody; AMA = antimitochondrial antibody; ASMA = anti–smooth muscle antibody; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; MR = magnetic resonance; MRI = magnetic resonance imaging. WWW.BOOKBAZ.IR

Asymptomatic Aminotransferase Abnormalities

Epidemiologic data suggest that up to 25% of asymptomatic adult Americans have a mild to moderate elevation of aminotransferase levels. The incidental discovery of such abnormalities is currently the most frequent means by which liver disease is first recognized. Whereas up to one third of such patients have no elevation on subsequent testing, others may prove to have any of the common forms of liver disease including chronic viral hepatitis (Chapter 135) and nonalcoholic fatty liver disease (Chapter 138). Persistent elevations of liver test levels should prompt careful clinical evaluation (Fig. 133-2), including laboratory testing of aminotransferase levels and hepatic synthetic function. Serologic studies for viral, autoimmune, and metabolic conditions can provide further insights into diagnosis. When appropriate, changes in aminotransferase levels observed in response to weight loss, the withdrawal of medications, or alcohol sobriety can be very helpful. The evaluation can be further aided by elastography to assess for hepatic fibrosis or liver biopsy when tissue characterization is necessary for a diagnosis (Chapter 132).

Alkaline Phosphatase Elevation

A careful history identifies patients at risk for intrahepatic cholestasis related to drugs or toxins (Chapter 136). The presence of hilar adenopathy or arthritis may implicate sarcoidosis (Chapter 83), although hepatic sarcoidosis can be present without extrahepatic disease. Many patients with isolated elevation of the alkaline phosphatase level have nonhepatic causes, such as pregnancy or bone disease. The origin of an elevated alkaline phosphatase can be determined by fractionation into its constituent fractions (Fig. 133-3). A hepatic source is highly likely if the serum GGT is also abnormal.

Imaging of the liver and biliary tree is necessary when the alkaline phosphatase is of hepatobiliary origin. The diagnostic approach typically begins with liver ultrasound, but MRCP may be an appropriate first choice in, for example, individuals who have inflammatory bowel disease (Chapter 127), in which the probability of primary sclerosing cholangitis (Chapter 141) is increased. Serologic studies should include an antimitochondrial antibody; a positive result suggests primary biliary cholangitis. Other less common (and nonexhaustive) causes of cholestatic liver test include amyloidosis (Chapter 174), tuberculosis (Chapter 299), fungal infections, extramedullary hematopoiesis, Langerhans cell histiocytosis (Chapter 155), infiltrative neoplasms, and sepsis.

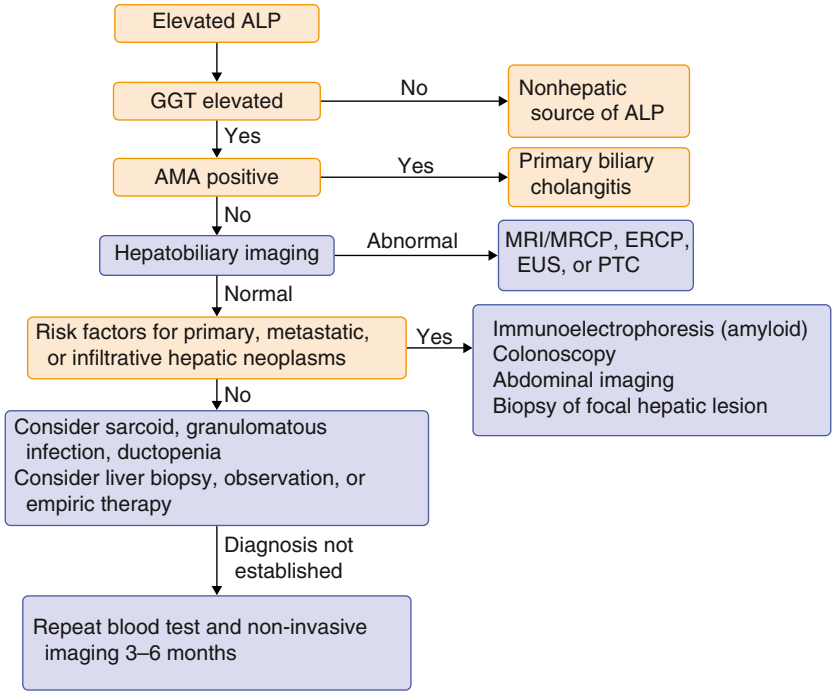

FIGURE 133-3. Approach to the asymptomatic patient with isolated elevated levels of serum alkaline phosphatase (*ALP*). In cases with a high index of suspicion of biliary tract disease (e.g., sclerosing cholangitis), cholangiography may be warranted even in the face of normal ultrasound imaging. AMA = antimitochondrial antibody; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; GGT = γ-glutamyl transpeptidase; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; PTC = percutaneous transhepatic cholangiogram; US = ultrasonography.

134 ACUTE VIRAL HEPATITIS

JEAN-MICHEL PAWLOTSKY

Infection with a hepatotropic virus causes an acute episode of liver inflammation, referred to as *acute hepatitis*, which can lead to either spontaneous clearance of the infectious agent or its persistence, which in turn leads to chronic infection for a subset of these viruses. Five hepatitis viruses are responsible for the vast majority of acute hepatitis cases (Table 134-1):[1] hepatitis A virus (HAV); hepatitis B virus (HBV); hepatitis C virus (HCV); hepatitis D, or delta, virus (HDV), which is a defective viroid using the hepatitis B surface antigen (HBsAg) as its envelope; and hepatitis E virus (HEV).[2] Other viruses may cause acute inflammatory liver disease, including members of the Herpesviridae family such as human cytomegalovirus, Epstein-Barr virus, and herpes simplex virus. In one study from Spain, the most common causes of acute viral hepatitis cases were: 28% hepatitis B, 18% hepatitis C, 14% hepatitis A, and 14% Epstein-Barr virus (Chapter 348),[3] but severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection also is often accompanied by acute hepatitis. Adenovirus infection has led to outbreaks of hepatitis in children. It is unclear to what extent other viruses, such as parvovirus B19 or human herpesvirus 6, can also cause acute hepatitis. Patients who present with an acute viral hepatitis syndrome but negative virologic tests are referred to as having non–A-to-E hepatitis, perhaps attributable to hepatotropic viruses that have yet to be identified. The worldwide incidence of acute viral hepatitis is decreasing because of global improvements in hygiene and the development and use of efficient vaccines against HBV, to a lesser extent against HAV, and perhaps in the future, HEV.

TABLE 134-1 VIRUSES RESPONSIBLE FOR ACUTE VIRAL HEPATITIS AND LIKELIHOOD OF CHRONIC EVOLUTION

VIRUS	EVOLUTION TO CHRONIC VIRAL HEPATITIS
Hepatitis A virus	Never
Hepatitis B virus	>90% (perinatal acquisition) to <1% (adult infection)
Hepatitis C virus	50-80%
Hepatitis D or delta virus	2% (coinfection) to 90% (superinfection)
Hepatitis E virus	Occasionally in immunosuppressed patients
Other viruses Human cytomegalovirus Epstein-Barr virus Herpes simplex virus Human herpesvirus 6 Parvovirus B19 SARS-CoV-2	May establish chronic infection (except SARS-CoV-2), not associated with chronic hepatitis

GENERAL FEATURES OF ACUTE VIRAL HEPATITIS

PATHOBIOLOGY

Acute viral hepatitis is characterized by acute necroinflammation of the liver. Because none of the hepatotropic viruses is cytopathic, liver injury is mediated by a strong cytotoxic T cell–mediated reaction against infected hepatocytes that express viral antigens at their surface. Pro-inflammatory cytokines, natural killer cells, and antibody-dependent cellular cytotoxicity also appear to play a role in liver necroinflammation. Successful immune elimination may lead to viral clearance, which may or may not be associated with lifelong immunity, depending on the infecting agent. The immune reaction is sometimes so potent that the patient develops subfulminant or even fulminant hepatitis that requires liver transplantation (Chapter 140). In some patients—the proportion varies, according to the virus responsible for acute hepatitis—the immune response fails and chronic infection is established (Chapter 135).

CLINICAL MANIFESTATIONS

After infection, there is an incubation period from a few days to a few weeks, depending upon the causative agent (Fig. 134-1). This incubation period is generally characterized by nonspecific symptoms, including fatigue, nausea, loss of appetite, flulike symptoms, and/or right upper quadrant pain (Table 134-2). The incubation period is often characterized by leukopenia and relative

The incubation period is often characterized by leukopenia and relative

ABSTRACT

Infection with a hepatotropic virus causes an acute episode of liver inflammation, referred to as acute hepatitis, which can lead to either spontaneous clearance of the infectious agent or its persistence, which in turn leads to chronic infection for a subset of these viruses. Five hepatitis viruses are responsible for the vast majority of acute hepatitis cases: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D or delta virus (HDV), and hepatitis E virus (HEV). Hepatitis B and C viruses can cause chronic infections. HDV infection can become chronic in chronic HBV carriers. Finally, HEV may become chronic in profoundly immunosuppressed patients. Antiviral treatment is indicated only for the treatment of acute hepatitis C because of the high risk (50 to 80%) of chronicity. The other causes of acute viral hepatitis are self-resolving in the vast majority of cases. Prevention is based on: the improvement of hygiene (HAV and HEV); safe medical and surgical procedures, as well as safe injection drug practices (HBV, HCV, and HDV); treatment of mother-to-infant transmission (HBV); and HBV vaccination (HBV and HDV).

lymphocytosis. Immune-mediated symptoms, including rash, hives, arthralgias, angioneurotic edema, and fever, are observed in 10 to 20% of patients during the preicteric phase.

During the acute stage of the disease, symptoms may vary widely, from asymptomatic to subicteric, icteric or severe, and fulminant. The icteric form, which is not frequent, is characterized by fatigue, anorexia, nausea, dysgeusia, jaundice, dark urine, light-colored stool, and weight loss. Physical examination reveals jaundice and hepatic tenderness. Hepatomegaly and splenomegaly may be present. On laboratory testing, acute viral hepatitis is characterized by elevated total and direct serum bilirubin levels and aminotransferase levels that are often greater than 10 times the upper limit of normal. Cholestatic acute hepatitis is associated frequently with prolonged and fluctuating jaundice and pruritus. After 1 to 3 weeks, on average, both clinical and laboratory signs progressively improve and return to normal. Some patients, however, may experience a relapse before definitive resolution.

Signs of hepatic failure (Chapter 140), including changes in personality, aggressive behavior, sleeping disorders, and hepatic encephalopathy, characterize fulminant forms of acute viral hepatitis. Coma can supervene rapidly, and widespread hemorrhage may develop.

DIAGNOSIS

The diagnosis of acute hepatitis is suspected based on elevated serum aminotransferase levels, which are generally more than 10 times the upper limit

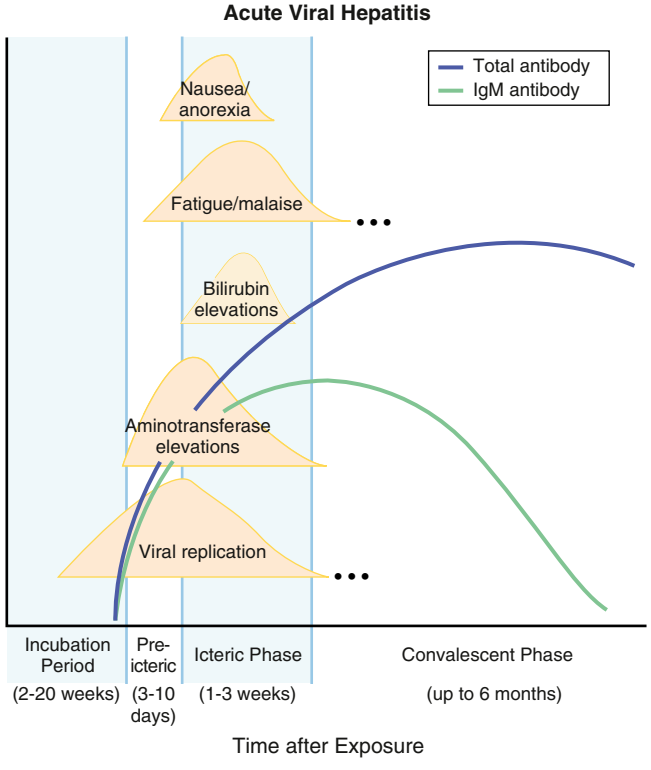

FIGURE 134-1. Typical course of acute viral hepatitis. IgM = immunoglobulin M.

of normal (Table 134-3). Total and direct bilirubin levels are elevated if the acute hepatitis is subicteric or icteric. Alkaline phosphatase levels may be elevated in cases of cholestatic hepatitis.

Serologic and eventually molecular testing identifies the causal agent. Liver biopsy or a non-invasive assessment of liver inflammation and fibrosis are generally not required. All cases of acute hepatitis should be reported to the local, state, or national health department as soon as possible after diagnosis.

TREATMENT

In addition to virus-specific therapy for HBV and HCV,[4] patients with acute viral hepatitis should avoid alcohol consumption and acetaminophen. Sexual contact should be avoided if the partner is not protected (i.e., not HBV vaccinated). Patients with subfulminant or fulminant hepatitis should be supported in an intensive care unit setting and evaluated for possible liver transplantation (Chapter 140).

TABLE 134-2 COMMON CLINICAL MANIFESTATIONS OF ACUTE VIRAL HEPATITIS

PHASES OF INFECTION	DURATION*	MANIFESTATIONS*
Incubation	2-20 weeks	Virus detectable in blood Aminotransferase and bilirubin levels normal No antibody detectable
Preicteric	3-10 days	Nonspecific symptoms: fatigue, anorexia, nausea, vague right upper quadrant pain Viral titers peak Aminotransferase levels begin to rise Immune complex-mediated hypersensitivity reaction (≈10-20% of cases) with rash, hives, arthralgias, fever
Icteric	1-3 weeks	Jaundice appears; dark urine and light stools seen Nonspecific symptoms worsen Weight loss, dysgeusia, pruritus may occur Hepatosplenomegaly may develop Aminotransferase levels typically >10 times normal Antibodies appear Viral titers decline Rare extrahepatic manifestations (aseptic meningitis, encephalitis, seizures, ascending flaccid paralysis, nephrotic syndrome, seronegative arthritis)
Recovery	Up to 6 months	Symptoms resolve gradually Antibody levels rise Aminotransferase and bilirubin levels normalize
Chronic	After 6 months	See Chapter 135

*Varies by virus.

GENERAL EVALUATION
Alanine aminotransferase Aspartate aminotransferase Alkaline phosphatase International normalized ratio (INR)
FIRST-LINE DIAGNOSTIC TESTS
Anti-HAV IgM HBsAg, anti-HBc IgM Anti-HCV antibodies HCV RNA Anti-HEV IgM
SECOND-LINE DIAGNOSTIC TESTS
Anti-HAV IgM present: none advised HBsAg and anti-HBc IgM present: HDV antigen, anti-HDV antibodies HCV RNA present with or without anti-HCV antibodies: none advised Anti-HEV IgM present: none advised No virologic marker: See Fig. 134-3

HAV = hepatitis A virus; HBc = hepatitis B core; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HDV = hepatitis D virus; HEV = hepatitis E virus; IgM = immunoglobulin M.

PROGNOSIS

Prognosis depends on the degree of prolongation of the prothrombin time, as well as the degree of elevation of the bilirubin and lactate levels. A factor V level less than 40% or any signs of encephalopathy are indications for hospitalization. Death is extremely rare and occurs only in fulminant cases. Other signs of poor prognosis are persistently worsening jaundice, ascites, and an acute decrease in the size of the liver. Serum aminotransferase levels and viral genome levels have no prognostic value.

HEPATITIS A

DEFINITION

The Pathogen

HAV is a member of the Picornaviridae family, genus *Hepatovirus*. The hepatitis A viral particle is a 27-nm nonenveloped icosahedral nucleocapsid that expresses the hepatitis A antigen and contains a positive-stranded RNA genome approximately 7.5 kb long. Three different HAV genotypes have been described in humans (genotypes I, II, and III, further divided into subtypes A and B), with genotype I predominating worldwide. Other genotypes have been isolated in nonhuman primates. It is currently unclear to what extent different genotypes are associated with distinct clinical courses of infection.

EPIDEMIOLOGY

HAV infection has a worldwide distribution, and infections can be sporadic or occur in epidemic outbreak. The incidence of acute cases and the seroprevalence vary according to the hygiene, sanitation, housing, and socioeconomic standards of a given region, with a seroprevalence as low as approximately 13% in Sweden but up to 100% in many countries with poor sanitary conditions and hygienic practices. In developing countries, infection generally occurs at a young age and most of the population has been exposed and is protected after age 10 years. In countries with good sanitary and hygienic conditions, however, infection can occur at any age, and the prevalence of exposed, immune subjects slowly increases with age. In the United States, according to the Centers for Disease Control and Prevention, the incidence of acute hepatitis A declined from 12.0 cases per 100,000 individuals in 1995 to 0.5 cases per 100,000 individuals by 2012, but has subsequently increased to 3.8 cases per 100,000 individuals in 2018 owing to widespread outbreaks among persons reporting drug use and homelessness.

HAV is generally transmitted via the fecal-oral route, most often directly from person to person or through the ingestion of fecally contaminated food[5] or water. Transmission by blood transfusion has been reported, and isolated cases of apparent perinatal transmission have been described. High-risk groups for acute hepatitis A include travelers to developing countries, children in day care centers and their parents, men who have sex with men, injection drug users, homeless persons, patients who receive plasma products for hemophilia, and persons in institutions.[6]

PATHOBIOLOGY

The genome serves as a messenger RNA and contains a single open reading frame that encodes both structural and non-structural viral proteins. After attachment to a specific receptor at the surface of hepatocytes, the virus penetrates into cells and is uncoated. Subsequent events occurring exclusively in the cytoplasm include translation of the single open reading frame into a polyprotein that is later processed to generate the mature viral proteins; replication in a membrane-bound replication complex that generates new viral genomes, which are subsequently used for viral protein production and viral particle assembly; and packaging of newly formed genomes into new particles that are exported out of the cells. The virus is secreted into bile and, to a lesser extent, serum.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 15 to 45 days (see Table 134-2). In most cases, acute infection takes a mild and unrecognized course. The incidence of symptomatic, icteric cases increases with the age at infection.[7] Acute hepatitis A in adults may require hospitalization in up to 13% of cases; prolonged courses of 6 to 9 months have been reported in 10% of adult patients with a diagnosis of acute hepatitis A. Hepatitis A is the most common cause of relapsing cholestatic hepatitis.

DIAGNOSIS

The diagnosis of acute hepatitis A is based on the detection of anti-HAV immunoglobulin M (IgM) in serum by enzyme immunoassay. IgM serum levels peak during the second month of infection (Fig. 134-2). HAV RNA can be transiently detected in stool and other body fluids by polymerase chain reaction (PCR) 3 to 10 days before the onset of illness and for 1 to 2 weeks thereafter; however, HAV RNA testing is not necessary. When the infection resolves, anti-HAV IgM disappears after 4 to 12 months, but anti-HAV IgG persists for life and confers definitive and durable protection against infection.

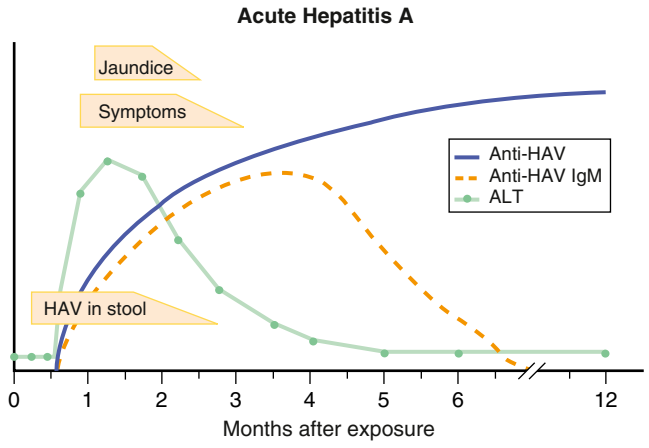

FIGURE 134-2. Serologic course of acute hepatitis A. ALT = alanine aminotransferase; HAV = hepatitis A virus; IgM = immunoglobulin M.

TREATMENT

Because HAV infection is self-limited, no specific antiviral treatment is required. In severe cases, patients may need to be hospitalized. If liver function is deteriorating, patients may need to be assessed for liver transplantation, which is the only therapeutic option for acute liver failure (Chapter 140).

PREVENTION

HAV vaccines (Chapter 15) consist of inactivated hepatitis A antigen purified from cell culture. Two doses of the vaccine are recommended at a 6- to 18-month interval. All vaccines are highly immunogenic, and virtually all healthy persons who are vaccinated develop protective anti-HAV antibodies. Patients with chronic liver disease also respond to vaccination but may display lower anti-HAV titers. An accelerated vaccine schedule, with vaccination on days 0, 7, and 21, is also effective and may be recommended for those planning to travel to endemic areas. HAV vaccines are well tolerated, and no serious adverse events have been linked with their administration; they can be safely administered with other vaccines or immunoglobulins without compromising the development of protective antibodies. A combination HAV and HBV vaccine is also available. Seroconversion rates are lower in immunocompromised individuals.

HAV vaccination is recommended for nonimmune individuals who plan to travel to endemic countries, medical health professionals, men who have sex with men, persons who are in contact with hepatitis A patients, and individuals with chronic liver diseases. A childhood vaccination program leads to a significant decline in HAV infection, justifying its use as part of control efforts in endemic countries. Serologic testing for anti-HAV IgG can be performed before vaccination in adults born in endemic countries and in individuals older than 50 years born in industrialized areas; persons with detectable IgG are protected and should not be vaccinated. For postexposure prophylaxis, both HAV vaccination and immunoglobulin are about 98% effective, with vaccination having the advantage of preventing secondary cases. HAV vaccine and immunoglobulin commonly are used together in this setting.

Long-term follow-up studies after complete HAV vaccination show that anti-HAV IgG titers sharply decline during the first year after vaccination but remain detectable in almost all individuals for at least 10 years. Protective anti-HAV antibody titers persist for at least 27 years after the successful vaccination of children and young adults.

PROGNOSIS

Acute hepatitis A infection generally resolves without complications in 3 to 4 weeks and never evolves to chronic infection. Prolonged elevation of serum aminotransferase levels has been reported. Relapses a few weeks after the acute case also have been observed. Prolonged courses may occur in children and immunosuppressed individuals.

Cholestatic hepatitis A is unusual and has a good prognosis, with full recovery within a few weeks. Fulminant hepatitis A is rare, occurring in less than 0.1% of cases, but its incidence and mortality increase with the patient's age at acquisition. In the United States, 4% of all cases of fulminant hepatitis are caused by HAV infection. Overall, mortality of acute hepatitis A is 1.8% in

patients older than 50 years. In patients with chronic hepatitis B, superinfection with HAV is associated with a 6- to 23-fold higher morbidity and mortality.

ACUTE HEPATITIS B

DEFINITION

The Pathogen

HBV is a member of the Hepadnaviridae family, genus *Hepadnavirus*. The infectious virion, the Dane particle, is 42 to 47 nm in diameter. It possesses an envelope and a capsid or core that contains the partially double-stranded, circular DNA genome and the HBV polymerase. The HBV genome is the smallest known human virus genome, with approximately 3000 nucleotides.

EPIDEMIOLOGY

Two billion individuals worldwide have been in contact with HBV, and approximately 300 million individuals have chronic infection. In the United States, approximately 0.3% of the population is chronically infected. Although the worldwide incidence of chronic HBV infection is decreasing as a result of prevention and vaccination, the absolute prevalence of chronically infected individuals has increased as a result of the increase in the world population. HBV virions are produced and circulate in very high amounts in HBV-infected individuals, who are highly contagious. Four principal routes of transmission are responsible for acute HBV infections: (1) sexual transmission, which is the principal route in industrialized areas; (2) perinatal mother-to-infant transmission, which is associated with a very high (>90%) rate of chronic infection and is the principal cause of HBV transmission in Asia; (3) horizontal transmission through nonsexual interindividual contact, which is frequent at a young age in Africa and is associated with evolution to chronicity in approximately 15% of cases; and (4) percutaneous transmission by blood and blood products, unsafe medical or surgical materials, or injection drug use.

In industrialized countries, groups at high risk for HBV infection include individuals born in areas where HBV is endemic, including immigrants and adopted children; individuals who were not vaccinated as infants and whose parents were born in regions where HBV is endemic; household and sexual contacts of HBsAg-positive individuals; persons who have ever injected drugs; persons with multiple sexual partners or a history of sexually transmitted disease; men who have sex with men; inmates of correctional facilities; patients infected with HCV or HIV; patients undergoing renal dialysis; recipients of blood or blood products before 1987; and health care workers.[8]

PATHOBIOLOGY

The HBV genome contains four overlapping open reading frames that encode a number of structural and non-structural viral proteins. The pre-S/S gene encodes the three surface proteins—small (S), middle (M), and large (L)—that express HBsAg. The pre-C/C gene encodes the core protein, that expresses the hepatitis B core (HBc) antigen, and the hepatitis B e (HBe) protein, a secreted non-structural protein that plays a role in immune tolerance to HBV replication. The P gene encodes the HBV polymerase, whose two motifs—a reverse transcriptase motif and an RNAse H motif—code for two enzymes involved in HBV replication. Finally, the X gene encodes the X protein, which is a transactivator involved in HBV replication that bears oncogenic properties. The blood of infected patients contains not only infectious viruses but also a large excess of empty, non-infectious HBV envelopes.

The complex HBV life cycle involves multiple steps: fixation to the sodium taurocholate cotransporting polypeptide, which is the main HBV receptor molecule at the surface of hepatocytes; internalization; fusion and release of the nucleocapsid containing the HBV DNA genome and the associated HBV polymerase molecule in the cell cytoplasm; transport into the nucleus, where decapsidation occurs and the DNA genome molecule is released; transformation of the viral genome by the viral polymerase into a covalently closed circular DNA, which is the episomal form responsible for persistence of the HBV genome in the nucleus of infected hepatocytes; generation of messenger RNAs and viral protein synthesis; generation of a pregenomic RNA, which serves as a template for reverse transcription that generates the long DNA strand; degradation of the pregenomic RNA by the RNAse H activity of the viral polymerase; DNA-dependent DNA polymerase activity of the reverse transcriptase motif, which synthesizes the short complementary DNA strand in newly formed nucleocapsids; and, finally, budding into the endoplasmic reticulum, maturation, and export of newly formed virions.

Ten HBV genotypes (A through J), which differ by approximately 8% of their genomic nucleotide sequence, have different geographic distributions and may be associated with different clinical outcomes. Genotype A predominates in Northern and Western Europe, whereas genotype D is the most frequent genotype in the Mediterranean area and in Eastern Europe. In non-Asian populations in the United States, genotype A predominates in men who have sex with men, whereas genotype D is the most frequent in intravenous drug users. In Asia and in Asian immigrants living in industrialized countries, genotypes B and C predominate. Genotype C has been associated with a higher incidence of severe liver disease and hepatocellular carcinoma compared with genotype B in Asia, perhaps because this genotype spread earlier than the others.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 30-150 days. Jaundice has been reported in up to one third of adult patients with acute hepatitis B, but most cases are unrecognized. Among symptomatic patients (see Table 134-2), the manifestations are similar to those of other causes of acute viral hepatitis.

DIAGNOSIS

Four markers should be sought for the diagnosis of acute hepatitis B: HBsAg, total anti-HBc antibodies, anti-HBc IgM, and anti-HBs antibodies (Table 134-4). Acute hepatitis B is characterized by the simultaneous presence of both HBsAg and anti-HBc IgM (Fig. 134-3). Total anti-HBc antibodies are also present, whereas anti-HBs antibodies are not. During the convalescence phase, patients lose HBsAg before the appearance of anti-HBs antibodies; they have isolated anti-HBc antibodies, and the diagnosis is based on the presence of anti-HBc IgM. Recovery is characterized by the appearance of anti-HBs antibodies. The presence of both total anti-HBc and anti-HBs antibodies characterizes recovery from acute hepatitis B. Anti-HBc IgG remains at high levels for the patient's lifetime, whereas anti-HBs antibody titers may fluctuate and sometimes become undetectable after several years. Quantitative HBsAg assessment may be useful during the course of acute hepatitis B because if the HBsAg level does not rapidly decrease, the patient is at risk for chronic evolution. Patients who remain positive for HBV DNA or HBeAg 6 weeks after the onset of symptoms are likely to develop chronic infection.

TREATMENT

Acute HBV infection usually does not require antiviral therapy, and most patients spontaneously clear the infection. Overall, antiviral therapy does not reduce 1-year mortality.[A1] However, antiviral therapy with a nucleoside or a nucleotide analogue (currently entecavir [0.5mg daily] or tenofovir [tenofovir disoproxil fumarate, 245 mg daily, or tenofovir alafenamide, 25 mg daily] until the signs of severity regress) is recommended in patients with severe acute hepatitis B, characterized by a coagulopathy or persistent symptoms or marked jaundice for more than 4 weeks, to prevent progression to acute liver failure and avoid subsequent liver transplantation or death.[9] Treatment should be initiated before signs of acute liver failure are present. Antiviral therapy does not cause hepatitis B to become a chronic infection.

PREVENTION

Because not everyone has been vaccinated, individuals who are aware that they are infected with HBV should take steps to avoid transmitting the infection to others. This is accomplished by ensuring that their sexual contacts and household members are vaccinated; using barrier protection during sexual intercourse; not sharing instruments such as toothbrushes, razors, and combs; cleaning blood spills with detergent or bleach; and not donating blood, organs, or sperm.

TABLE 134-4 SEROLOGIC PROFILES OBSERVED IN DIFFERENT PHASES OF ACUTE, SELF-RESOLVING HEPATITIS B

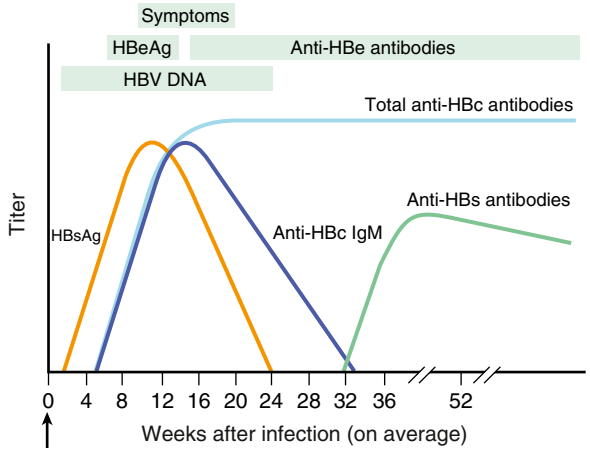

FIGURE 134-3. Kinetics of hepatitis B virus (HBV) markers during acute self-resolving hepatitis B. The *arrow* indicates infection. HBc = hepatitis B core; HBeAg = hepatitis B e antigen; HBs = hepatitis B surface; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M.

Prevention of HBV infection is based on vaccination. Universal infant vaccination programs have been initiated in many countries. High-risk individuals (e.g., health care workers, dialysis patients, family members and sexual partners of HBV carriers, pregnant women, and men who have sex with men) should be screened for HBV infection by HBsAg and anti-HBs antibody testing, and seronegative persons should be vaccinated.[10]

Vaccination consists of the administration of recombinant HBsAg in three injections at 0, 1, and 6 months in adults. A lower dose is given at the same time points in newborns, children, and adolescents. Adults on dialysis require four injections at months 0, 1, 2, and 6. HBV vaccination elicits a potent neutralizing response, characterized by the presence of isolated anti-HBs antibodies at high titers. A titer greater than 10 IU/L is considered protective. The seroconversion rate is higher than 90% in healthy individuals. HBV vaccines are well tolerated. Injection site reactions within 1 to 3 days, as well as mild general reactions, are common and transient. Post-vaccination testing for anti-HBs antibodies to document seroconversion is not routinely recommended. However, persons who remain at risk for HBV infection, such as infants of HBsAg-positive mothers, health care workers, dialysis patients, and sexual partners of HBV carriers, should be tested to determine their response to vaccination.

Of vaccinated persons, 3 to 10% respond poorly or do not respond, especially smokers, obese patients, and elderly individuals. Non-responders should receive another full course of vaccination, often with an increased dose. Other options include intradermal application and the co-administration of adjuvants and cytokines. One third to two thirds of vaccinated individuals lose their anti-HBs antibodies after 10 to 15 years. It is unclear whether these persons are still protected. Thus, persons at risk should receive booster immunization if anti-HBs antibodies have been lost.

When nonimmune persons or vaccinated individuals with an anti-HBs titer below 10 IU/L have contact with HBV-contaminated materials (e.g., needles) or have sexual intercourse with an HBV-infected person, active-passive immunization (i.e., infusion of hepatitis B immunoglobulin) plus active immunization (vaccination) is recommended within 48 hours after exposure. Vaccination alone is sufficient in persons with anti-HBs antibody titers between 10 to 100 IU/L, and no action is required if the anti-HBs titer is above 100 IU/L.

Tenofovir disoproxil fumarate (245 mg orally per day from 24 to 28 weeks of gestation until up to 12 weeks after delivery) can substantially reduce mother-to-child transmission of HBV in mothers with high viral loads (>200,000 IU/mL) or high HBsAg levels (>10,000 IU/mL).[A2] However, this long-standing practice may not be required in settings in which the baby is ensured to be given HBV immune globulin at birth as well as HBV vaccine at birth and at months 1, 2, 4, and 6.[A3]

Infants born to HBsAg-positive mothers must receive hepatitis B immunoglobulin and be vaccinated within 12 hours of birth; this regimen reduces the rate of vertical HBV transmission from 95% to less than 5%. Cesarean section is not needed if active-passive immunization is to be performed. Mothers of vaccinated infants can breast-feed, and breast-feeding is not contraindicated on tenofovir treatment.

PROGNOSIS

Fulminant hepatitis is more frequent in acute HBV infection than in other types of acute viral hepatitis, with an incidence of approximately 0.1%. Factors associated with adverse outcomes of acute hepatitis B include advanced age, female sex, and perhaps some strains of virus. Whether infection with a precore mutant strain is associated with more severe or fulminant disease is still debated.

Among patients infected at birth, the rate of spontaneous recovery after an acute HBV infection is less than 5%, whereas adult infections spontaneously resolve in 95 to 99% of cases. Spontaneous resolution confers lifelong immunity, which is usually characterized by the presence of both anti-HBs antibodies and anti-HBc antibodies. Anti-HBs antibodies may become undetectable several years after resolution, but patients rapidly produce protective antibodies if they are re-exposed to HBV.

ACUTE HEPATITIS C

DEFINITION

The Pathogen

HCV is a member of the Flaviviridae family, genus *Hepacivirus*. The genome is a single-stranded, positive, linear RNA molecule whose 5′ end contains an internal ribosome entry site involved in polyprotein translation; the genome also includes one single open reading frame and a short 3′ noncoding region involved in replication. The genome is contained in a protein capsid or core, which itself is surrounded by a lipid bilayer envelope into which two inserted viral glycoproteins mediate viral entry into target cells.

EPIDEMIOLOGY

HCV is present in all continents, and an estimated 58 million individuals are chronically infected, with about 1.5 million new infections occurring each year. In industrialized countries, the incidence of HCV infection has declined considerably owing to blood screening and measures to prevent viral infections in people who inject drugs. However, approximately 50,000 new cases of acute hepatitis C have been estimated to occur annually in the United States according to the Centers for Disease Control and Prevention, mostly in intravenous drug users. HCV incidence and prevalence are higher in developing areas of the world, where the main route of HCV infection is unsafe medical or surgical procedures; only approximately 50% of blood products are screened for anti-HCV antibodies in these countries, and approximately 40% of all injections are given with reused equipment. Egypt's estimated 7% prevalence in people 19 to 65 years is the highest worldwide, owing to unsafe injection campaigns for the treatment of schistosomiasis in the 1950s to 1960s and subsequent person-to-person transmission. Although the incidence of acute hepatitis C has declined in Egypt during the past 15 years, a substantial number of cases of acute hepatitis are still caused by HCV.

HCV is transmitted almost exclusively by infected blood. Preventive screening with highly sensitive enzyme immunoassays and, in many settings, nucleic acid testing has virtually eliminated the risk for post-transfusion HCV infection (theoretical risk: <1 in 2 million donations in the United States, 1 in 34 million donations in France). As a result, the principal route for HCV transmission in industrialized countries is now drug injection, which is responsible for 60 to 80% of new cases. The incidence of HCV infection in people who inject drugs is as high as 39 per 100 person years. In this context, imprisonment is an important risk factor for acquiring HCV infection in industrialized countries.

Nosocomial transmission through the use of improperly decontaminated materials or the contaminated hands or gloves of health care workers is responsible for a substantial number of new infections worldwide. HCV also can be transmitted by tattooing, piercing, or acupuncture if standard precautions are not implemented. Although HCV can be acquired after accidental needlestick exposure, the risk for infection is low (<1%), and health care workers have only a slightly higher prevalence of HCV than the general population. HCV can be transmitted to household members who share instruments such as scissors, razors, and combs. Sexual transmission is unusual, but outbreaks of acute hepatitis have been reported in communities of men who have high-risk sex with men. The risk for mother-to-infant transmission of HCV is less than 5% and is generally related to exposure to the mother's blood in the perinatal period. Cesarean sections are not recommended, and breast-feeding is not contraindicated (except in the presence of cutaneous nipple lesions). Factors possibly associated with high transmission rates include the level of HCV viremia and maternal intravenous drug use. In 10 to 30% of cases, no apparent risk factor for HCV infection is identifiable, suggesting other potential sources of community-acquired hepatitis C.

PATHOBIOLOGY

Entry of HCV into cells is mediated by several receptor molecules, including glycosaminoglycans, CD81, scavenger receptor B1, claudin-1, and occludin. Entry is followed by fusion. Decapsidation of viral nucleocapsids liberates free genomic RNAs into the cell cytoplasm, where they serve, together with newly synthesized RNAs, as messenger RNAs for synthesis of the HCV polyprotein. The post-translational processing of the HCV polyprotein results in the generation of 10 proteins, including 3 structural proteins (the core protein and the two envelope glycoproteins) and 7 non-structural proteins. HCV replication takes place in the replication complex (or "membranous web") that associates viral proteins, cellular components, and nascent RNA strands. It is catalyzed by the RNA-dependent RNA polymerase. Viral particle formation is initiated by the interaction of the core protein with genomic RNA. Newly produced virus particles leave the host cell via constitutive secretory pathways.

Phylogenetic analyses of HCV strains isolated in various regions of the world have identified eight main HCV genotypes, designated 1 through 8 (with genotypes 1 to 6 being the most prevalent worldwide). These HCV types comprise a large number of subtypes, identified by lowercase letters (1a, 1b, etc.). The genotypes' nucleotide sequences differ by 31 to 34%, and their amino acid sequences differ by approximately 30%; in contrast, the subtypes' nucleotide sequences differ by between 20 and 23%, with marked differences in particular genomic regions. The high prevalence and diversity of HCV genotype 3 and 6 strains in Asia and of genotype 1, 2, 4, and 5 strains in Africa suggest that these types and subtypes emerged and diversified in these regions. In industrialized countries, a small number of HCV genotypes, including 1a, 1b, 2a, 2b, 2c, 3a, and 4a, have been introduced and spread rapidly among exposed populations. Subtypes 1a and 1b predominate all over the world. The most common genotypes in the United States are 1a and 1b (≈75%), 2a, 2b and 3a (15% to 20%), and 4, 5, and 6 (below 5%). Genotype 3a is more prevalent in Western Europe, where it accounts for up to 35% of cases, especially among people who inject drugs. Genotype 4 is highly prevalent in the Middle East and Africa. Its incidence and prevalence are increasing in people who inject drugs in industrialized countries. Genotype 5 is rare outside South Africa, and genotype 6 is rare outside Southeast Asia. Genotype 7 was identified in Central Africa and genotype 8 in Punjab, India. Infections with different genotypes do not differ in terms of the clinical manifestations, progression, or disease severity.

CLINICAL MANIFESTATIONS

HCV RNA becomes detectable in the serum 3 to 7 days after exposure. HCV core antigen becomes detectable 1 to 3 days later. HCV RNA and HCV core antigen levels rise rapidly during the first weeks, followed by serum aminotransferase levels 2 to 8 weeks after exposure. Anti-HCV antibodies arise late in the course of acute hepatitis C and may not be present at the onset of symptoms and serum aminotransferase elevation.

After an incubation period that ranges from 15 to 120 days, acute hepatitis C usually remains asymptomatic and is undiagnosed. Nonspecific symptoms such as fatigue, low-grade fever, myalgias, nausea, vomiting, or itching may be present. Jaundice occurs in only 20 to 30% of patients, usually 2 to 12 weeks after infection. Serum aminotransferase levels commonly exceed 10 times the upper limit of normal in the acute stage, even in the absence of symptoms. Patients who are coinfected with human immunodeficiency virus have more severe acute symptoms.[11] Fulminant hepatitis C has been reported but appears to be exceptional in the absence of another chronic underlying liver disease.

DIAGNOSIS

When acute hepatitis C is suspected, patients should be tested for both anti-HCV antibodies by enzyme immunoassay and HCV RNA with a sensitive molecular biology technique. HCV core antigen detection by means of rapid enzyme immunoassay can be used as an alternative to HCV RNA detection.[12] Four marker profiles can be observed, based on the presence or absence of either marker (Table 134-5). The presence of HCV RNA in the absence of anti-HCV antibodies is strongly indicative of acute HCV infection, which will be confirmed by seroconversion (i.e., the appearance of anti-HCV antibodies) a few days to weeks later. Acutely infected patients can have both HCV RNA and anti-HCV antibodies at the time of diagnosis; in this case, it is difficult to distinguish acute hepatitis C from an acute exacerbation of chronic hepatitis C or acute hepatitis of another cause in a patient with chronic hepatitis C.

Acute hepatitis C is very unlikely if both anti-HCV antibodies and HCV RNA are absent or if anti-HCV antibodies are present without HCV RNA (Fig. 134-4). Patients in the latter group should be retested in a few weeks, however, because HCV RNA may be temporarily undetectable owing to transient, partial control of viral replication before the infection becomes chronic (Fig. 134-5). Apart from such cases, the presence of anti-HCV antibodies in the absence of HCV RNA is generally seen in patients who have recovered from a past HCV infection. Nevertheless, this pattern cannot be differentiated from a false-positive enzyme immunoassay result, the exact prevalence of which is unknown.

TABLE 134-5 PATTERNS OF HEPATITIS C VIRUS (HCV) MARKERS AND THEIR SIGNIFICANCE DURING ACUTE HEPATITIS C

ANTI-HCV ANTIBODIES	HCV RNA	DIAGNOSIS
–	–	Not acute hepatitis C
–	+	Acute hepatitis C
+	–	Probably not acute hepatitis C (retest in a few weeks)
+	+	Difficult to differentiate acute from chronic hepatitis C

HCV = hepatitis C virus.

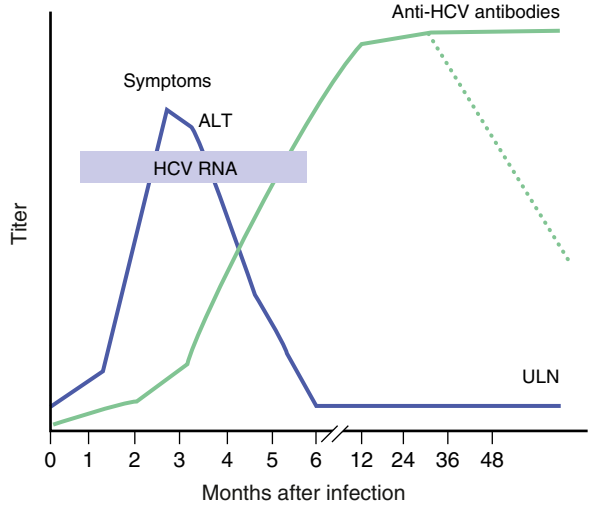

FIGURE 134-4. Kinetics of hepatitis C virus (HCV) markers during acute self-resolving hepatitis C. ALT = alanine aminotransferase; ULN = upper limit of normal.

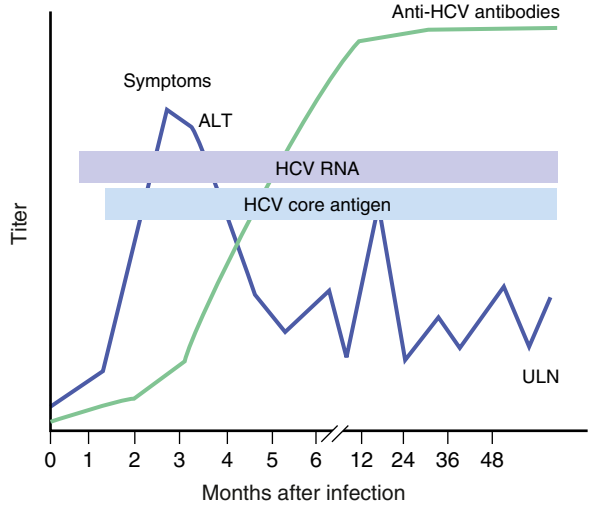

FIGURE 134-5. Kinetics of hepatitis C virus (HCV) markers during acute hepatitis C that evolves toward chronic infection. ALT = alanine aminotransferase; ULN = upper limit of normal.

TREATMENT

Treatment of acute hepatitis C should be considered not only because it prevents chronic HCV infection, which can lead to serious clinical sequelae, but also because HCV viremia is associated with a risk for transmitting HCV to other persons, especially in high-risk groups. Although 20 to 50% of patients will spontaneously clear the virus without treatment, immediate treatment is cost-effective and recommended[13] because it provides higher rates of viral clearance, mostly because asymptomatic patients tend to be less adherent with the close follow-up needed to monitor them for the institution of appropriately timed delayed therapy.[14]

Patients with acute hepatitis C should be treated with an all-oral combination of pan-genotypic, direct-acting antiviral drugs for 8 weeks. Options include the fixed-dose, once daily combination of sofosbuvir (400 mg) and velpatasvir (100 mg) or the fixed-dose combination (3 pills in the morning) of glecaprevir (100 mg) and pibrentasvir (40 mg) (see Table 134-5).[15,16] The cure of HCV infection should be assessed by HCV RNA disappearance from serum or plasma at 12 and 24 weeks post-treatment, because late relapses have been reported.

After accidental needlestick exposure, neither immunoglobulin nor post-exposure prophylaxis is recommended. Patients should be monitored with HCV RNA and aminotransferase level testing at baseline, week 2, and 4 and 6 months after exposure. Patients who have documented infection should be treated as described earlier.

PREVENTION

Prevention of HCV transmission is based on standard precautions such as screening of blood and blood products by an enzyme immunoassay for anti-HCV antibodies and/or nucleic acid testing for HCV RNA, application of standard medical and surgical hygiene procedures, and safe use of syringes and materials for drug preparation in people who inject drugs. One-time screening is also recommended for all individuals over age 18 years.[17] Needle exchange programs and education regarding the risks of drug use (including intranasal cocaine) and the risk for transmission from shared injection equipment are important. These interventions combined with effective treatment of chronic hepatitis (Chapter 135) will substantially reduce the risk of acute hepatitis C in the future.[18]

No prophylactic vaccine is or will soon be available against HCV.

PROGNOSIS

Approximately 50 to 80% of patients are unable to clear HCV spontaneously and develop chronic infection. Spontaneous recovery is more frequent if infection is acquired at birth (≈50%) and if acute hepatitis is symptomatic. It is unclear whether the genotype influences recovery rates. Other factors associated with better rates of spontaneous recovery include female sex, early decline of HCV RNA levels, and high aminotransferase or bilirubin levels. Patients who spontaneously recover may retain detectable anti-HCV antibodies for years to decades, but they are not protected against HCV reinfection.

ACUTE HEPATITIS D (DELTA)

DEFINITION

The Pathogen

HDV, which is a satellite of HBV, can be transmitted only to patients who are acutely or chronically infected with HBV. Its single, negative-strand, circular RNA genome of approximately 1700 nucleotides folds in native conditions into a nearly complementary rodlike structure that contains a ribozyme. The HDV genome encodes one single structural protein, the hepatitis D (HD) protein, which expresses HDAg. The 36-nm infectious HDV virion comprises the HD protein and the genome, both enclosed within an HBsAg-expressing coat derived from empty HBV envelopes.

EPIDEMIOLOGY

Pooled data suggest that about 5% of chronic HBV carriers, or approximately 15 million individuals worldwide, are also infected with HDV.[19] The prevalence of HDV infection in HBV-infected patients varies according to the geographic area because it is transmitted primarily through parenteral exposure. As a result, its prevalence in Western countries is 20-fold higher on average in HBsAg-positive individuals who inject drugs than in non–drug users. By comparison, the prevalence of HDV has decreased substantially in southern Europe, probably owing to universal HBV vaccination programs, improvement in hygiene and living conditions, and implementation of standard precautions to prevent HIV infection. The incidence of HDV is increasing in Russia, Eastern Europe, Japan, and India.

PATHOBIOLOGY

HDV uses host RNA polymerase II for its replication, following the rolling circle model. Within cells, HDV RNA is associated with multiple copies of the HD protein to form a ribonucleoprotein complex. This complex is exported by the HBV envelope, which contains the three HBV envelope proteins, into the Golgi apparatus before being secreted.[20]

HDV has eight genotypes (HDV-1 to HDV-8), which differ from one another by at least 20% of their nucleotide sequences. HDV genotypes can be segregated into 2 to 4 sub-genotypes, which differ from one another by at least 10% of their nucleotide sequences. HDV-1 is the most prevalent HDV genotype worldwide, whereas other genotypes have regional geographic distributions.

CLINICAL MANIFESTATIONS

HDV can be acquired at the same time as HBV (coinfection) or by a chronic HBsAg carrier (superinfection). Coinfection is characterized by one or two episodes of acute hepatitis, depending on the respective amounts of HBV and HDV present in the inoculum; acute hepatitis can range from mild to fulminant. In contrast, when chronic HBV carriers are superinfected by HDV, acute hepatitis D is generally severe, often fulminant, and generally becomes chronic.

DIAGNOSIS

Three markers of HDV infection are total anti-HD antibodies, anti-HD IgM, and HDV RNA; the latter can be detected and quantified by real-time PCR. All HBsAg-positive patients should be tested, and the diagnosis of HDV infection is based on the presence of anti-HD antibodies. Chronic HBV carriers with risk factors for HDV superinfection should be tested regularly.

In patients with a self-resolving HBV-HDV coinfection, HDV RNA and anti-HD IgM are only transiently present and are often missed. Anti-HBc IgM indicates concomitant acute HBV infection.

In HDV superinfection of a chronic HBsAg carrier, no anti-HBc IgM is present. HDV RNA is found in serum or plasma before and during the acute episode, whereas both total anti-HD antibodies and anti-HD IgM are present during the acute phase. Anti-HD antibodies and sometimes anti-HD IgM remain at high levels if the disease becomes chronic.

TREATMENT

No treatments are of proven benefit for acute hepatitis D, although several are being actively investigated.[21]

If, however, patients are coinfected with hepatitis B, then treatment of the hepatitis B should be pursued.

PREVENTION

The most effective means of preventing HDV infection is HBV vaccination, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and behavioral precautions should be practiced to avoid superinfection with HDV.

PROGNOSIS

In patients who are acutely coinfected with HBV and HDV, only approximately 2% become chronic HDV carriers. In contrast, when HDV infection is acquired by chronic HBV carriers, approximately 90% also become chronic carriers of HDV, and the risk of developing cirrhosis is increased four-fold.[22]

ACUTE HEPATITIS E

DEFINITION

The Pathogen

HEV is a member of the genus *Orthohepevirus* in the Hepeviridae family. HEV is a small, nonenveloped virus. Its genome is a positive sense, single-stranded RNA molecule. Eight HEV genotypes (1 to 8) have been described: genotypes 1 and 2 appear to be strictly human, whereas genotypes 3 to 8 appear to be of animal origin but can also infect humans.

PATHOBIOLOGY AND EPIDEMIOLOGY

HEV transmission is principally fecal-oral. HEV is endemic in most developing areas of the world, where acute infections are sporadic or occur during large epidemics related to the contamination of drinking water. Seroprevalence data suggest that one third of the world's population has been infected with HEV.[23] Every year, an estimated 20 million HEV infections worldwide lead to an estimated 3.3 million symptomatic cases of hepatitis E.

Genotype 1 has been found principally in Asia and North Africa, whereas genotype 2 has been isolated in cases from Central America and Western Africa. No animal reservoir is known for these genotypes, and transmission appears to be linked to the contamination of food or drinking water. In industrialized countries, HEV genotypes 1 and 2 are not present. HEV genotypes 3 and 4 are endemic in various wild and domestic animal species, and zoonotic transmission appears to be the main route of transmission in Europe, the United States, and Asia. Diagnosed cases of acute hepatitis E have increased constantly in Western Europe and North America in recent years, and high HEV seroprevalence has been described in special at-risk populations, such as butchers or farmers. Transmission may be favored by the consumption of uncooked meat and direct contact with infected animals. It is now thought to be the most common cause of acute viral hepatitis worldwide. Additionally, acute HEV may be observed in immunocompromised patients.

CLINICAL MANIFESTATIONS

The incubation period is 3 to 8 weeks. HEV infection causes only mild, nonspecific symptoms in the majority of cases, especially if the infection is acquired early in life. Immunocompetent individuals clear the virus spontaneously. The peak of viremia occurs early during infection, whereas the peak of aminotransferase activity is reached approximately 6 weeks after infection. Severe disease is more frequent in pregnant women and in patients with underlying chronic liver disease, who may rarely progress to fulminant hepatic failure. Some patients with Guillain-Barré syndrome (Chapter 388) have had a preceding acute hepatitis E infection. Chronic infections have been reported in immunosuppressed patients, especially recipients of organ transplants.

DIAGNOSIS

Patients with acute hepatitis should be tested for hepatitis E. Diagnosis of acute hepatitis E is based on the detection of anti-HEV IgM antibodies, which appear within 6 weeks and persist for 3 to 12 months. No assays are yet approved by the U.S. Food and Drug Administration. HEV RNA also can be detected in feces, serum, or plasma, where its presence is transient. Anti-HEV IgG generally persists for life after acute infection.

TREATMENT

Treatment of acute hepatitis E is not recommended because the vast majority of patients recover spontaneously.[24] Severe and fulminant cases should be referred to specialized units, where ribavirin monotherapy can be successful.

PREVENTION

Improving public hygiene and eating well-cooked meat are the best defenses against hepatitis E. Travelers to areas of the world where hygiene standards are low, particularly pregnant women, should be cautioned about drinking the water and eating uncooked food. A prophylactic vaccine based on recombinant HEV proteins has been approved in China, but is not yet available elsewhere. Its efficacy remains 87% at 4.5 years.[A4] Other HEV vaccines are in the developmental phase.

PROGNOSIS

Acute cases can be severe in elderly patients, and fulminant cases are frequent among pregnant women who are infected during large-scale waterborne epidemics. Overall case fatality rates range from zero to 10%, and less than 1% of fatal cases of acute hepatitis in the United States are attributed to hepatitis E. HEV genotypes 3 and 4 are less virulent than genotypes 1 and 2. Sporadic cases in industrialized areas are generally benign. HEV does not commonly evolve into chronic infection, but immunosuppressed patients can become chronic carriers.

OTHER TYPES OF ACUTE VIRAL HEPATITIS

Infection by members of the Herpesviridae family, such as cytomegalovirus (Chapter 347), Epstein-Barr virus (Chapter 348),[25] and herpes simplex virus (Chapter 345), should be considered in the differential diagnosis of unclear episodes of elevated liver enzymes in the absence of markers of acute hepatitis virus infection, especially in immunocompromised individuals. For instance, cytomegalovirus infection can be associated with graft loss after liver transplantation (Chapter 140). Parvovirus B19 (Chapter 342) may persist in the liver and worsen liver disease in patients with chronic hepatitis B and perhaps in patients with chronic HCV infection. Human herpesvirus 6 variant A has been linked with syncytial giant-cell hepatitis. Transient anicteric elevations of aminotransferase levels are often observed in patients with SARS-CoV-2 infection. Human adenovirus infection (Chapter 333) has caused outbreaks of acute hepatitis in children.[26]

NON–A-TO-E HEPATITIS

Rare patients develop acute hepatitis of presumed viral cause but have no markers of known hepatitis viruses. Some of these cases may be due to variants of known hepatitis viruses, in particular HBV, that are not detected by the usual serologic and molecular methods. However, the existence of other, unknown hepatotropic viruses cannot be excluded.

135 CHRONIC VIRAL AND AUTOIMMUNE HEPATITIS

JEAN-MICHEL PAWLOTSKY

DEFINITION

Chronic hepatitis is defined by chronic necroinflammation of the liver and may be due to various causes, including hepatotropic viruses (Chapter 134), autoimmunity, alcohol (Chapter 138), metabolic disorders (Chapter 132), and other less common factors. Chronic infection by hepatitis viruses is by far the main cause of chronic hepatitis worldwide, with nearly 300 million individuals chronically infected with hepatitis B virus (HBV) and nearly 60 million individuals infected with hepatitis C virus (HCV). Chronic viral hepatitis B and C are the leading causes of cirrhosis (Chapter 139) and hepatocellular carcinoma (Chapter 181) worldwide and account for more than 1 million deaths per year.[1] Chronic HBV infection can be associated with infection by hepatitis D virus (HDV). Hepatitis A virus does not cause chronic hepatitis. Hepatitis E virus (HEV) generally does not cause chronic hepatitis, except in immunosuppressed patients.

CLINICAL MANIFESTATIONS

The clinical symptoms of chronic viral and autoimmune hepatitis are typically nonspecific, and many patients have no symptoms. Fatigue, sleep disorders, and right upper quadrant pain may be present. Often the diagnosis is made when liver test abnormalities are identified by blood testing during a routine health evaluation or assessment for an unrelated problem or at the time of voluntary blood donation. More advanced symptoms include poor appetite, nausea, weight loss, muscle weakness, itching, dark urine, and jaundice. Patients can progress to full-blown cirrhosis (Chapter 139), with its typical clinical manifestations. If cirrhosis is present, weakness, weight loss, abdominal swelling, edema, bruisability, gastrointestinal bleeding, and hepatic encephalopathy with mental confusion may arise. Other findings may include spider angiomas, palmar erythema (see Fig. 132-2), ascites (see Fig. 132-4), edema, and skin excoriations.

Genotype 1 has been found principally in Asia and North Africa, whereas genotype 2 has been isolated in cases from Central America and Western Africa. No animal reservoir is known for these genotypes, and transmission appears to be linked to the contamination of food or drinking water. In industrialized countries, HEV genotypes 1 and 2 are not present. HEV genotypes 3 and 4 are endemic in various wild and domestic animal species, and zoonotic transmission appears to be the main route of transmission in Europe, the United States, and Asia. Diagnosed cases of acute hepatitis E have increased constantly in Western Europe and North America in recent years, and high HEV seroprevalence has been described in special at-risk populations, such as butchers or farmers. Transmission may be favored by the consumption of uncooked meat and direct contact with infected animals. It is now thought to be the most common cause of acute viral hepatitis worldwide. Additionally, acute HEV may be observed in immunocompromised patients.

CLINICAL MANIFESTATIONS

The incubation period is 3 to 8 weeks. HEV infection causes only mild, nonspecific symptoms in the majority of cases, especially if the infection is acquired early in life. Immunocompetent individuals clear the virus spontaneously. The peak of viremia occurs early during infection, whereas the peak of aminotransferase activity is reached approximately 6 weeks after infection. Severe disease is more frequent in pregnant women and in patients with underlying chronic liver disease, who may rarely progress to fulminant hepatic failure. Some patients with Guillain-Barré syndrome (Chapter 388) have had a preceding acute hepatitis E infection. Chronic infections have been reported in immunosuppressed patients, especially recipients of organ transplants.

DIAGNOSIS

Patients with acute hepatitis should be tested for hepatitis E. Diagnosis of acute hepatitis E is based on the detection of anti-HEV IgM antibodies, which appear within 6 weeks and persist for 3 to 12 months. No assays are yet approved by the U.S. Food and Drug Administration. HEV RNA also can be detected in feces, serum, or plasma, where its presence is transient. Anti-HEV IgG generally persists for life after acute infection.

TREATMENT

Treatment of acute hepatitis E is not recommended because the vast majority of patients recover spontaneously.[24] Severe and fulminant cases should be referred to specialized units, where ribavirin monotherapy can be successful.

PREVENTION

Improving public hygiene and eating well-cooked meat are the best defenses against hepatitis E. Travelers to areas of the world where hygiene standards are low, particularly pregnant women, should be cautioned about drinking the water and eating uncooked food. A prophylactic vaccine based on recombinant HEV proteins has been approved in China, but is not yet available elsewhere. Its efficacy remains 87% at 4.5 years.[A4] Other HEV vaccines are in the developmental phase.

PROGNOSIS

Acute cases can be severe in elderly patients, and fulminant cases are frequent among pregnant women who are infected during large-scale waterborne epidemics. Overall case fatality rates range from zero to 10%, and less than 1% of fatal cases of acute hepatitis in the United States are attributed to hepatitis E. HEV genotypes 3 and 4 are less virulent than genotypes 1 and 2. Sporadic cases in industrialized areas are generally benign. HEV does not commonly evolve into chronic infection, but immunosuppressed patients can become chronic carriers.

OTHER TYPES OF ACUTE VIRAL HEPATITIS

Infection by members of the Herpesviridae family, such as cytomegalovirus (Chapter 347), Epstein-Barr virus (Chapter 348),[25] and herpes simplex virus (Chapter 345), should be considered in the differential diagnosis of unclear episodes of elevated liver enzymes in the absence of markers of acute hepatitis virus infection, especially in immunocompromised individuals. For instance, cytomegalovirus infection can be associated with graft loss after liver transplantation (Chapter 140). Parvovirus B19 (Chapter 342) may persist in the liver and worsen liver disease in patients with chronic hepatitis B and perhaps in patients with chronic HCV infection. Human herpesvirus 6 variant A has been linked with syncytial giant-cell hepatitis. Transient anicteric elevations of aminotransferase levels are often observed in patients with SARS-CoV-2 infection. Human adenovirus infection (Chapter 333) has caused outbreaks of acute hepatitis in children.[26]

NON–A-TO-E HEPATITIS

Rare patients develop acute hepatitis of presumed viral cause but have no markers of known hepatitis viruses. Some of these cases may be due to variants of known hepatitis viruses, in particular HBV, that are not detected by the usual serologic and molecular methods. However, the existence of other, unknown hepatotropic viruses cannot be excluded.

135 CHRONIC VIRAL AND AUTOIMMUNE HEPATITIS

JEAN-MICHEL PAWLOTSKY

DEFINITION

Chronic hepatitis is defined by chronic necroinflammation of the liver and may be due to various causes, including hepatotropic viruses (Chapter 134), autoimmunity, alcohol (Chapter 138), metabolic disorders (Chapter 132), and other less common factors. Chronic infection by hepatitis viruses is by far the main cause of chronic hepatitis worldwide, with nearly 300 million individuals chronically infected with hepatitis B virus (HBV) and nearly 60 million individuals infected with hepatitis C virus (HCV). Chronic viral hepatitis B and C are the leading causes of cirrhosis (Chapter 139) and hepatocellular carcinoma (Chapter 181) worldwide and account for more than 1 million deaths per year.[1] Chronic HBV infection can be associated with infection by hepatitis D virus (HDV). Hepatitis A virus does not cause chronic hepatitis. Hepatitis E virus (HEV) generally does not cause chronic hepatitis, except in immunosuppressed patients.

CLINICAL MANIFESTATIONS

The clinical symptoms of chronic viral and autoimmune hepatitis are typically nonspecific, and many patients have no symptoms. Fatigue, sleep disorders, and right upper quadrant pain may be present. Often the diagnosis is made when liver test abnormalities are identified by blood testing during a routine health evaluation or assessment for an unrelated problem or at the time of voluntary blood donation. More advanced symptoms include poor appetite, nausea, weight loss, muscle weakness, itching, dark urine, and jaundice. Patients can progress to full-blown cirrhosis (Chapter 139), with its typical clinical manifestations. If cirrhosis is present, weakness, weight loss, abdominal swelling, edema, bruisability, gastrointestinal bleeding, and hepatic encephalopathy with mental confusion may arise. Other findings may include spider angiomas, palmar erythema (see Fig. 132-2), ascites (see Fig. 132-4), edema, and skin excoriations.

ABSTRACT

Chronic hepatitis, which is defined by chronic necroinflammation of the liver, may be due to various causes, most frequently viral hepatitis, but also autoimmunity, alcohol, or metabolic disorders. Chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections affect more than 350 million individuals worldwide and are the leading global causes of cirrhosis and hepatocellular carcinoma, accounting for more than 1 million deaths per year. Chronic HBV infection, which can be associated with hepatitis D virus (HDV) infection, can be treated with pegylated interferon alpha for 48 weeks, but most patients receive lifelong oral therapy with entecavir, tenofovir disoproxil fumarate, or tenofovir alafenamide. Such antiviral treatment efficiently prevents the complications of chronic hepatitis B, including fibrosis, cirrhosis, decompensation of cirrhosis, and hepatocellular carcinoma. Treatment of chronic hepatitis C with pan-genotypic oral combinations of direct-acting antiviral drugs can cure more than 95% of patients and prevent the liver and extrahepatic complications of HCV infection.

DIAGNOSIS

Levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are usually elevated (generally two to five times the upper limit of normal), but they can remain within the normal range for long periods of time in patients with chronic viral hepatitis B or C. The ALT level is generally higher than the AST level. Both can reach 10 to 25 times the upper limit of normal during acute exacerbations. Biologic tests can establish the etiologic diagnosis (Table 135-1).

Alkaline phosphatase and γ-glutamyl transpeptidase levels are usually minimally elevated unless cirrhosis is present. Serum bilirubin and albumin levels and the prothrombin time are normal unless the patient has advanced cirrhosis. Serum immunoglobulin levels are mildly elevated or normal in chronic viral hepatitis but may be very elevated in autoimmune hepatitis. Results that suggest the presence of advanced fibrosis are a platelet count below 160,000, AST levels higher than ALT levels, elevation in serum bilirubin, decrease in serum albumin, prolongation of the prothrombin time, elevation in α-fetoprotein levels, and presence of high globulin levels.

Liver ultrasound can determine the texture and size of the liver and spleen, exclude hepatic masses, and assess the gallbladder, intrahepatic bile ducts, and portal venous flow. Computed tomography and magnetic resonance imaging of the liver are helpful if a mass or other abnormality is found by ultrasound.

Liver biopsy has been critical for diagnosis and to determine the severity of disease. Hepatocellular necrosis is typically eosinophilic degeneration or ballooning degeneration throughout the parenchyma, greater in the periportal area, spotty, or piecemeal. Fibrosis also typically begins in the periportal regions and can link adjacent portal areas or portal and central areas (bridging fibrosis), distort the hepatic architecture, and lead to cirrhosis and portal hypertension. The histologic grade of chronic hepatitis can be determined by combining scores for periportal necrosis and inflammation, lobular necrosis and inflammation, and portal inflammation.

Recently, noninvasive physical methods (such as hepatic transient elastography or acoustic radiation force impulse imaging) and serologic markers have proved accurate for the assessment of mild fibrosis and cirrhosis, without requiring liver biopsy, in patients with chronic hepatitis B and C. However, these tests are less accurate for distinguishing moderate or advanced fibrosis, and their results may be influenced by ongoing liver inflammation, so liver biopsy remains the reference method in chronic hepatitis of nonviral causes. For example, liver biopsy can help exclude other causes of chronic hepatitis, including alcoholic liver disease, fatty liver and steatohepatitis (Chapter 138), drug-induced liver disease (Chapter 136), sclerosing cholangitis (Chapter 141), iron overload (Chapter 196), and veno-occlusive disease (Chapter 129), each of which can coexist with viral or autoimmune hepatitis.

TREATMENT AND PROGNOSIS

Chronic HBV infection is not curable, but it usually can be controlled by appropriate antiviral drugs. HCV infection is curable, and more than 95% of treated patients are cured. Autoimmune hepatitis responds to immunosuppression with corticosteroids and azathioprine.

TABLE 135-1 ETIOLOGIC DIAGNOSIS OF CHRONIC HEPATITIS

DIAGNOSIS	SCREENING TESTS	CONFIRMATORY TESTS
Chronic hepatitis B	HBsAg	HBV DNA
Chronic hepatitis C	Anti-HCV antibodies	HCV RNA
Chronic hepatitis D	Anti-HDV antibodies	HDV RNA
Autoimmune hepatitis	Auto-antibodies (ANA; anti-SMA; anti-LKM1; anti-LC1; anti-SLA/LP)	Exclusion of other causes and patterns of clinical disease
Drug-induced liver disease	History	Rechallenge, if necessary, if considered safe
Wilson disease	Ceruloplasmin	Urine copper concentration
Cryptogenic hepatitis	Exclusion of other causes	

ANA = antinuclear antibody; anti-LC1 = anti–liver cytosol type 1; anti-LKM1 = anti–liver-kidney microsomal 1 antibody; anti-SLA/LP = anti–soluble liver antigen/liver pancreas antibodies; anti-SMA = anti–smooth muscle actin; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HDV = hepatitis D virus.

CHRONIC HEPATITIS B

EPIDEMIOLOGY

Approximately 300 million individuals, or 4% of the world's population, are carriers of chronic HBV.[2] Two billion individuals, or one human being in three, have been in contact with the virus. In North America, Western and Northern Europe, and Australia, less than 2% of the population are chronic hepatitis B surface antigen (HBsAg) carriers. In the United States, the prevalence is approximately 0.3%, so approximately 860,000 Americans are infected. In Eastern Europe, South America, the Mediterranean basin, and the Indian subcontinent, the prevalence of chronic HBsAg carriage is between 2 and 8%. Highly endemic areas, with a rate of chronic HBsAg carriage exceeding 8%, include China, Southeast Asia, sub-Saharan Africa, and the native populations of the Far North of America.

HBV is the main cause of primary liver cancer (hepatocellular carcinoma; Chapter 181) worldwide, with approximately 350,000 new cases attributable to HBV every year. Hepatocellular carcinoma is more likely in the presence of underlying cirrhosis, but HBV has oncogenic properties of its own, and hepatocellular carcinoma can occur in noncirrhotic HBV patients.

PATHOBIOLOGY

HBV is not a cytopathic virus. Rather, liver injury in chronic hepatitis B is a consequence of the local immune response at the immune elimination phase. In particular, liver injury is related to cytotoxic T cells that recognize and kill infected hepatocytes that express HBV antigens at their surface and to the local production of cytokines. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. The hepatitis B X protein may also directly activate fibrogenesis. As a result, many patients with chronic hepatitis B have progressive fibrosis, which may evolve into cirrhosis.

The rate of chronicity after an acute HBV infection is more than 95% among infants infected at birth. This risk diminishes as the age at acquisition increases, and it is less than 5% in individuals infected as adults. Chronic HBV infection is defined by HBsAg carriage that persists for more than 6 months after the acute episode. Chronic HBsAg carriage typically evolves through three phases: immune tolerant, immune elimination, and inactive.

The immune tolerant phase is generally short if the infection occurred during adulthood, but it persists for years to decades in patients infected at birth or during early childhood. At the immune tolerant stage, the immune response of the host "tolerates" HBV infection and does not cause liver inflammation or hepatocyte destruction. The immune tolerant phase is characterized by the presence of hepatitis B e antigen (HBeAg), very high levels of HBV DNA in blood, normal serum or plasma aminotransferase levels, and no or minimal inflammatory activity on liver biopsy. However, these patients have detectable immune responses against HBV antigens, their liver histology is not strictly normal, and they display a high level of HBV DNA integration and clonal hepatocyte expansion, indicating that hepatocarcinogenesis is already underway.

The immune elimination phase is characterized by an active immune response that causes necroinflammatory lesions and triggers hepatic fibrogenesis and progressive fibrosis. ALT and AST levels are increased, but HBV DNA levels are lower than during the immune tolerant phase and frequently fluctuate. The immune elimination phase has a variable duration, ranging from a few weeks to several decades. HBeAg, when present, defines HBeAg-positive chronic hepatitis B. HBeAg can be cleared and replaced by anti-HBe antibodies, defined as HBe seroconversion. HBe seroconversion may lead to the persistence of HBV replication and chronic inflammation, defined as HBeAg-negative chronic hepatitis B, or to the inactive HBsAg carrier state. Patients with HBeAg-positive chronic hepatitis B are infected with a wild-type virus and are able to secrete the HBe protein. Patients with HBeAg-negative chronic hepatitis B are infected with so-called precore mutant viruses, which cannot produce the HBe protein because they have a stop codon in the pre-C gene, or with core promoter mutant viruses, which produce considerably lower amounts of HBe protein. Because of the prevalence of the HBV genotype D in Euro-Mediterranean and African countries, HBeAg-negative/anti–HBe-positive chronic hepatitis B is seven to nine times more frequent than HBeAg-positive disease in those locations.

The inactive HBsAg carriage phase is the result of successful immune elimination leading to HBe seroconversion. ALT and AST levels are normal, HBV DNA is undetectable or at very low levels, and patients without preexisting cirrhosis have normal liver histology.

CLINICAL MANIFESTATIONS

Patients with chronic hepatitis B are generally asymptomatic. The most common symptom is fatigue, but sleep disorders, difficulty concentrating, and upper

right quadrant pain are often observed. Chronic hepatitis B is characterized biologically by elevated aminotransferase levels, and ALT levels can fluctuate substantially during the immune elimination phase. Moderate cholestasis, with mildly elevated alkaline phosphatase and γ-glutamyl transpeptidase levels, also can be present, especially in patients with cirrhosis.

HBeAg-negative chronic hepatitis B is generally more severe than the HBeAg-positive variety. The incidence of spontaneous HBe seroconversion among HBeAg-positive patients is 8 to 12% per year when they are in the immune elimination phase; HBe seroconversion often follows a transient ALT flare. Some of these patients evolve toward inactive HBsAg carriage, whereas others switch into an HBeAg-negative form of chronic hepatitis B, with elevated ALT levels and an HBV DNA level greater than 2000 IU/mL.

The annual incidence of cirrhosis varies from 2 to 10% in patients with chronic HBV infection, with a cumulative incidence of approximately 20% at 5 years. The risk for cirrhosis is two- to four-fold higher in HBeAg-negative patients compared with HBeAg-positive ones. The annual incidence of hepatocellular carcinoma in patients with chronic hepatitis B varies from 1% in patients without cirrhosis to 2 to 8% in cirrhotic patients, with the higher rates occurring in older patients. Patients with cirrhosis (Chapter 139), hepatocellular carcinoma (Chapter 181), or both have the typical signs associated with these conditions. Rarely, chronic HBV infection is associated with extrahepatic manifestations, including glomerulonephritis (Chapter 107), most often in children, and polyarteritis nodosa (Chapter 249), mostly in adults.

DIAGNOSIS

Serologic markers used to diagnose chronic hepatitis B (Table 135-2) include HBsAg, anti-HBs antibodies, total anti–hepatitis B core (HBc) antibodies and anti-HBc immunoglobulin M (IgM), HBeAg, and anti-HBe antibodies. Molecular markers include HBV DNA; real-time polymerase chain reaction (PCR)–based or transcription-mediated amplification (TMA)–based assays are the best way to detect and quantify HBV DNA.[3]

Chronic HBV infection is defined by the persistence of HBsAg in the serum for more than 6 months after the acute episode. The majority of subjects with isolated anti-HBc antibodies are not viremic. However, some individuals who test positive for anti-HBc antibodies, but not for HBsAg or anti-HBs antibodies, may be viremic; in these cases, some viruses' amino acid substitutions in the HBsAg sequence make HBsAg undetectable with current enzyme immunoassays. Other individuals may have such low-level HBV replication in their livers that HBV DNA is not detectable in blood ("occult" hepatitis B). Screening is recommended periodically in high-risk individuals and once (together with HCV and HIV testing) in all adults.[A1]

Serum or plasma ALT and HBV DNA levels are important markers of severity and prognosis. The assessment of severity, including the grade of necroinflammation and the stage of fibrosis, has traditionally been based on the liver biopsy (Fig. 135-1), but serologic markers, transient elastography, or acoustic radiation force impulse imaging have replaced liver biopsy in the pretreatment assessment of the severity of chronic hepatitis B in most patients.

PREVENTION AND TREATMENT

Patients with chronic hepatitis B should be vaccinated against hepatitis A virus, abstain from alcohol, and avoid immunosuppressive therapies unless absolutely necessary. HBV-infected patients who require corticosteroids, rituximab, or other chemotherapy for other conditions should receive entecavir 0.5 mg/day, tenofovir disoproxil fumarate 245 mg/day, or tenofovir alafenamide 25 mg/day during therapy and for 12 months after its cessation as prophylaxis against reactivation of hepatitis B.

The goals of chronic hepatitis B therapy are to suppress HBV replication, reduce the histologic activity of chronic hepatitis, and lessen the risk for cirrhosis and hepatocellular carcinoma.[4,5] HBV infection cannot be completely eradicated because of the persistence of covalently closed circular DNA (cccDNA) in the nucleus of infected hepatocytes. As a result, therapy attempts to reduce HBV DNA levels as much as possible—ideally, below the limit of detection of real-time PCR or TMA assays (10 to 15 IU/mL)—to ensure a degree of viral suppression that will lead to biochemical remission, histologic improvement, and prevention of complications.

Two different types of drugs for the treatment of chronic hepatitis B are pegylated interferon-α (IFN-α) and nucleoside/nucleotide analogues. Pegylated IFN-α2a, administered subcutaneously at a dose of 180 μg/week for 48 weeks, improves various markers of HBV infection in both HBeAg-positive (Table 135-3) and HBeAg-negative (Table 135-4) patients. The most frequent side effects of IFN-α are flulike symptoms after the injections, fatigue, anorexia, weight loss, and alopecia. The most concerning side effects are neutropenia, thrombocytopenia, anxiety, irritability, depression, and suicidal ideation.

Nucleoside analogues (e.g., entecavir) require triple phosphorylation to be active, whereas nucleotide analogues (e.g., tenofovir) need only two phosphorylations to be active. These drugs are given orally (PO) once daily at the following dosages: 0.5 mg for entecavir, 245 mg for tenofovir administered as the pro-drug tenofovir disoproxil fumarate, or 25 mg for tenofovir administered as the pro-drug tenofovir alafenamide. All have short-term benefits on various markers of HBV infection in HBeAg-positive (see Table 135-3) and HBeAg-negative (see Table 135-4) patients. Entecavir and tenofovir are used because they are the most potent inhibitors of HBV replication,[A2,A3] and they are the least likely to select for resistant HBV variants. These drugs are generally well tolerated. Renal impairment and decreases in mineral bone density are rarely seen with tenofovir disoproxil fumarate; these side effects are not observed with tenofovir alafenamide because the active compound is concentrated in the liver.

Patients should be considered for treatment when their HBV DNA levels are greater than 2000 IU/mL and/or their serum ALT levels are abnormal if noninvasive assessment or liver biopsy shows moderate to severe active necroinflammation, fibrosis, or both. Patients with an HBV DNA level above 20,000 IU/mL and ALT above 2 times the upper limit of normal should be treated regardless of the degree of fibrosis. Indications for treatment must also consider the patient's age and health status, as well as the availability of antiviral agents in individual countries. Patients in the immune tolerant phase and those with mild hepatitis on liver biopsy or noninvasive markers should not be treated, but follow-up ALT levels and HBV DNA assays are mandatory. Patients with compensated cirrhosis and detectable HBV DNA should be treated even if their ALT levels are normal, their HBV DNA levels are below 2000 IU/mL, or both. Patients with decompensated cirrhosis require urgent antiviral treatment.

Two treatment strategies can be considered: a 48-week course of pegylated IFN-α or long-term oral treatment with nucleoside/nucleotide analogues. Their combined use does not seem to improve the rate of sustained virologic response after treatment.

Pegylated IFN-α can provide a sustained virologic response, defined as a sustained HBe seroconversion (clearance of HBeAg, which is replaced by anti-HBe antibodies) and an HBV DNA level that remains below 2000 IU/mL after a 48-week course of treatment; an ALT flare can be observed at the time of HBeAg loss in patients in whom treatment is successful. Pegylated IFN-α treatment can be considered as an initial treatment option in patients with mild to moderate HBeAg-positive or -negative chronic hepatitis B. Practically, it should be reserved for patients with the best chance of a sustained virologic response off treatment—HBeAg-positive patients with high baseline ALT levels (more than three times the upper limit of normal) and HBV DNA levels below 2×10^6 IU/mL. Pegylated IFN-α therapy is contraindicated in patients with advanced cirrhosis and in immunosuppressed patients. Patients infected with HBV genotypes A and B generally respond better to IFN-α therapy than do patients infected with genotypes C and D, but the predictive value of the HBV genotype for an individual patient is weak. Patients who fail to achieve a sustained virologic response after a single course of pegylated IFN-α are candidates for nucleoside/nucleotide analogue therapy.

(Courtesy Prof. Elie-Serge Zafrani, Department of Pathology, Henri Mondor Hospital, Créteil, France.)

Long-term treatment with nucleoside/nucleotide analogues is indicated in the majority of patients with chronic hepatitis B. Tenofovir (available as tenofovir disoproxil fumarate or liver-targeted tenofovir alafenamide) or entecavir, which are the most potent drugs with an optimal resistance profile, are recommended as first-line monotherapies. Entecavir or tenofovir alafenamide should be selected over tenofovir disoproxil fumarate in patients >60 years old, patients with bone disease (chronic steroid use or use of other medications that worsen bone density, history of fragility fracture, osteoporosis) and patients with renal alteration (eGFR <60 mL/min/1.73 m^2, albuminuria >30 mg/24 hour or moderate dipstick proteinuria, low phosphate <2.5 mg/dL, dialysis). HBV DNA should be suppressed to undetectable levels (<10 to 15 IU/mL) with a sensitive real-time PCR-based or TMA-based assay. If the HBV DNA level is reduced but still detectable in a compliant patient, the other agent may be added; however, the long-term safety of combined tenofovir and entecavir is unknown. When HBeAg-positive patients seroconvert to anti-HBe antibody-positive or HBeAg-negative patients lose their HBsAg (with or without anti-HBs seroconversion), treatment should be continued for at least an additional 12 months. In all other cases, treatment should be continued for life and adherence is particularly important.

Virologic breakthroughs—defined by a subsequent increase of the HBV DNA level of 1 log or more above the nadir level—in patients receiving entecavir or tenofovir are exclusively a result of nonadherence. Virologic breakthrough is generally followed a few weeks later by a biochemical breakthrough in which a previously normal ALT level rises above normal. In a patient who develops resistance to any nucleoside/nucleotide analogue other than entecavir or tenofovir, switching to tenofovir (either tenofovir disoproxil fumarate or tenofovir alafenamide) and possibly adding entecavir are the only efficient strategies, although the long-term safety of the combination of tenofovir and entecavir is not known. In patients with lamivudine, telbivudine, or entecavir resistance, treatment should be switched to tenofovir. Patients who have resistance to adefovir should be switched to tenofovir, and entecavir should be added if HBV DNA plateaus. Patients with multidrug resistance should receive the combination of tenofovir and entecavir. The combination of tenofovir and emtricitabine, a nucleoside analogue similar to lamivudine, in a single tablet (approved for HIV but not for HBV therapy) is also a valid option in cases of resistance to any of these drugs.

In patients with cirrhosis, nucleoside/nucleotide analogue therapy is the only option. In patients with decompensated disease, efficient antiviral treatment with entecavir or tenofovir most often stabilizes the patient's condition and can also delay or obviate the need for liver transplantation. If transplantation is needed, post-transplant administration of anti-HBV immunoglobulins in combination with entecavir or tenofovir prevents recurrent HBV in the vast majority of cases. Patients with a low risk of recurrence can discontinue anti-HBV immunoglobulins but should continue monoprophylaxis with entecavir or tenofovir.

PROGNOSIS

Every year, approximately 0.5% of inactive HBsAg carriers spontaneously lose HBsAg, and most of them acquire anti-HBs antibodies. Reactivations are possible in inactive HBV carriers, especially if they become immunosuppressed, such as when they are treated for other conditions with corticosteroids, rituximab, or other chemotherapeutic agents. HBV reactivations often evolve into a subfulminant or fulminant form.

The risk of cirrhosis (Chapter 139) in chronic hepatitis B is 2 to 10% per year, and it is significantly associated with a higher HBV DNA level, older age, alcohol consumption, coinfection with other hepatotropic viruses, and coinfection with human immunodeficiency virus (HIV). The cumulative incidence of liver decompensation is about 15 to 20% at 5 years in patients with compensated cirrhosis. The complications of cirrhosis, including hepatocellular carcinoma, are among the main causes of mortality in HBV-infected patients, and the annual incidence of death is about 3 to 4%. In patients who are treated with long-term entecavir/tenofovir, however, 8-year survival is now similar to the general population.[6] The likelihood of developing hepatocellular carcinoma (Chapter 181) is approximately 1% per year in patients without cirrhosis and

	PLACEBO/CONTROL GROUPS	**PegIFN-α2a 180 µg ONCE WEEKLY**	**ENTECAVIR 0.5 mg DAILY**	**TENOFOVIR DISOPROXIL FUMARATE 245 mg DAILY**	**TENOFOVIR ALAFENAMIDE 25 mg DAILY**
HBV DNA <60-80 IU/mL	0-20%*	19%	90%	93%	94%‡
ALT normalization†	10-29%	59%	78%	76%	83%
HBsAg loss	0%	4%	0%	0%	0%

*HBV DNA levels were assessed with various molecular assays, with different lower limits of detection.
†The definition of ALT normalization varied among different trials.
‡The lower limit of HBV DNA detection/quantification was different across studies (<29 IU/mL for tenofovir alafenamide studies).
Ag = antigen; ALT = alanine aminotransferase; HBe = hepatitis B e; HBs = hepatitis B surface; HBV = hepatitis B virus; IFN = interferon.
Modified from: EASL 2017 clinical practice guidelines on the management of hepatitis B virus infection. *J Hepatol*. 2017;67:370-398.

2 to 8% per year in patients with cirrhosis, and it is significantly associated with a higher HBV DNA level, male sex, old age, a family history of hepatocellular carcinoma, reversion from anti-HBe–positive to HBeAg-positive, and coinfection with other hepatotropic viruses. HBV carriers who have cirrhosis or who are at risk for hepatocellular carcinoma should be screened every 6 to 12 months with an ultrasound examination and an α-fetoprotein level.

Liver histology, including necroinflammation and fibrosis, improves in patients who have chronic hepatitis B, who are on long-term nucleoside/nucleotide analogue therapy, and who maintain low/undetectable HBV DNA levels. In addition, the risks of developing cirrhosis, of decompensation of cirrhosis, and of hepatocellular carcinoma are significantly reduced but not eliminated as compared with untreated patients, especially patients who already have cirrhosis or have a family history of hepatocellular carcinoma.

CHRONIC HEPATITIS C

EPIDEMIOLOGY

HCV, which is present on all continents, is estimated to cause chronic infection in approximately 58 million individuals. The prevalence of chronic HCV infection, which varies geographically, is estimated to be about 0.7% in the United States (affecting 2.4 million individuals), 0.5% in the Americas overall, 1.3% in Europe, 0.5% in Southeast Asia, 0.9% in Africa, and 0.5% in the Western Pacific region. The highest prevalence is in Egypt (9% overall, but up to 40% in certain rural areas), where infection was initially spread by intramuscular injections for schistosomiasis during treatment campaigns several decades ago. Hepatitis C virus still causes more deaths in the United States than does HIV, largely because most cases remain undiagnosed, and it causes approximately 290,000 deaths per year worldwide.

PATHOBIOLOGY

Acute HCV infection evolves into chronic infection in 50 to 80% of cases depending on the age at acquisition (children versus adults, respectively). Even patients who spontaneously recover and maintain detectable anti-HCV antibodies are not protected against reinfection. Persistence of infection is related to a qualitatively and quantitatively altered CD4+ T-helper cell and cytotoxic T lymphocyte response that fails to eradicate infection. The plasticity of the viral genomes is responsible for the coexistence of closely related but genetically different viral populations in equilibrium in the patient's replicative environment. This genetic diversity allows continuously generated variant viral populations to be selected by timely changes in the replicative environment.

Chronic HCV infection is responsible for necroinflammatory lesions of varying severity, sometimes associated with steatosis, which is the accumulation of triglycerides in hepatocytes. HCV is not a cytopathic virus. Liver injury in chronic hepatitis C is related to the action of immune effectors that recognize and kill infected hepatocytes that express HCV antigens at their surface and the local production of various cytokines and chemokines. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. Fibrosis progresses at nonlinear rates that are generally faster in older patients, in males, and in the presence of chronic alcohol intake, viral coinfections, or immunosuppression. The severity of chronic hepatitis is independent of the HCV RNA level and of the HCV genotype. This chronic inflammation and progression of fibrosis predispose patients to cirrhosis (Chapter 139), which is present in approximately 20% of HCV-infected patients, and hepatocellular carcinoma (Chapter 181), which occurs at an incidence rate of 1 to 5% per year in patients with cirrhosis.

CLINICAL MANIFESTATIONS

Acute hepatitis C (Chapter 134) is most often asymptomatic and therefore undiagnosed. The most common symptom associated with chronic HCV infection is fatigue, but it may remain inapparent for years. ALT levels are usually moderately elevated and fluctuate, but they can remain normal for weeks to months despite active hepatitis on liver biopsy. Moderate cholestasis can be present in patients with cirrhosis. Patients with cirrhosis (Chapter 139),

hepatocellular carcinoma (Chapter 181), or both have the typical signs associated with these conditions.

HCV is the main cause of type II and type III mixed cryoglobulinemia (Chapter 173). Low levels of circulating cryoglobulins, which contain HCV RNA, anti-HCV antibodies, rheumatoid factor, and low levels of complement, can be found in 50 to 70% of cases, whereas elevated rheumatoid factor (Chapter 243) is found in 70% of cases. Fewer than 1% of HCV-infected patients develop symptoms of cryoglobulinemic vasculitis (Chapter 249), including fatigue, myalgias, arthralgias, rash (purpura, hives, leukocytoclastic vasculitis), neuropathy, and membranoproliferative glomerulonephritis.[7] Cryoglobulinemia can be severe and lead to end-stage renal disease or severe neuropathies, and long-term cryoglobulinemia has been linked to non–Hodgkin B-cell lymphomas (Chapter 171).

Low titers of antinuclear and anti–smooth muscle antibodies can be found in HCV-infected patients, but they do not have any clinical significance. HCV has been reported to trigger the symptoms of porphyria cutanea tarda (Chapter 194), and an association with lichen planus (Chapter 405) has been suggested.

DIAGNOSIS

Chronic HCV infection is defined by the persistence of HCV RNA for more than 6 months. Chronic hepatitis C is diagnosed by the simultaneous presence of anti-HCV antibodies and HCV RNA (or HCV core antigen where available). Detectable HCV replication in the absence of anti-HCV antibodies is observed almost exclusively in patients who are profoundly immunosuppressed, on hemodialysis, or agammaglobulinemic.

The strategy for HCV screening varies in different areas according to the local prevalence. In the United States, screening for HCV is recommended once between the ages of 18 and 79 years for everyone. HCV screening is based upon detecting anti-HCV antibodies in a centralized laboratory. However, tests performed at the patient's care site, such as rapid diagnostic tests using fingerstick whole blood or saliva (or fingerstick whole blood sampled on dried blood spots), can improve access to screening and linkage to care. Confirmation of infection is based upon the detection of HCV RNA by a molecular method, or alternatively, HCV core antigen by enzyme immunoassay. Reflex testing (HCV RNA confirmation on the same sample as was used to detect anti-HCV antibody) is recommended to improve linkage-to-care. The level of HCV replication does not correlate with the severity of liver disease or with the risk for progression to cirrhosis or hepatocellular carcinoma.

Determination of the HCV genotype is no longer recommended. Laboratory testing often reveals high levels of monoclonal rheumatoid factor and cryoglobulins.

TREATMENT

Chronic HCV infection is curable by antiviral therapy. The goal of therapy is to achieve a sustained virologic response, defined by undetectable HCV RNA at 12 weeks (possibly 24 weeks) after the end of therapy using a sensitive HCV RNA assay with a lower limit of detection of 10 to 20 IU/mL. Sustained virologic response corresponds to a definitive cure of infection.

All treatment-naïve and previously treated patients with chronic HCV infection should be treated without delay, regardless of the severity of liver disease or extra-hepatic manifestations, except in highly unusual situations in which they have contraindications to available oral anti-HCV drugs. Noninvasive assessment of liver fibrosis prior to therapy is required to identify patients who have advanced fibrosis and cirrhosis and who therefore will need post-treatment follow-up for the possible development of hepatocellular carcinoma. Careful assessment of drug-drug interactions is also required prior to initiating therapy (www.hep-druginteractions.org).

Treatment regimens are based on combinations of orally administered antiviral drugs (Chapter 328) that have pan-genotypic antiviral properties (i.e., are active against all known HCV genotypes and subtypes). These combinations provide a sustained virologic response and cure infection in more than 95% of patients. Current anti-HCV drugs belong to three classes, including nucleotide analogues (sofosbuvir), protease inhibitors (glecaprevir, voxilaprevir), and NS5A inhibitors (daclatasvir, velpatasvir, pibrentasvir). These medications, which are available as standalone drugs (sofosbuvir, daclatasvir) or as one-pill fixed-dose combinations of two or three drugs (sofosbuvir/velpatasvir, glecaprevir/pibrentasvir, sofosbuvir/velpatasvir/voxilaprevir), are safe and well-tolerated, with headache and fatigue as the most frequently reported side effects. Generic formulations of HCV drugs are available in low- and middle-income countries and can be used, provided that quality controls are met and guaranteed by the provider.

Due to their virologic efficacy, ease of use, safety, and tolerability, pan-genotypic combination regimens must be used to treat chronic hepatitis C. Treatment is guided by the presence of compensated or decompensated cirrhosis, and prior exposure to oral anti-HCV drugs. Patients infected with HCV can be treated with one of four regimens[8-10] (Table 135-5): the fixed-dose combination of sofosbuvir and velpatasvir[A4-A6]; the fixed-dose combination of glecaprevir and pibrentasvir[A7-A12]; the fixed-dose triple combination of sofosbuvir, velpatasvir, and voxilaprevir[A13]; and the combination of sofosbuvir with the fixed-dose combination of glecaprevir and pibrentasvir. In settings where these combinations are not available or not affordable, the pan-genotypic combination of sofosbuvir and daclatasvir, often available as generic drugs, can also be used with a high probability of sustained virologic response.

Sofosbuvir/velpatasvir should be administered for 12 weeks in patients with chronic hepatitis C without cirrhosis or with compensated cirrhosis. Glecaprevir/pibrentasvir should be administered for 8 weeks in patients without cirrhosis and in patients with compensated cirrhosis who are treatment-naïve, and for 12 weeks in patients with compensated cirrhosis who failed a previous treatment with pegylated interferon α and/or sofosbuvir plus ribavirin.

For patients who do not have a sustained virologic response after treatment with oral anti-HCV drug regimens, retreatment with the triple combination of sofosbuvir, velpatasvir, and voxilaprevir for 12 weeks provides a high rate of sustained virologic response.[A14] In very difficult-to-cure patients (patients who failed twice or more to achieve a sustained virologic response after a combination regimen including a protease and/or an NS5A inhibitor), the triple combination of sofosbuvir, velpatasvir, and voxilaprevir, or the triple combination of sofosbuvir and glecaprevir/pibrentasvir for 12 weeks with weight-based ribavirin (1000 or 1200mg in patients <75 kg or ≥75 kg, respectively) should be administered, and/or treatment duration can be prolonged to 16 to 24 weeks.

Because the risk of advanced liver disease is significantly increased in patients with other coexisting causes of liver disease, patients with chronic hepatitis C should abstain from alcohol and, unless there are other contraindications, should be vaccinated for hepatitis A and B (Chapter 15).

Patients Coinfected with HIV

Patients with coexisting HIV infection should be considered like non-HIV coinfected patients in terms of treatment indications and virologic response to therapy. The only difference to take into account is potential drug-drug interactions with antiretroviral drugs.[A15,A16]

Patients with Decompensated Cirrhosis or Recurrent HCV after Liver Transplantation

In patients who have decompensated cirrhosis or a history of decompensation, protease inhibitors are contraindicated, so these patients should be treated with the combination of sofosbuvir and velpatasvir plus weight-based ribavirin (1000 mg for patients <75 kg, 1200 mg for patients ≥75 kg). When ribavirin cannot be used because of contraindications (anemia, significant coronary or cerebrovascular disease, or renal insufficiency) or poor tolerance, 24 weeks of treatment without ribavirin is recommended. Because ribavirin is teratogenic, it is essential that adequate contraception be practiced during therapy and for at least 6 months thereafter in both men and women.

For patients who have decompensated cirrhosis with an indication for liver transplantation (Chapter 140), those with a Model for End-Stage Liver Disease (MELD; Table 139-2) score below approximately 20 are likely to benefit from curing HCV prior to transplantation. In patients with more severe liver disease (MELD score >20), transplant followed by treatment of graft reinfection with sofosbuvir and velpatasvir or with glecaprevir and pibrentasvir is recommended.

PROGNOSIS

Spontaneous HCV clearance in patients with chronic hepatitis C is exceptional. The HCV RNA level has no prognostic value in chronic hepatitis C. An estimated 20% of patients with chronic hepatitis C develop cirrhosis (Chapter 139) after an average of 20 years of progression in the absence of therapy. Cirrhosis remains compensated for many years in the vast majority of patients, but decompensation occurs at an annual rate of 2 to 5% in cirrhotic patients. After a first decompensation, the mortality rate related to portal hypertension, hepatocellular insufficiency, and hepatocellular carcinoma is 10% per year, with a 50% survival rate at 5 years. The risk for death increases with advancing age, male gender, and the severity of cirrhosis.

Hepatocellular carcinoma (Chapter 181) is rare in patients with chronic hepatitis C without cirrhosis. In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2 to 4% per year, most often in patients with compensated cirrhosis. HCV has become the most common cause of hepatocellular carcinoma in most industrialized countries.

After successful anti-HCV therapy, the risk of hepatocellular carcinoma is eliminated for patients who do not have cirrhosis or other causes of liver disease. The risk is considerably reduced but not eliminated in patients with cirrhosis, especially in the presence of other causes of liver disease. Late relapses in patients who have achieved a sustained virologic response are most often reinfections in individuals with high-risk practices.

CHRONIC HEPATITIS D

EPIDEMIOLOGY

HDV infection occurs only in HBsAg carriers. Only approximately 2% of patients acutely coinfected with HDV and HBV develop chronic hepatitis D. In chronic HBV carriers superinfected by HDV, however, 90% of patients become chronic HDV carriers. Overall, 4.5% of chronic HBsAg carriers, or about 12 million individuals, are chronically infected with HDV.

CLINICAL MANIFESTATIONS

Chronic hepatitis D is generally severe, with more than 80% of patients developing cirrhosis. Compared with patients who have chronic hepatitis B alone, patients with chronic infection with both HBV and HDV are three times as likely to develop hepatocellular carcinoma and twice as likely to die.

DIAGNOSIS

Markers of HDV infection should be sought at least once in every chronic HBsAg carrier. Total anti-HD antibodies remain at high levels in chronic HDV infection, and HDV RNA is present. Although all chronic HDV carriers also are chronic HBsAg carriers, chronic HDV carriers generally have low or undetectable HBV DNA levels because HDV inhibits HBV replication.

PREVENTION

Chronic HDV infection is best prevented by HBV vaccination, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and behavioral precautions should be practiced to avoid superinfection with HDV. Once acute HDV infection occurs, no secondary prevention strategy is successful.

TREATMENT

Pegylated IFN-α2a (180 μg once weekly) for 48 weeks can provide a virologic response rate that is approximately 50% on treatment,[11] but only about 25% of patients have undetectable HDV RNA 24 weeks after the end of treatment. Longer treatment duration may increase the virologic response rates.

Bulevirtide, an HDV entry inhibitor (2 mg once daily by subcutaneous injection as monotherapy or coadministered with a nucleoside or a nucleotide analogue for treatment of underlying HBV infection),[A17] also suppresses HDV. The optimal treatment duration is unknown, and treatment should be continued as long as associated with clinical benefit. Whether HDV-infected patients might benefit from the combination of bulevirtide and pegylated IFN-α2a remains to be determined.

†Ribavirin should be administered at the dose of 1000 or 1200 mg in patients <75 kg or ≥75 kg, respectively.

CHRONIC HEPATITIS E

HEV infection is usually an acute self-limiting disease, but in developed countries it causes chronic infection with rapidly progressive cirrhosis in organ transplant recipients, patients with hematologic malignancies that require chemotherapy, and immunosuppressed HIV-infected individuals, either from a latent virus reactivated by immunosuppression or from a virus transmitted at the time of transplantation. Almost all cases of chronic infection have been in immunosuppressed patients. About one in 3000 blood donors in England are HEV-RNA–positive, even though they are usually seronegative despite their viremia, and can transmit the infection to more than 40% of the recipients of their blood products.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Diagnosis of acute hepatitis E is based on the detection of anti-HEV IgM antibodies. HEV RNA also can be detected in blood or feces, where its presence is transient. Immunosuppressed patients, such as solid organ transplant recipients, with chronic hepatitis E harbor repeatedly positive anti-HEV antibodies and HEV RNA in blood.

TREATMENT AND PREVENTION

There is no validated treatment of chronic HEV infection.[12] In the transplant setting, reduction in the levels of immunosuppression lead to viral clearance in 30% of cases. Ribavirin (600 mg/day) is associated with about an 80% sustained virologic response rate and is considered first-line treatment.[13] Pegylated interferon-α also can be effective. Reducing the level of immunosuppression can result in viral clearance in approximately one third of patients. A vaccine to prevent HEV infection has been developed and is licensed in China but is not yet available elsewhere.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic inflammatory liver disorder characterized by the presence of autoantibodies in serum, high levels of serum immunoglobulins, and a frequent association with other autoimmune diseases.

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoimmune hepatitis typically manifests between the ages of 15 and 25 years or between the ages of 45 and 60 years, and it is more common in women. The incidence rate is approximately 1.7 per 100,000 population per year. Along with primary biliary cirrhosis (Chapter 141) and primary sclerosing cholangitis (Chapter 141), autoimmune hepatitis is one of the three major autoimmune liver diseases.

Autoimmune hepatitis is believed to be caused by autoimmune reactions against normal hepatocytes in genetically predisposed persons or persons exposed to unidentified triggers of an autoimmune process against liver antigens. Associations are seen with the human leukocyte antigen (HLA) class I B8 and class II DR3 and DRS2a loci. In Asians, autoimmune hepatitis is associated with HLA DR4.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Autoimmune hepatitis tends to be more severe at its onset than chronic hepatitis B or C, and it progresses to end-stage liver disease if not treated with immunosuppression.[14] Although it is occasionally detected by elevated serum aminotransferase levels on a routine health evaluation, most patients present with fatigue and jaundice.[15] Elevations of bilirubin or alkaline phosphatase indicate more severe or advanced disease. Patients typically have marked elevations in serum γ-globulin, specifically immunoglobulin G, as well as autoantibodies directed at non–organ-specific cellular constituents.

Type 1 autoimmune hepatitis (approximately 90% of cases) is characterized by titers of 1:80 or higher (>1:20 in children) of antinuclear, anti–smooth muscle, anti-actin, and/or anti–soluble liver antigen/liver pancreas antibodies. Type 2 autoimmune hepatitis is characterized by similar elevations of anti–liver-kidney microsomal 1 antibodies and/or anti–liver cytosol 1 antibodies, without antinuclear or anti–smooth muscle antibodies. However, auto-antibodies are not detected in 20 to 35% of cases.

Liver biopsy shows features that are typical of all chronic types of hepatitis, except plasma cell infiltrates. Noninvasive physical markers, such as transient elastography, magnetic resonance elastography, or acoustic radiation force impulse imaging, correlate strongly with the histologic stage of fibrosis, but their accuracy may be impaired by inflammation at the time of diagnosis and during the first months of treatment.

The differential diagnosis of autoimmune hepatitis includes drug-induced liver injury (Chapter 136). Sustained biochemical resolution after glucocorticoid withdrawal reinforces the diagnosis of a self-limited drug-induced liver injury, whereas recrudescence of laboratory abnormalities is consistent with autoimmune hepatitis.

TREATMENT

The clinical symptoms and liver test abnormalities of autoimmune hepatitis generally respond promptly to prednisone.[16,17] Induction therapy should be based on 0.5 to 1.0 mg/kg/day prednisone or prednisolone. If the initial response is good, azathioprine should be added gradually, up to 1.0 to 2.0 mg/kg/day, starting 2 weeks after steroid initiation, while the steroid dose is gradually tapered.[18] In patients without cirrhosis and or acute severe autoimmune hepatitis, budesonide (3 mg three times daily, reduced to twice daily following remission), can be used instead of prednisone/prednisolone in combination with azathioprine. The dose of immunosuppression should be individualized to achieve and maintain normal ALT and immunoglobulin G levels.

In cases of treatment failure, incomplete response, or intolerance to first-line agents, either mycofenolate mofetil (20 mg/kg/day initially, increased to a maximum of 3 g/day) or tacrolimus (1 to 8 mg/day) chronically can achieve and maintain biochemical remission.[19] Infliximab or rituximab are possible alternative therapies after first-line and second-line regimens have failed. After 3 years or more of remission, therapy can be carefully withdrawn, but severe and even fatal flares can occur weeks to months later.

PROGNOSIS

The prognosis is generally related to the histologic stage of the disease. Patients who initially respond to therapy may do well for many years. Patients who progress to end-stage liver disease require liver transplantation (Chapter 140).[20]

CRYPTOGENIC CHRONIC LIVER DISEASE

Cryptogenic chronic liver disease refers to chronic hepatitis or cirrhosis of unknown cause after excluding hepatitis B, C, D, and E; autoimmune hepatitis; steatohepatitis (Chapter 138); alcoholic liver disease (Chapter 138); drug-induced hepatitis (Chapter 136); and inherited and metabolic liver diseases (Chapter 132). Tests to exclude these conditions include serum levels of α_1-antitrypsin, iron, and ceruloplasmin and, if necessary, urine and liver copper concentrations. In its later stages, nonalcoholic steatohepatitis may be associated with little or no fat.

136 DRUG-INDUCED LIVER INJURY

PAUL B. WATKINS

DEFINITION

Drug-induced liver injury can be caused by drugs or by druglike substances, including herbal products. Because some drugs can cause minor abnormalities of liver chemistries that are of no health concern, drug-induced liver injury is defined in terms of threshold values for liver chemistries (Table 136-1).[1] The clinical presentation of drug-induced liver injury can be predominantly hepatocellular, cholestatic, or a mixture of each, as defined by the ratio of the serum alanine aminotransferase (ALT) level to the alkaline phosphatase level. A hepatocellular presentation primarily reflects death of hepatocytes with release of their contents, including ALT and aspartate aminotransferase (AST), into circulation, whereas a cholestatic presentation reflects injury to the bile ductular epithelium (cholangiocytes) or to processes that selectively affect the liver's ability to make and secrete bile. A mixed injury reflects a combination of these processes. Since no tests can definitively confirm most cases, the diagnosis is often one of exclusion.[2]

EPIDEMIOLOGY

Drug-induced liver injury is a rare event considering the very large number of different drugs used by patients. Estimated rates are fewer than 20 drug-induced liver injuries per 100,000 person-years in Western countries[3] but higher in mainland China. However, due to challenges in diagnosing drug-induced liver injury and incomplete reporting, the true incidence may be 10 times higher. Antimicrobial agents are the major class of implicated drugs in Western countries, whereas herbal medications are the most frequently reported cause in Asian countries.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Autoimmune hepatitis tends to be more severe at its onset than chronic hepatitis B or C, and it progresses to end-stage liver disease if not treated with immunosuppression.[14] Although it is occasionally detected by elevated serum aminotransferase levels on a routine health evaluation, most patients present with fatigue and jaundice.[15] Elevations of bilirubin or alkaline phosphatase indicate more severe or advanced disease. Patients typically have marked elevations in serum γ-globulin, specifically immunoglobulin G, as well as autoantibodies directed at non–organ-specific cellular constituents.

Type 1 autoimmune hepatitis (approximately 90% of cases) is characterized by titers of 1:80 or higher (>1:20 in children) of antinuclear, anti–smooth muscle, anti-actin, and/or anti–soluble liver antigen/liver pancreas antibodies. Type 2 autoimmune hepatitis is characterized by similar elevations of anti–liver-kidney microsomal 1 antibodies and/or anti–liver cytosol 1 antibodies, without antinuclear or anti–smooth muscle antibodies. However, auto-antibodies are not detected in 20 to 35% of cases.

Liver biopsy shows features that are typical of all chronic types of hepatitis, except plasma cell infiltrates. Noninvasive physical markers, such as transient elastography, magnetic resonance elastography, or acoustic radiation force impulse imaging, correlate strongly with the histologic stage of fibrosis, but their accuracy may be impaired by inflammation at the time of diagnosis and during the first months of treatment.

The differential diagnosis of autoimmune hepatitis includes drug-induced liver injury (Chapter 136). Sustained biochemical resolution after glucocorticoid withdrawal reinforces the diagnosis of a self-limited drug-induced liver injury, whereas recrudescence of laboratory abnormalities is consistent with autoimmune hepatitis.

TREATMENT

The clinical symptoms and liver test abnormalities of autoimmune hepatitis generally respond promptly to prednisone.[16,17] Induction therapy should be based on 0.5 to 1.0 mg/kg/day prednisone or prednisolone. If the initial response is good, azathioprine should be added gradually, up to 1.0 to 2.0 mg/kg/day, starting 2 weeks after steroid initiation, while the steroid dose is gradually tapered.[18] In patients without cirrhosis and or acute severe autoimmune hepatitis, budesonide (3 mg three times daily, reduced to twice daily following remission), can be used instead of prednisone/prednisolone in combination with azathioprine. The dose of immunosuppression should be individualized to achieve and maintain normal ALT and immunoglobulin G levels.

In cases of treatment failure, incomplete response, or intolerance to first-line agents, either mycofenolate mofetil (20 mg/kg/day initially, increased to a maximum of 3 g/day) or tacrolimus (1 to 8 mg/day) chronically can achieve and maintain biochemical remission.[19] Infliximab or rituximab are possible alternative therapies after first-line and second-line regimens have failed. After 3 years or more of remission, therapy can be carefully withdrawn, but severe and even fatal flares can occur weeks to months later.

PROGNOSIS

The prognosis is generally related to the histologic stage of the disease. Patients who initially respond to therapy may do well for many years. Patients who progress to end-stage liver disease require liver transplantation (Chapter 140).[20]

CRYPTOGENIC CHRONIC LIVER DISEASE

Cryptogenic chronic liver disease refers to chronic hepatitis or cirrhosis of unknown cause after excluding hepatitis B, C, D, and E; autoimmune hepatitis; steatohepatitis (Chapter 138); alcoholic liver disease (Chapter 138); drug-induced hepatitis (Chapter 136); and inherited and metabolic liver diseases (Chapter 132). Tests to exclude these conditions include serum levels of α_1-antitrypsin, iron, and ceruloplasmin and, if necessary, urine and liver copper concentrations. In its later stages, nonalcoholic steatohepatitis may be associated with little or no fat.

136 DRUG-INDUCED LIVER INJURY

PAUL B. WATKINS

DEFINITION

Drug-induced liver injury can be caused by drugs or by druglike substances, including herbal products. Because some drugs can cause minor abnormalities of liver chemistries that are of no health concern, drug-induced liver injury is defined in terms of threshold values for liver chemistries (Table 136-1).[1] The clinical presentation of drug-induced liver injury can be predominantly hepatocellular, cholestatic, or a mixture of each, as defined by the ratio of the serum alanine aminotransferase (ALT) level to the alkaline phosphatase level. A hepatocellular presentation primarily reflects death of hepatocytes with release of their contents, including ALT and aspartate aminotransferase (AST), into circulation, whereas a cholestatic presentation reflects injury to the bile ductular epithelium (cholangiocytes) or to processes that selectively affect the liver's ability to make and secrete bile. A mixed injury reflects a combination of these processes. Since no tests can definitively confirm most cases, the diagnosis is often one of exclusion.[2]

EPIDEMIOLOGY

Drug-induced liver injury is a rare event considering the very large number of different drugs used by patients. Estimated rates are fewer than 20 drug-induced liver injuries per 100,000 person-years in Western countries[3] but higher in mainland China. However, due to challenges in diagnosing drug-induced liver injury and incomplete reporting, the true incidence may be 10 times higher. Antimicrobial agents are the major class of implicated drugs in Western countries, whereas herbal medications are the most frequently reported cause in Asian countries.

ABSTRACT

Drug-induced liver injury can be caused by most medications in current clinical use. Drugs that cause liver injury can be divided into three categories: direct/intrinsic toxins, which cause liver injury that is clearly dose-related and generally occurs within days of dosing; idiosyncratic toxins, for which the relationship between the dose and liver injury is not evident and injury typically occurs suddenly after weeks to months of chronic treatment; and indirect toxicity, in which liver injury occurs as a side effect of the drug's desired therapeutic actions (typically immune suppressants that activate viral hepatitis or immune checkpoint inhibitors that result in a liver-directed T-cell response). Acetaminophen (paracetamol) is the most important cause of direct/intrinsic liver injury, not only because it is a frequent cause of liver failure but also because an antidote (N-acetyl cysteine) is effective if given soon after ingestion of an overdose. Idiosyncratic drug-induced liver injury generally reflects an adaptive immune attack on the liver. Oftentimes it is challenging to establish the diagnosis of idiosyncratic drug-induced liver injury and to identify the culprit drug in patients who are receiving multiple medications, but many drugs have characteristic clinical presentations that can be helpful for assessing causality. Aside from stopping treatment with the offending drug, treatment of idiosyncratic drug-induced liver injury is generally supportive, with liver transplantation considered in cases of liver failure. Indirect drug-induced liver injury is treated by reducing or discontinuing treatment with the culprit drug, plus antiviral treatment if indicated.

genetics

In U.S. tertiary medical centers, about 10% of cases of severe acute hepatitis may be caused by drug-induced liver injury. Acetaminophen is the dominant cause of acute and fatal drug-induced liver injury. About 10 to 15% of cases are related to dietary and herbal supplements.

PATHOBIOLOGY

The liver is particularly susceptible to drug-induced injury because it sees the highest concentration of drugs after oral administration and because it is the major site for the metabolism of drugs, thereby resulting in a high concentration of potentially toxic drug metabolites. Drugs that cause liver injury can be divided into three categories: direct/intrinsic toxins, which cause liver injury that is clearly dose-related and generally occurs within days of dosing; idiosyncratic toxins, for which the relationship between the dose and liver injury is complex, and liver injury typically occurs suddenly after weeks to months of chronic treatment; and indirect toxicity, in which liver injury occurs as a side effect of the drug's desired therapeutic actions (typically immune suppressants that activate viral hepatitis or immune checkpoint inhibitors that result in a liver-directed T-cell response) (Table 136-2).[4] Acetaminophen (paracetamol) is the most important direct/intrinsic drug that causes liver injury, not only because it is a frequent cause of liver failure but also because an antidote (N-acetyl cysteine) is effective if given soon after ingestion of an overdose. Idiosyncratic drug-induced liver injury generally reflects an adaptive immune attack on the liver.

If drugs are not directly excreted as unchanged in the urine, the liver is the major site where they are metabolized. Most drugs are lipophilic and are transformed in the liver from nonpolar compounds into more hydrophilic metabolites via oxidative pathways mediated by the cytochromes P-450 (CYPs), often followed by conjugation to polar ligands so they can be excreted in the urine or bile. Other important metabolic pathways for some drugs may include acetylating enzymes, glutathione-*S*-transferase, and alcohol dehydrogenase.

TABLE 136-1 INTERNATIONAL CONSENSUS CRITERIA FOR DRUG-INDUCED LIVERY INJURY

A. Drug-induced liver injury is defined by any of the following peak serum values (assuming a healthy liver prior to the event):
- Serum alanine aminotransferase level 5 or more times the upper limit of normal
- Serum alkaline phosphatase level 2 or more times the upper limit of normal in the absence of bone pathology
- Serum alanine aminotransferase level 3 or more times the upper limit of normal and total serum bilirubin level 2 or more times the upper limit of normal in the absence of hemolysis or Gilbert syndrome

B. The clinical pattern of drug-induced liver injury is defined by the R-value, which is calculated as the alanine aminotransferase : alkaline phosphatase ratio, where each is expressed in terms of the upper limit of normal when the patient first meets the criteria for drug-induced liver injury:
- Hepatocellular drug injury if R ≥ 5.0
- Mixed drug injury if R > 2.0 to < 5.0
- Cholestatic drug injury if R ≤ 2.0

Drug-Induced liver Injury (DILI): Current status and future directions for drug development and post-market settings. A consensus by a CIOMS Working Group 2020. Council for International Organizations of Medical Sciences; 2020. Available at https://cioms.ch/publications/product/drug-induced-liver-injury/.

DIRECT/INTRINSIC HEPATOTOXICITY

PATHOBIOLOGY

In cases of direct/intrinsic hepatotoxicity, the parent drug or, more usually, a toxic (or "reactive") metabolite formed by the metabolism of the parent drug, directly causes injury and death to liver cells. Virtually every user will develop this liver toxicity if they receive a high enough dose, but the threshold dose that causes toxicity can vary substantially among individuals.

Acetaminophen

The most important drug that causes direct hepatotoxicity is acetaminophen (also called paracetamol), which accounts for over 50% of cases of acute liver failure in the United States, Europe, and Australia. After a person consumes a therapeutic dose of acetaminophen, the majority of the drug undergoes glucuronidation or sulfation, thereby resulting in harmless metabolites that are rapidly excreted in urine (E-Fig. 136-1). Less than 10% of acetaminophen is normally converted to the potentially toxic metabolite, N-acetyl-p-benzoquinone imine (NAPQI). Therapeutic doses of acetaminophen are generally safe because NAPQI is rapidly detoxified through conjugation to glutathione. However, when a healthy person consumes a very large dose of acetaminophen (typically more than 12 grams as a single dose), the sulfation pathway can become saturated, thereby resulting in a greater fraction of this larger dose being converted to NAPQI. The excess NAPQI results in an increase in covalent binding to cellular proteins, particularly in mitochondria. This protein binding activates a subsequent series of signaling pathways that involve c-Jun N terminal kinase and can lead to the death of hepatocytes. The time taken to activate these pathways presumably accounts for the typical 24-hour latency between consumption of a toxic dose of acetaminophen and onset of elevated liver chemistries. Patient-specific factors that can significantly reduce the dose threshold for acetaminophen toxicity include poor nutrition and fasting (which can deplete the substrate for glucuronidation), as well as excessive ethanol intake (which can induce CYP2E1; see E-Fig. 136-1). Patients with cirrhosis (Chapter 139) may also be more susceptible, thereby leading to the current recommendation not to exceed 2 g in 24 hours in this population.

Other Direct Liver Toxins

Other drugs that cause liver toxicity by direct mechanisms include cocaine, aspirin, nicotinic acid, many anticancer drugs, and pyrrolizidine alkaloids that are contained in some plant products (Table 136-3). For *Amanita* poisoning (Chapter 96) after ingestion of the mushrooms *Amanita phalloides* (death cap) or *Amanita virosa* (deadly agaric), the dose-dependent toxic effect on the liver is attributed to amatoxin, an ingredient of the mushrooms that enhances the toxic effect by its enterohepatic recirculation characteristics; the toxic effect is exerted on each cycle of the recirculation through the liver.[5]

Statin drugs (Chapter 190) can cause dose-dependent, asymptomatic elevations in serum ALT in 1 to 4% of treated individuals, but clinically significant liver injury is quite rare, and progression to liver failure is almost unheard of. Hence, no patient should be denied statin treatment over liver safety concerns.

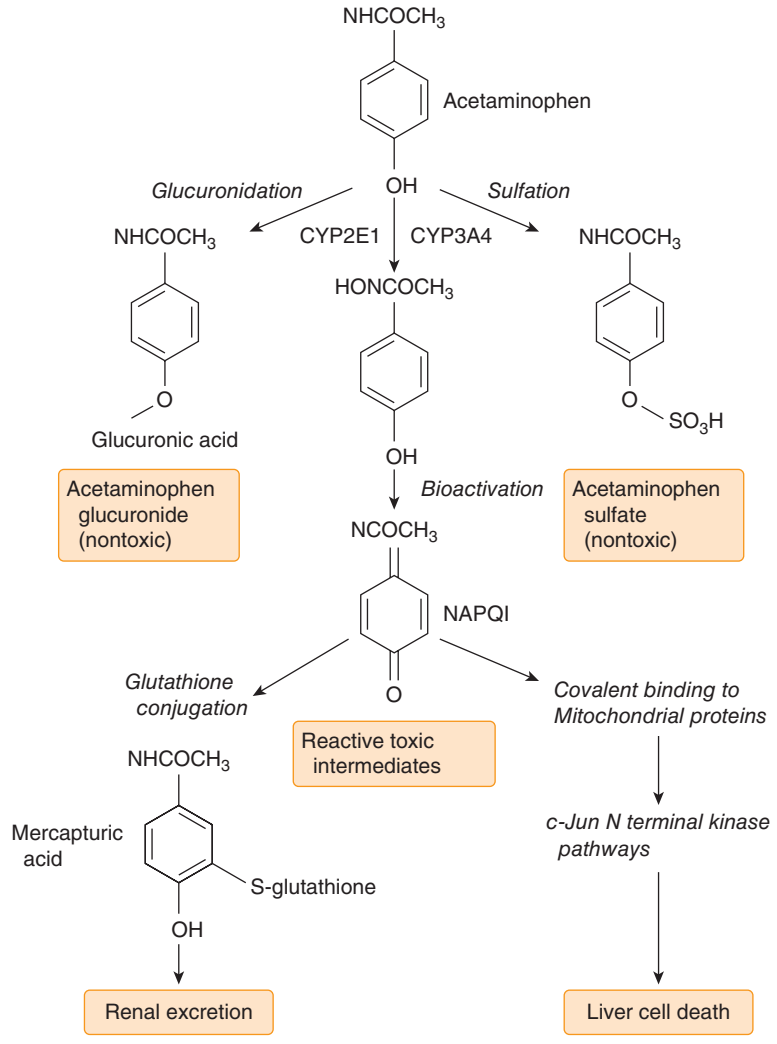
CLINICAL MANIFESTATIONS

Acetaminophen

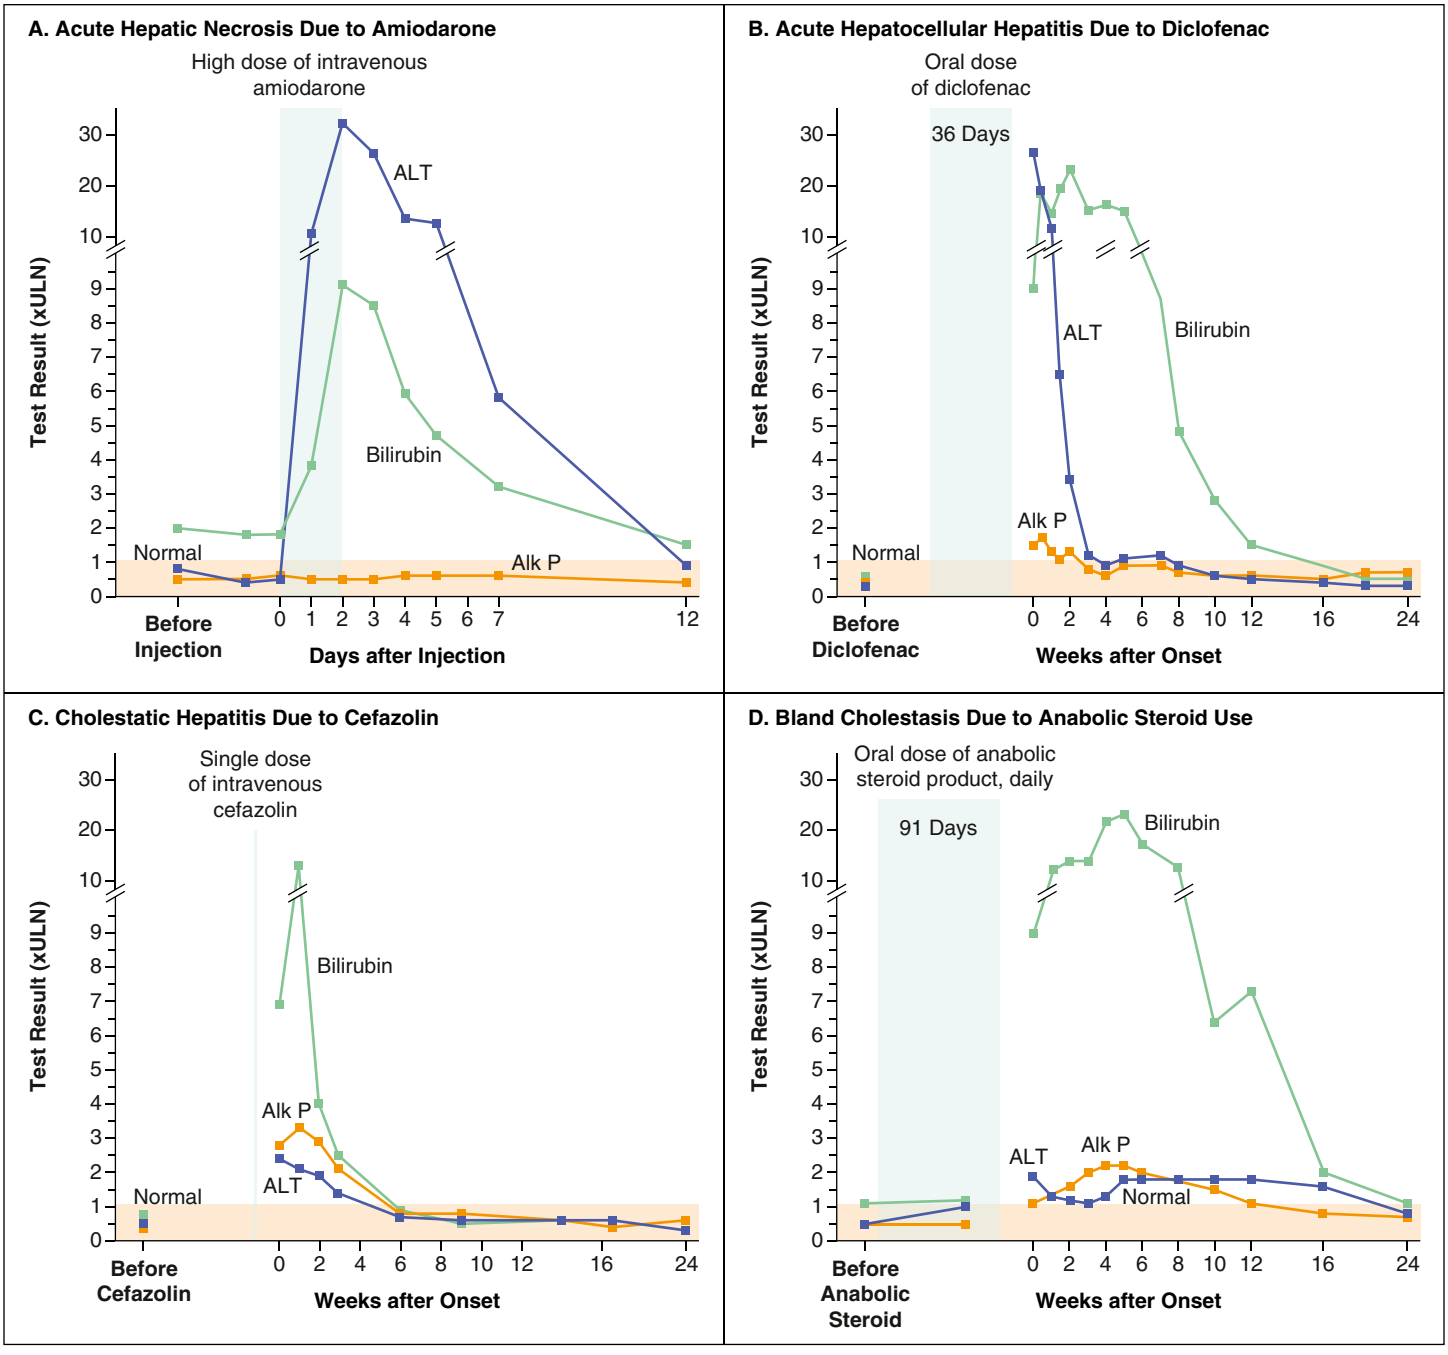
After a single and usually intentional overdose of acetaminophen, the clinical presentation has four potential stages (E-Fig. 136-2).[6] The first stage includes up to 24 hours after the ingestion, during which symptoms may include nausea, vomiting, and abdominal discomfort. The second stage, which marks the

TABLE 136-2 TYPICAL FEATURES OF DRUG-INDUCED LIVER INJURY

	DIRECT/INTRINSIC	IDIOSYNCRATIC	INDIRECT
Implicated drugs	Acetaminophen is major cause (see Table 136-3)	Many drugs, especially antibiotics and herbal products (see Table 136-4)	Immune modulators, including checkpoint inhibitors
Dose-related	Yes	Less likely at doses <50 mg/day	No
Latency	1 to several days	1-3 months	1-6 months
Genetic predisposition	Variants in phase 1 or phase 2 metabolism	HLA risk alleles	Unknown
Pathogenesis	Reactive metabolites	Adaptive immune attack on the liver	Viral cytolysis or an adaptive immune attack on the liver
Pathophysiology	Reactive metabolites damage organelles and initiate death-signaling pathways	Cytotoxic T cells kill liver cells	Activation of viral infection or reduced immune tolerance
Pathology	Pericentral necrosis with little inflammation	Panacinar inflammation and cell death	Variable



E-FIGURE 136-1. Liver metabolism of acetaminophen. After a therapeutic dose in a healthy adult, liver injury does not occur because there is sufficient glutathione present to inactivate N-acetyl-p-benzoquinone imine (NAPQI). However, after an overdose of acetaminophen, the production of NAPQI may exhaust glutathione supplies, thereby resulting in a cascade of events that lead to liver injury. N-acetyl cysteine restores glutathione and prevents injury if administered early in the course of events (see text).



E-FIGURE 136-2. **Common clinical presentations of drug-induced liver injury A,** Direct/intrinsic hepatotoxins. Liver injury occurs soon after exposure, with rapid resolution. **B,** Idiosyncratic hepatocellular drug-induced liver injury. Latency is typically between 1 and 3 months, and resolution of jaundice can be prolonged; some patients progress to global liver dysfunction. **C,** Idiosyncratic cholestatic drug-induced liver injury. The short latency in this case supports prior sensitization to the drug-induced neoantigen or to a structurally similar peptide. **D,** Prolonged bland cholestasis, in this case in a young male bodybuilder who was consuming an androgen-containing product. ALT = alanine aminotransferase; Alk P = alkaline phosphatase; ULN = upper limit of normal. (Reproduced with permission from Hoofnagle JH, Björnsson ES. Drug-induced liver injury-types and phenotypes. *N Engl J Med*. 2019;381:264-273.)

TABLE 136-3 DRUGS AND TOXINS THAT CAUSE DOSE-RELATED INJURY

DRUG OR TOXIN
Acetaminophen
Alcohol
Amiodarone
Cocaine
Cyclophosphamide
Cyclosporine
Methotrexate
Niacin
Nonsteroidal anti-inflammatory drugs (principally bromfenac, phenylbutazone)
Oral estrogens or androgens
Tetracyclines
Toxins (yellow phosphorus, carbon tetrachloride, *Amanita* toxin, bacterial toxins)
Zidovudine

initial elevation of liver chemistries, typically starts about 24 hours after the ingestion when the patient may feel entirely well. Serum AST and ALT levels rise rapidly to very high levels, initially with AST levels typically higher than ALT levels. Elevations in the serum bilirubin level and international normalized ratio (INR) reflect significant loss of liver function. The third stage, which is marked by the peaking of serum ALT and AST, typically occurs 3 to 4 days after the ingestion. If the injury is severe, the serum bilirubin level and INR will continue to increase, and the patient may develop fulminant hepatic failure, often accompanied by kidney failure. The fourth stage is recovery with return of all liver chemistries and the INR to normal over 2 weeks. Because death of liver cells ceases after the first several days after ingestion, the serum enzymes fall at the rate of their half-lives (ALT about 2 days, AST about 1 day).

Other Direct Liver Toxins

Other direct liver toxins cause hepatic steatosis and lactic acidosis, which typically present with fatigue, nausea, and weight loss within the first month of starting treatment with the culprit drug. Drugs implicated in causing this type of liver injury include intravenous tetracycline and d-nucleosidase drugs, including zidovudine (AZT). Liver chemistries may be only minimally elevated, and liver histology reveals microvesicular steatosis similar to that observed when aspirin causes Reye syndrome. Chronic treatment with several drugs (e.g., tamoxifen or methotrexate) can cause fatty liver without lactic acidosis, often in the setting of obesity or type 2 diabetes. Acute alcoholic injury also results in fatty liver (Chapter 138).

Bland cholestasis occurs in healthy young men who consume androgen-containing supplements to build muscle bulk (see E-Fig. 136-2D).[7] Long-term use of estrogens, especially in high doses, is associated with benign liver adenomas, and long-term use of androgen-containing supplements can cause liver cancer.

Sinusoidal obstruction syndrome (previously termed veno-occlusive disease), which can be acute or subacute forms of this phenotype, presents with abdominal pain and weight gain owing to the rapid accumulation of ascites. Offending drugs are generally chemotherapeutic agents, typically alkylating agents such as cyclophosphamide.

DIAGNOSIS

In an otherwise healthy person, sudden development of extremely high (more than 50 times the upper limit of normal) ALT and AST values, followed by resolution at the half-lives of these enzymes, is almost pathognomonic for acetaminophen overdose.[8] Nevertheless, the diagnosis of acetaminophen drug-induced liver injury can be challenging during the first stage, when it is based on the history of the amount ingested and the timing of the ingestion. Since some patients may not admit to having taken an overdose and liver chemistries will generally not be abnormal during the first stage, measurement of an acetaminophen blood level is key to diagnosis. For other causes of direct liver injury, the diagnosis is based on exposure to a known toxin.

Rare exposures to other liver toxins (Table 136-3), such as poisonous mushrooms or industrial solvents, also can present with a clinical picture similar to acetaminophen poisoning. The diagnosis is based on evidence of exposure since there is no definitive diagnostic test.

TREATMENT

N-acetyl cysteine, which repletes liver stores of glutathione, is a very effective treatment for acetaminophen overdose,[A1] especially if administered during stage 1. Intravenous dosing can begin with 140 mg/kg in 300 mL of 5% dextrose given over 1 hour, followed by a dose of 70 mg/kg in 5% dextrose given over a 1-hour period every 4 hours for 48 hours. Alternatively, a loading dose of 140 mg/kg can be given orally, followed by 70 mg/kg every 4 hours for 17 doses (72 hours), with subsequent dosing dependent on the predicted and measured toxic levels of acetaminophen as a function of time since a single overdose (https://www.mdcalc.com/acetaminophen-overdose-nac-dosing#next-steps). Critically ill patients require intensive care. Liver transplantation (Chapter 140) is often required for fulminant hepatic failure.

For other direct liver injuries, no specific treatments are available. Care is supportive, with liver transplantation often required for liver failure.

PREVENTION

Patients who have accidentally overdosed should be advised to read the labels on all analgesics, cold, and sleep remedies to keep total acetaminophen dosing within the recommended range. Patients who have intentionally overdosed require psychiatric consultation (Chapter 362).

PROGNOSIS

The prognosis is excellent if NAC is administered within stage 1. If serial assessments of acetaminophen levels indicate that the half-life is longer than 5.5 hours, progressive liver injury is likely.

IDIOSYNCRATIC HEPATOTOXICITY

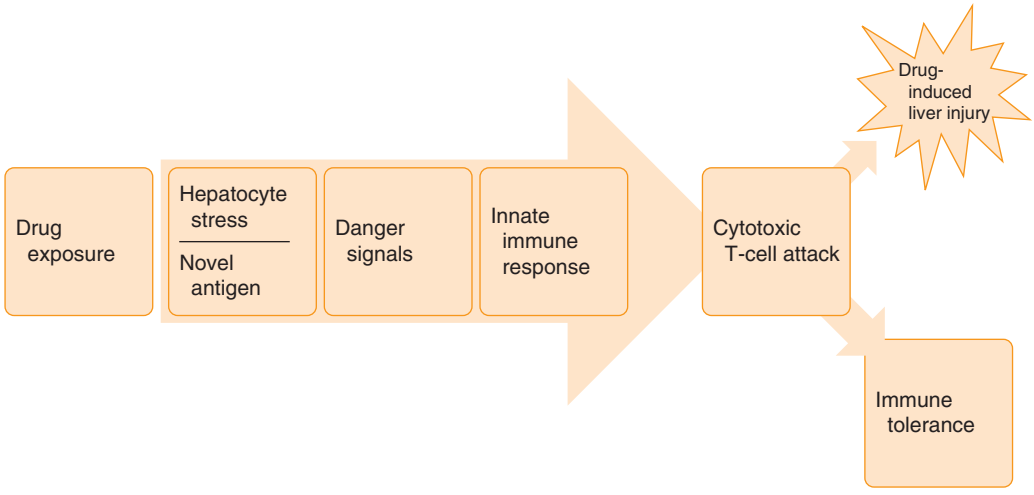
EPIDEMIOLOGY

Idiosyncratic drug-induced liver injury is a rare but potentially serious event that occurs during recommended dosing of the implicated drug at a frequency less than 1 : 1000 treated patients. Although idiosyncratic hepatotoxicity is not generally dose-related, it is less likely to occur when the daily dose of drug is less than 50 mg per day and can occasionally occur when the daily dose is increased after prolonged treatment (>1 year) at a lower dose. The most common drugs that cause idiosyncratic drug-induced liver injury are antimicrobial agents (e.g., fluoroquinolones) and herbal and dietary supplements (Table 136-4). Herbal supplements dominate in China[9] and other parts of Asia, and the incidence of drug-induced liver injury related to dietary and herbal supplements is increasing in the United States as well.[10] The risk appears to increase with factors such as older age and alcohol use (Table 136-5).

PATHOBIOLOGY

Idiosyncratic drug-induced liver injury often results from a cytotoxic T-cell response to drug-induced neoantigen(s) presented on the surface of liver cells. This response typically occurs because of covalent binding of a drug metabolite to an endogenous liver protein, thereby resulting in altered peptide fragments presented by class 1 HLA molecules.[11] However, creation of a novel antigen alone is not thought to be sufficient to initiate an immune attack on the liver (E-Fig. 136-3).[12] A number of genetic variants, particularly HLA alleles (Table 136-6), increase the susceptibility to idiosyncratic hepatotoxicity[13]. Due to the rarity of idiosyncratic drug-induced liver injury, however, the vast majority of patients treated with these drugs do not get drug-induced liver injury even if they carry the corresponding risk allele. Genetic variants in CYP isoenzymes likely also partially explain a predisposition to drug-induced liver injury. In addition, a polymorphism in the *PTPN22* gene, which is believed to influence T-cell activation, also is associated with about a 50% increased risk for drug-induced liver injury.

The usual response to an initial adaptive immune attack on the liver due to a drug is spontaneous resolution, even with continued exposure to the offending drug, because of immune tolerance mechanisms. The typical latency reflects, at least in part, the time needed to complete the multiple sequential steps involved (E-Fig. 136-3). Once the injury is initiated, it may progress for days or rarely weeks after discontinuing the offending drug. In some cases (see E-Fig. 136-2, panel B), the adaptive immune attack can occur within days after starting treatment, presumably as a reflection of a sufficient pre-existing



E-FIGURE 136-3. The pathogenesis of idiosyncratic drug-induced liver injury. Most idiosyncratic drug-induced liver injury is because the drug produces neoantigen(s) in the liver and hepatocytic stress (but not necessarily cell death) due to intrinsic toxicity. In susceptible individuals, these events lead to the release of signals that result in activation of innate immune cells, which in turn activate antigen-presenting cells that program cytotoxic T cells to kill liver cells. The resulting adaptive immune attack generally results in asymptomatic elevations in serum liver chemistries, but these elevations typically resolve, despite continued drug treatment, due to immune tolerance mechanisms. If immune tolerance does not promptly occur, progressive and symptomatic liver injury may result.

TABLE 136-4 MOST COMMON CAUSES OF IDIOSYNCRATIC DRUG-INDUCED LIVER INJURY

TYPE OF MEDICATION	%	SPECIFIC DRUGS*	%
Antimicrobials	32	Amoxicillin-clavulanate	8
Herbal and dietary supplements	12	Isoniazid	4

Ximelagatran	DRB1*07:01-DQA1*02:01	4.4

population of appropriately primed T cells prior to starting treatment with the implicated drug, perhaps due to prior treatment with the same drug, or prior exposure to a structurally similar viral antigen.

CLINICAL MANIFESTATIONS

About 50% of cases present within 30 days of starting the drug, and about 80% of cases present within 90 days (see E-Fig. 136-2, panel B).[14] Occurrences beyond 1 year of treatment are very rare and usually occur with drugs that are not taken continuously, such as minocycline for acne or nitrofurantoin for urinary tract infections.

TABLE 136-7 IDIOSYNCRATIC TOXIN AND DRUG REACTIONS

REACTION TYPE	SOME IMPLICATED DRUGS OR TOXINS
Hepatocellular	Carbamazepine, fluoroquinolones, cyclosporine, herbs, methimazole, isoniazid, lovastatin, nefazodone, trazodone, venlafaxine
Cholestatic or mixed	Anabolic steroids, captopril, carbamazepine, chlorpromazine, estrogen, erythromycin, amoxicillin/clavulanate
Fibrosis	Methotrexate, excess vitamin A
Granulomatous	Allopurinol, diltiazem, nitrofurantoin, sulfa drugs, quinidine
Autoimmune	Nitrofurantoin, minocycline
Immunoallergic	Halothane, phenytoin, sulfamethoxazole
Steatohepatitis	Amiodarone, perhexiline maleate, tamoxifen

Different drugs can cause different types of liver reactions (Table 136-7), but clinically the damage presents as a hepatocellular, cholestatic, or mixed injury. Most cases of drug-induced liver injury are hepatocellular reactions, which account for 60% of cases and are characterized by elevated levels of AST and ALT. Cholestatic reactions[15] can be caused by trimethoprim-sulfamethoxazole, captopril, and body-building dietary supplements that contain androgenic compounds. Nodular regenerative hyperplasia manifests with fatigue, weight loss, ascites, and other complications of portal hypertension, usually after at least 6 months of continuous treatment with the offending drug. Drugs implicated as causing this phenotype include azathioprine, mercaptopurine, and thioguanine.

DIAGNOSIS

The most commonly used tool to aid in the diagnosis of drug-induced liver injury is the Roussel Uclaf Causality Assessment Method (RUCAM; Table 136-8; https://www.ncbi.nlm.nih.gov/books/NBK548272/), which considers answers to a series of questions such as time to detection of drug-induced liver injury from start of treatment, rate of resolution after stopping treatment, and whether the drug is known to cause hepatotoxicity. The sum of the points (>8 = highly probable, 6 to 8 = probable, 3 to 5 = possible, 1 to 2 = unlikely, 0 = excluded) after completing the exercise corresponds to scales of confidence on a causal link.

The RUCAM instrument does not consider the characteristic clinical presentations (or signatures) of the drugs that cause idiosyncratic reactions (see Table 136-4 and https://www.ncbi.nlm.nih.gov/books/NBK548473/). However, one drug can have more than one "signature," and many drugs have similar signatures.

A liver biopsy is generally not necessary to make the diagnosis of idiosyncratic drug-induced liver injury but is generally recommended when other potentially treatable diseases that have characteristic histology are being considered, such as autoimmune hepatitis (Chapter 135). For drugs for which specific genetic polymorphisms (see Table 136-6) increase risk, genetic testing may occasionally be helpful, particularly if the patient is being treated with multiple potential culprit drugs.

TREATMENT

Other than stopping treatment with the offending drug, no specific treatments are usually recommended for idiosyncratic drug-induced liver injury.[16,17] Drug-induced liver injury due to valproate, which presents with elevated blood levels of ammonia and altered mental status, may respond to treatment with carnitine (loading dose of 100 mg/kg intravenously [6 g maximum] over 30 minutes followed by maintenance doses of 15 mg/kg every 4 hours over 10 to 30 minutes). Oral administration of cholestyramine (8 g orally 3 times daily for 11 days) can hasten removal of some lipophilic drugs with long half-lives (e.g., leflunomide). Nevertheless, corticosteroids (typically starting with the equivalent of 40 mg prednisone daily with subsequent titration and tapering according to the patient's response) are often administered if the drug-induced liver injury mimics autoimmune hepatitis (Chapter 135) or if the liver injury is progressing towards liver failure, especially if clinical signs of hypersensitivity (fever, rash, and peripheral eosinophilia) are present.[18]

TABLE 136-8 SCORING SYSTEM TO ASSESS CAUSALITY OF HEPATOCELLULAR REACTIONS

FACTOR	SCORE*
TEMPORAL RELATIONSHIP OF START OF DRUG TO START OF ILLNESS	
Initial treatment: 5-90 days; subsequent treatment course: 1-15 days	+2
Initial treatment: <5 or >90 days; subsequent treatment course: >15 days	+1
From cessation of drug: ≤15 days†	+1
COURSE	
ALT decreases ≥50% from peak within 8 days	+3
ALT decreases ≥50% from peak within 30 days	+2
If the drug is continued, inconclusive	0

Causality assessment of adverse reactions to drugs. II. An original model for validation of drug causality assessment methods: case reports with positive rechallenge. *J Clin Epidemiol.* 1993;46:1331-1336.

PREVENTION

Patients who have a suspected drug-induced liver injury should have this fact prominently noted in the medical record and should not receive that drug again. To capture an idiosyncratic drug-induced liver injury early in its course and prior to the onset of jaundice, patients taking some drugs (e.g., antibiotic treatment for more than 2 weeks and many anticancer drugs, including kinase inhibitors, azathioprine, and most antiseizure drugs) should be routinely monitored with liver chemistries during the first 3 to 6 months of treatment, although the value of routine liver test monitoring has not been conclusively established by randomized trials.

PROGNOSIS

The vast majority of patients with drug-induced liver injury will recover after discontinuing treatment with the offending drug, but up to 20% will still have biochemical evidence of drug-induced liver injury at 6 months. Patients who develop hepatocellular jaundice have a greater than 10% chance of developing liver failure, regardless of the causative drug. The number of liver transplantations (Chapter 140) for liver failure caused by herbal products continues to rise.[19]

INDIRECT HEPATOTOXICITY

Indirect drug-induced liver injury refers to liver injuries that result as a consequence of the desired therapeutic actions of the drug. This phenomenon is a quite common form of drug-induced liver injury that is increasing as more immune modulatory medications enter the marketplace.

Examples of indirect drug-induced liver injury include flaring of preexisting viral hepatitis due to immune suppression that may result from treatment with corticosteroids and some monoclonal antibodies (e.g., daclizumab and anti–tumor necrosis factor alpha agents).[20] The other major type of indirect hepatotoxicity results from drugs that increase immune responses to cancer, such as checkpoint inhibitors[21] (which remove immune tolerance and spark an adaptive immune attack on the liver and other organs). Liver cell stress and neoantigen presentation must also be present for the reduction in immune tolerance to cause liver injury (E-Fig. 136-3), and concomitant treatment with a drug that can cause liver injury increases the risk.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Indirect hepatotoxicity is usually hepatocellular or mixed. It typically arises within 3 months after the start of therapy but can appear later. Many cases are anicteric and asymptomatic; sometimes, however, the hepatitis can worsen and rarely become life-threatening if untreated.

Indirect hepatotoxicity is typically detected by routine monitoring of liver chemistries during therapy with the offending agent. Reactivation of viral hepatitis is detected by serum viral counts.

TREATMENT AND PROGNOSIS

Reactivation viral hepatitis may require antiviral treatment (Chapter 134). Liver injury due to checkpoint inhibitors appears to respond to corticosteroids (e.g., 40 mg of prednisone daily, with subsequent titration and tapering according to the patient's response).

Concomitant treatment with drugs well-recognized to be hepatotoxic should be avoided. Full recovery is expected with timely recognition and appropriate treatment.

137 BACTERIAL, PARASITIC, FUNGAL, AND GRANULOMATOUS LIVER DISEASES

K. RAJENDER REDDY

INFECTIONS OF THE LIVER

Infections of the liver can be due to a variety of pathogens, including bacteria, fungi, amebae, protozoa, helminths, spirochetes, and rickettsiae.[1] The manifestations of these infections are protean; some are generic to all infections, whereas others are specific to particular infections. The epidemiology can vary and depend upon the geographic region of the world. In endemic areas, *Entamoeba histolytica* (Chapter 323) is a key consideration in the differential diagnosis of a liver abscess (Table 137-1).

BACTERIAL INFECTIONS

PYOGENIC LIVER ABSCESS

DEFINITION

Pyogenic liver abscess is a focal collection of purulent bacterial material and necroinflammatory debris. It can be solitary or multiple and can be caused by one or more aerobic and/or anaerobic bacteria.

EPIDEMIOLOGY

Pyogenic liver abscess has an estimated global incidence of approximately 1.1 to 2.3 per 100,000 person-years, whereas in the United States the incidence is reported to be approximately 3.6 per 100,000 and has been rising. The risk is about three-fold higher in patients with diabetes.[2] Biliary obstruction, caused by a malignancy or benign disease, accounts for 50 to 60% of pyogenic liver abscesses, whereas portal pyemia, due to appendicitis or other intra-abdominal infections (e.g., diverticulitis), accounts for about 20% of cases.[3] Studies from Asia, where *Klebsiella pneumoniae* is the primary etiologic source of pyogenic liver abscess,[4] have proposed a correlation with underlying colorectal neoplasms, some of which are evident at the time of diagnosis but also with a five- to eight-fold higher risk of newly diagnosed colorectal cancers in the 3 years after diagnosis. However, it is yet to be determined whether these findings can be extrapolated to other regions of the world.

PATHOBIOLOGY

Bacteria can enter the liver via the portal system from infections in areas drained by the mesenteric system into the portal system, such as appendicitis. Other mechanisms for pyogenic liver abscess include bacterial cholangitis owing to benign or malignant obstruction and infection of the liver from a systemic bacteremia, such as an infection of the oral cavity. Pyogenic liver abscess can also be caused by blunt or penetrating trauma, including such unusual causes as the ingestion of a toothpick or fish bone that can cause an intestinal perforation, fistula to the liver, and subsequent abscess formation. Liver abscesses can occur in a transplanted graft owing to vascular compromise caused by hepatic artery thrombosis and ischemic bile duct strictures.

Multiple organisms can cause pyogenic liver abscess. The most common organism, *Klebsiella pneumoniae* (Chapter 281) often is associated with biliary tract disease. Other aerobes include *Escherichia coli*, group D streptococci, β-hemolytic streptococci, and *Staphylococcus aureus*. Anaerobic infection is often seen with colonic disease. Less common causes of liver abscesses include *Actinomyces, Nocardia asteroides, Yersinia pseudotuberculosis* and *Yersinia enterocolitica, Listeria monocytogenes, Campylobacter jejuni, Legionella pneumophila, Mycobacterium tuberculosis, Salmonella typhi* or *Salmonella paratyphi, Candida albicans*, and *Bartonella henselae*. Most often, the organism recovered from an abscess cavity is single, but multiple organisms can be isolated in as many as a third of patients. Bacteria may not be isolated from the abscess because of prior antibiotic therapy or the failure to perform proper anaerobic cultures.

CLINICAL MANIFESTATIONS

The signs and symptoms associated with a liver abscess typically include fever, right upper quadrant abdominal pain, chills, nausea, vomiting, weight loss, and jaundice. The presentation can be acute or indolent. An associated bacteremia is seen in approximately 50% of the patients, and about 15% of patients may develop septic shock. About 10% of patients develop metastatic infections in other sites.

DIAGNOSIS

Appropriate diagnosis requires a high degree of clinical suspicion, and diagnosis is sometimes delayed. Usually, however, the diagnosis is made promptly with the wide availability of the various radiologic modalities. The two common causes of liver abscesses are pyogenic and amebic abscesses, and it is important to make a distinction because the prognosis and management differ.[5] Amebic abscesses can infrequently become secondarily infected with other bacteria.

The diagnosis of an abscess is based on a constellation of clinical, bacteriologic, and radiologic features.[6] Ultrasonography and computed tomography (CT) scanning are the most common radiologic modalities to diagnose an abscess cavity reliably,[7] either as single or multiple lesions (Fig. 137-1A and B). CT is the preferred diagnostic modality to detect an abscess, with sensitivity of more than 90%. Any concurrent biliary obstruction also can be diagnosed by these imaging modalities. Approximately 50% of patients have multiple abscesses. On CT the lesion is seen as a fluid collection with irregular borders and cavity wall edema. One drawback to this imaging modality is that no specific features differentiate a pyogenic abscess from other infectious causes (i.e., amebic or fungal). Another drawback is that a very early stage abscess may not be well formed and may have characteristics more suggestive of a solid mass. On noninvasive imaging studies, it is critical to distinguish an abscess from a tumor or a simple cyst. Various events, such as bleeding into a cyst, calcification, necrosis, and bleeding into a tumor, may confuse the distinction. A finding of smaller (<2 cm) peripheral lesions that surround a central abscess (the cluster sign) can help exclude a hepatic neoplasm. Calcification suggests

TABLE 137-1 FEATURES OF BACTERIAL AND AMEBIC ABSCESSES

	DEMOGRAPHICS	RISK FACTORS	SYMPTOMS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Bacterial liver abscess	50-70 years old Male = female	Recent bacterial infection, biliary obstruction, diabetes mellitus	Fevers, chills, malaise, anorexia, diarrhea, cough, pleuritic chest pain, RUQ pain	Leukocytosis, anemia, elevated alkaline phosphatase and bilirubin, low albumin, positive blood cultures (50%)	Multifocal (50%), usually right lobe, irregular margins	Aspirate (70-80% positive)	Percutaneous drainage and antibiotics
Amebic liver abscess	18-50 years old Male > female	Alcohol intake, HLA-DR3, oral and anal sex, contaminated enema apparatus, travel to or living in an endemic area	Fever, RUQ pain, hepatic tenderness, anorexia, weight loss, uncommon to have colitis	Leukocytosis, no eosinophilia, mild anemia, elevated alkaline phosphatase, elevated ESR, positive serology	Single abscess (80%), usually right lobe, wall enhancement seen on CT scan with IV contrast	Aspirate (trophozoites rarely seen) can rule out superimposed bacterial infection, positive serology and risk factors	Metronidazole and iodoquinol

CT = computed tomography; ESR = erythrocyte sedimentation rate; HLA = human leukocyte antigen; IV = intravenous; RUQ = right upper quadrant.

ABSTRACT

Infections of the liver can be due to a variety of pathogens, including bacteria, fungi, amebae, protozoa, helminths, spirochetes, and rickettsiae. The manifestations of these infections are protean; some are generic to all infections, whereas others are specific to particular infections. The epidemiology can vary depending on the geographic region of the world. In endemic areas, *Entamoeba histolytica* is a key consideration in the differential diagnosis of a liver abscess.

KEYWORDS

pyogenic liver abscess
hepatosplenic candidiasis
echinococcosis
hydatid cyst disease
schistosomiasis
granulomas
sarcoidosis

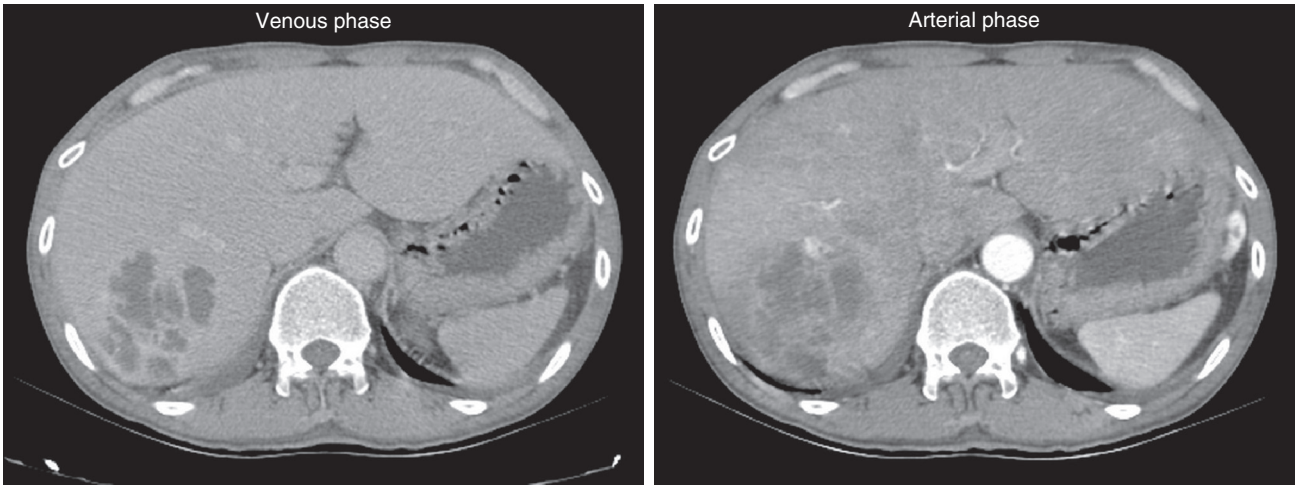

FIGURE 137-1. A and B, Computed tomographic scans of pyogenic liver abscess. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

bleeding into a tumor, but it also can be seen in the wall of an echinococcal cyst. Nonspecific radiologic features, including elevation of the right hemidiaphragm, right lower lung lobe atelectasis, and right pleural effusion, are seen in up to 30% of patients with pyogenic liver abscesses. Magnetic resonance imaging and tagged white blood scans add little to the diagnosis of a liver abscess.

Microbial cultures are essential. In addition to blood cultures, the abscess cavity should be aspirated percutaneously, with either ultrasound or CT guidance, and the aspirate should be cultured for aerobic and anaerobic organisms as well as examined for amebae if there is any suspicion of an amebic abscess. Blood cultures are positive in only approximately 50% of cases. In approximately 15 to 20% of cases, multiple organisms are identified in the abscess cavity, but 20 to 50% of cases may have negative cultures despite appropriate culture techniques.

TREATMENT

Immediate broad-spectrum antibiotic coverage and the prompt identification and treatment of the source of the infection are essential for successful outcomes.[8] As soon as the causative bacterium is identified, the antibiotic regimen can be tailored appropriately. Recommendations should be guided by the culture and by prevailing bacterial resistance patterns. Monotherapy with a β-lactam or β-lactamase inhibitor such as ampicillin-sulbactam (3 g intravenously [IV] every 6 hours) or piperacillin-tazobactam (3.375 or 4.5 g IV every 6 hours) or ticarcillin-clavulanate (3.1 g IV every 6 hours) can be used, or a third-generation cephalosporin such as ceftriaxone (1 g IV daily or 2 g IV every 12 hours for central nervous system infections) *plus* metronidazole (500 mg IV every 8 hours) can be considered. Alternate regimens for consideration include a fluoroquinolone (such as ciprofloxacin 400 mg IV every 12 hours or levofloxacin 500 or 750 mg IV daily) *plus* metronidazole (500 mg IV every 8 hours) and monotherapy with a carbapenem such as imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), doripenem (500 mg IV every 8 hours), or ertapenem (1 g IV daily). The duration of therapy is partly based on the response to therapy. An average of 4 to 6 weeks of antibiotic therapy is reasonable, and the last 2 to 4 weeks of the antibiotic regimen can be administered orally. For documented *Klebsiella pneumoniae* liver abscess treated with 5 to 7 days of intravenous antibiotics, an additional 28 days of oral ciprofloxacin is as good as an additional 28 days of intravenous ceftriaxone.[A1] Abscesses that are difficult to drain or are slow to demonstrate radiographic resolution require longer courses of therapy. Importantly, radiologic abnormalities resolve more slowly than clinical and biochemical features, so the latter should be used as a guide for tailoring the therapeutic regimen.

Antibiotics alone can sometimes successfully resolve small, multiple pyogenic abscesses, but most patients (≥70%) will require drainage of the abscesses. Percutaneous drainage is recommended, with subsequent management dictated by the size and number of abscesses. Abscesses of up to 5cm in diameter can be managed with a single aspiration. Larger abscesses are probably better managed with catheter drainage[A2,A3] until the output is less than approximately 20 to 25mL per day, at which time the catheter can be removed. Endoscopic ultrasound-guided drainage is an option if the abscess cannot be accessed percutaneously.[9] Surgical drainage is seldom required because of the advancements in percutaneous drainage and is reserved for loculated abscesses and abscesses that do not respond to percutaneous drainage and antibiotics. Biliary obstruction is treated with endoscopic retrograde cholangiopancreatography or transhepatic cholangiography (Chapter 141) with accompanying biliary drainage. For pyogenic abscesses in transplanted livers, management and proper biliary drainage may be difficult to achieve because of the diffuse nature of the biliary strictures.

PROGNOSIS

Abscesses smaller than 10 cm can take up to 16 weeks to resolve, whereas abscesses larger than 10 cm may take an average of an additional 6 weeks to resolve. Mortality from pyogenic liver abscess is associated with older age and with comorbidities such as cirrhosis, diabetes, chronic renal failure, and malignancy. Jaundice is an ominous sign. In developed countries the mortality rate ranges from 2 to 12%.

NON-ABSCESS HEPATIC BACTERIAL INFECTIONS

Bacterial infections of the liver can also cause more diffuse infections without frank abscess formation. Implicated organisms include *Listeria monocytogenes* (Chapter 272), *Yersinia enterocolitica* (Chapter 288), *Salmonella typhi* and *Salmonella paratyphi* (Chapter 284), *Legionella* (Chapter 290), *Ehrlichia* (Chapter 302), and gonococci (Chapter 275). There are no specific features associated with these infections, and these organisms do not necessarily cause abscesses. Patients with chronic liver disease are especially at risk for *Listeria* infection. Patients with active enteric *Yersinia* infection can have secondary liver involvement with or without liver abscesses. Disseminated gonococcal infections (Chapter 275) can cause a perihepatitis (Fitz-Hugh-Curtis syndrome), which can be manifested with right upper quadrant pain and tenderness.

Systemic bacteremia can cause a variety of hepatobiliary abnormalities, which may range from elevated aminotransferase and alkaline phosphatase levels (Chapter 133) to the cholestasis of sepsis with the development of jaundice. Several organisms can disrupt normal liver function after entering the blood stream, the most common of which are *E. coli*, *Klebsiella* spp, *Streptococcus pneumoniae*, and *S. aureus*. Typically, in patients suffering from jaundice, sources of bacteremia include pneumonia, urinary tract infection, and soft tissue infection, although organisms may originate from a range of other sites. The hepatic biochemical abnormalities associated with bacteremia may be related to factors such as hemodynamic instability and liver hypoperfusion, as well as to the infection. Associated renal failure, a blood transfusion–derived bilirubin load, and drugs may complicate the picture. The course of cholestasis may be prolonged for several days to a few weeks, but it typically resolves with resolution of the systemic infection. There is no specific treatment for the cholestasis related to a systemic infection, but it is important to rule out drug-induced cholestasis that may evolve as a consequence of one or more of the antibiotics.

FUNGAL DISEASES OF THE LIVER

Except for hepatosplenic candidiasis, clinically significant fungal diseases of the liver are unusual. Typically, other fungal infections will also be manifested as liver granulomas but will not show the high, swinging pyrexia that is characteristic of hepatosplenic candidiasis. Tissue cultures are required to confirm a diagnosis.

HEPATOSPLENIC CANDIDIASIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Hepatosplenic candidiasis typically is caused by *Candida albicans*, but other species, including *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and *C. krusei*, have occasionally been reported. It occurs as part of disseminated candidiasis (Chapter 310), most commonly in patients with solid organ or hematopoietic stem cell transplants or acute leukemia, but rarely in patients with lymphoma,

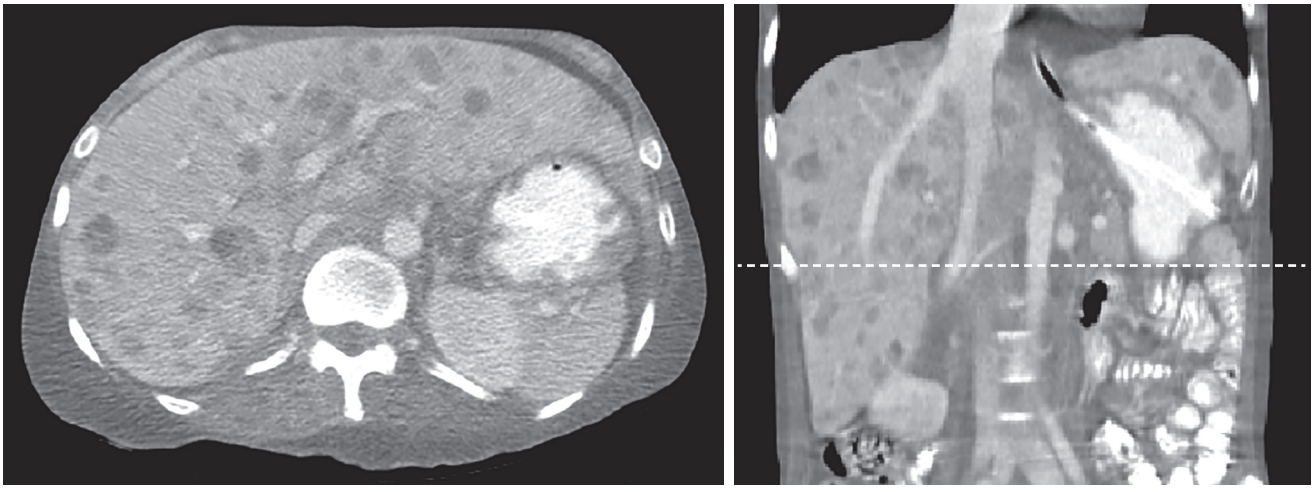

FIGURE 137-2. Multiple filling defects in the liver and spleen in a patient with hepatic and splenic candidiasis. (Courtesy of Dr. Sirina Ekpanyapong, Bangkok, Thailand.)

aplastic anemia, and sarcoma. With the current widespread use of prophylactic antifungal agents early in the course of the disease in patients with acute leukemia, hepatosplenic candidiasis develops in only 1 to 2% of patients, more commonly with acute lymphoblastic leukemia than with acute myeloid leukemia. Hepatosplenic candidiasis presumably results from translocation of *Candida* species from the gastrointestinal tract into the blood stream as a result of prolonged neutropenia and a breach in mucosal integrity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatosplenic candidiasis (Fig. 137-2) is manifested by persistent and high spiking fevers in a patient who was previously neutropenic and has now returned to a normal neutrophil count.[10] Right upper quadrant pain, nausea, vomiting, and anorexia may accompany fever.

Patients typically have elevated levels of alkaline phosphatase and less commonly of aminotransferases, bilirubin, and leukocytes. CT, which is the imaging modality of choice, classically shows multiple lucencies representing microabscesses in the liver, spleen, and kidneys. If the CT scan is nondiagnostic but clinical suspicion remains high, magnetic resonance imaging should be performed. A definitive diagnosis is usually made on a liver biopsy specimen that shows multiple granulomas and may show yeast and hyphal forms with special stains. However, biopsy often will not show evidence of infection, especially in cases in which antifungal therapy has been used. Although biopsy is the only means to establish a definitive diagnosis, it often is not required because the clinical, laboratory, and radiographic manifestations of the disease are almost always sufficient to establish a specific diagnosis.

TREATMENT AND PROGNOSIS

The mainstay of therapy is antifungal therapy. In clinically stable patients, oral fluconazole (400 mg orally, daily) can be used. In acutely ill patients a lipid formulation of amphotericin B (3 to 5 mg/kg IV daily) or an echinocandin for several weeks is recommended. The echinocandin options include caspofungin (70 mg loading dose then 50 mg IV daily), anidulafungin (200 mg loading dose then 100 mg IV daily), or micafungin (100 mg IV daily). After several weeks of such therapy, patients can be transitioned to oral fluconazole at 400 mg daily or to voriconazole (6 mg/kg IV q12 hours for first 24 hours, then 3 to 4 mg/kg IV q12 hours or 200 mg orally q12 hours) or posaconazole (IV: 300 mg IV 9 to 12 hours on day 1, then 300 mg IV daily or 300 mg orally 9 to 12 hours on day 1, then 300 mg orally daily) in fluconazole-resistant isolates. Treatment should continue until the lesions resolve on follow-up CT scans, typically within 6 months of treatment. Patients receiving chemotherapy or stem cell transplants are at a higher risk for developing hepatosplenic candidiasis; for this reason, patients who have a history of hepatosplenic candidiasis should be treated prophylactically with fluconazole (400 mg orally, daily) to prevent relapse.

PROGNOSIS

With prolonged treatment with antifungal agents, there has been good success at treating hepatosplenic candidiasis.

OTHER FUNGAL DISEASES

Several additional fungal infections affect the liver, although rarely. *Coccidioides immitis* is often asymptomatic but may lead to fungal hepatitis characterized by increased alkaline phosphatase and the development of hepatic granulomas. Hepatic *Cryptococcus neoformans* infection is rare but has a higher prevalence in patients with acquired immunodeficiency syndrome (AIDS), in whom it typically causes hepatomegaly. In the non–human immunodeficiency virus (HIV)–infected patient, disseminated cryptococcosis less frequently can result in focal granulomatous hepatitis, which may clinically mimic viral hepatitis, or can be manifested as obstructive jaundice secondary to sclerosing cholangitis. *Histoplasma capsulatum* infects individuals who inhale the fungus, but most cases are subclinical. In symptomatic hepatic histoplasmosis, two thirds of patients will present with hepatomegaly, with some showing splenic enlargement as well. On histologic examination, histoplasmosis can cause multiple granulomas diffusely distributed throughout the liver, although a more common finding is portal lymphohistiocytic infiltrate. *Paracoccidioides brasiliensis* most commonly infects adult men, and autopsy series have shown hepatic involvement in up to 50% of patients who die of this infection. Some individuals may present with hepatomegaly or jaundice, although the latter is found in less than 6% of patients. Aminotransferase levels are often elevated in the early stages of the disease; changes in alkaline phosphatase or bilirubin levels tend to occur in the later stages. Biopsy may reveal lesions ranging from small granulomas to diffuse infiltration of yeast forms and fibrosis, often with bile duct involvement. In all of these examples, fungal cultures are necessary to establish a definitive diagnosis.

PARASITIC, PROTOZOAL, AND HELMINTHIC INFECTIONS OF THE LIVER

AMEBIC LIVER ABSCESS

EPIDEMIOLOGY

Entamoeba histolytica is found throughout the world where the barriers between human feces and food and water are inadequate. After malaria, it is the second leading cause of death from parasitic diseases worldwide, accounting for an estimated 40,000 to 100,000 deaths annually. In the United States, most cases of amebiasis arise in immigrants from endemic areas and people living in states that border Mexico.[11] Travelers to endemic areas are also at risk; ingestion of amebic cysts and colonization of the gastrointestinal tract can occur years before the development of a liver abscess. Amebic liver abscesses mainly affect men between the ages of 18 and 50 years but are also more common in postmenopausal women, thereby suggesting a hormonal protective effect. Other risk factors include alcohol intake, human leukocyte antigen (HLA)-DR3, oral and anal sex, and contaminated enema apparatuses.

PATHOBIOLOGY

Entamoeba histolytica has a simple life cycle consisting of the cyst (infectious form) and trophozoite (the motile stage associated with disease); it infects only humans and some nonhuman primates. Cysts are ingested and mature into trophozoites in the intestinal lumen. The development of amebic colitis is not essential for liver abscess formation. *E. histolytica* trophozoites penetrate through the mucosa and submucosal tissues and enter the portal circulation. *E. histolytica* blocks intrahepatic portal venules. When the trophozoites reach the liver, they create their unique abscesses, which are well-circumscribed regions of dead hepatocytes, liquefied cells, and cellular debris that are surrounded by a rim of connective tissue, a few inflammatory cells, and amebic

trophozoites. The adjacent liver parenchyma is unaffected. Given the small numbers of amebae relative to the size of the abscess, it is suggested that *E. histolytica* can cause hepatocyte death without direct contact.

CLINICAL MANIFESTATIONS

Patients can present with amebic liver abscesses months to years after traveling to an endemic area, so a detailed travel history is essential for the diagnosis. The disease should be suspected in patients with an appropriate travel history, fever, right upper quadrant pain, and substantial hepatic tenderness. Jaundice is extremely uncommon. Symptoms are usually acute (<10 days in duration) but can be chronic, with anorexia and weight loss. Patients with acute disease tend to have multifocal disease, whereas patients with a more indolent course tend to have a solitary lesion. Laboratory data tend to demonstrate a leukocytosis without eosinophilia, mild anemia, an elevated alkaline phosphatase level, and a high erythrocyte sedimentation rate.

DIAGNOSIS

Although some individuals with amebic liver abscesses have concurrent amebic colitis, the majority of patients have no bowel symptoms; hence, the results of stool microscopy for *E. histolytica* trophozoites and cysts are usually negative. The diagnosis relies on identification of space-occupying lesions in the liver and a positive amebic serology.[12] Both ultrasound and CT scan are very sensitive (Fig. 137-3), but neither provides absolute specificity for amebic liver abscesses. Serologic testing is highly sensitive (>94%) and specific (>95%). False-negative test results can be obtained within the first 7 to 10 days of infection, but repeat testing will usually be positive. Polymerase chain reaction testing of the abscess aspirate has proved valuable for making the diagnosis in returning travelers. Aspiration of the lesion may be necessary to exclude a primary or secondary bacterial infection.

TREATMENT AND PROGNOSIS

Metronidazole (500 to 750 mg orally three times daily) is usually the first-line treatment. Clinical improvement is often seen within 72 to 96 hours, but treatment should be continued for 7 to 10 days. Tinidazole at 2g daily for 5 days is especially effective and may be better tolerated, in part because of its shorter treatment regimen.[A4] Alternatives include ornidazole (0.5g twice daily for 5 to 10 days) and nitazoxanide (500mg twice daily for 10 days).[A5] Drainage is not necessary, even for large abscesses of 5 to 10cm,[13] except in patients who do not respond within 5 days. The abscess usually will shrink by about 50% within a week, but the mean time to complete radiologic resolution is 3 to 9 months. Repeated imaging in a clinically improving patient may lead to unwarranted concern and unnecessary treatment.

Treatment must also address the removal of all of the cysts from the intestinal lumen in patients with evidence of intraluminal infection. A recommended treatment is iodoquinol (650 mg orally three times a day for 20 days) to prevent continued colonization and possible recurrence of the liver abscess. Alternative regimens for treating intraluminal infection include paromomycin (25 to 30 mg/kg per day orally in three divided doses for 7 days) or diloxanide furoate (500 mg orally three times day for 10 days). The overall mortality rate from amebic abscess is 1 to 3%, whereas it is less than 1% if diagnosed and treated early.

OTHER PROTOZOAL LIVER DISEASES

In addition to *E. histolytica*, other protozoal diseases that affect the liver include *Cryptosporidium* (Chapter 321), *Toxoplasma gondii* (Chapter 320), *Leishmania* (Chapter 319), *Plasmodium* (Chapter 316), and *Babesia microti* (Chapter 324) (Table 137-2).

HELMINTH INFECTIONS

Echinococcosis and Hydatid Cyst Disease

EPIDEMIOLOGY AND PATHOBIOLOGY

Human cystic echinococcosis (Chapter 325) is a zoonosis caused by the larval cestode *Echinococcus granulosus*. It is often referred to as hydatid cyst disease because of the watery cysts that characterize the infection.

The disease remains endemic in sheep-raising areas of the world, including Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand. Dogs are the definitive hosts for *E. granulosus*, and sheep are the major intermediate hosts, although yaks, goats, and camels are other relevant intermediate hosts. Humans are only accidental hosts when they ingest food or water that is fecally contaminated with eggs. Human contact with sheepdogs, which are in frequent contact with livestock, is a major risk for infection.

The disease cycle begins when an adult tapeworm infects the intestinal tract of the definitive host (dogs usually). The adult tapeworm then produces eggs, which are expelled in the host's feces. Intermediate hosts become infected by ingesting the eggs of the parasite in fecally contaminated food. Inside the intermediate host, the eggs hatch and release tiny hooked embryos (called oncospheres), which travel in the blood stream and eventually lodge in the liver, lungs, or kidneys, where they develop into hydatid cysts. Inside these cysts grow thousands of tapeworm larvae, the next stage in the life cycle of the parasite.

CLINICAL MANIFESTATIONS

The initial infection is asymptomatic, but an enlarging hydatid liver cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass. Patients may describe symptoms of mild upper right quadrant pain, urticarial rash, and episodes of pruritus. If the cyst ruptures, serious complications can develop. Cysts that perforate into the peritoneum can lead to the development of extrahepatic cysts and may induce an allergic reaction leading to an increase of eosinophils in the blood, pruritic urticaria, and systemic anaphylaxis. In most cases, however, cysts rupture into bile ducts, which can result in cholestatic jaundice, cholangitis, or biliary pain.

DIAGNOSIS

On ultrasound or CT scans (Fig. 137-4), the hydatid cysts are often large with a flaky appearance that is referred to as hydatid sand.[14] CT imaging also may show multiple daughter cysts or a fluid density cyst with peripheral focal areas of calcification.[15] Fluid is of variable density depending on the amount of proteinaceous debris.

Hydatid cysts of liver can be diagnosed by a serologic assay, the Weinberg reaction, but it can be falsely negative in up to 38% of cases. An enzyme-linked immunosorbent assay may be more sensitive. Eosinophilia is not a feature unless the cyst ruptures; in fact, there usually are no changes in blood chemistries.

TABLE 137-2 PARASITIC INFECTIONS INVOLVING THE LIVER

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS AND ENDEMIC AREAS	MAJOR HEPATIC MANIFESTATIONS	SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
MAJOR PROTOZOA									
Entamoeba histolytica	Ingested cysts develop into invasive trophozoites that colonize the colon and occasionally spread to the liver by the portal blood	Mexico, regions of Central and South America, India, and regions of Africa	Male gender, alcohol intake, HLA-DR3, oral and anal sex, and contaminated enema apparatuses	Amebic liver abscesses develop as a tissue response to trophozoite invasion with acute and chronic manifestations (see text)	Fever, RUQ pain, and substantial hepatic tenderness	Leukocytosis without eosinophilia, mild anemia, elevated serum AP, and high ESR	US, CT, and MRI can detect abscess but cannot always differentiate amebic from pyogenic. On CT or MRI, amebic abscess sometimes appears "cold" with bright rim	Imaging, serology, stool antigen test (microscopic evaluation of stool has a poor yield)	Metronidazole (500-750 mg PO tid × 7-10 days) *or* tinidazole (2 g daily × 5 days); Iodoquinol (650 mg PO tid × 20 days) *or* paromomycin (25-30 mg/kg PO daily in three divided doses × 7 days) *or* diloxanide furoate (500 mg PO tid × 10 days), also needed to eradicate intestinal colonization
OTHER PROTOZOA									
Cryptosporidium spp and microsporidia	Ingested cysts develop into trophozoites in intestinal mucosa	Worldwide distribution	AIDS	Biliary tract infection with obstruction and cholangitis	See Chapter 321	See Chapter 321	See Chapter 321	See Chapter 321	See Chapter 321
Toxoplasma gondii	Ingestion of oocysts in contaminated soil or water or in infected meat; systemic spread of tachyzoites in the circulation	Worldwide distribution	Consumption of undercooked meat, contact with soil, and travel outside the United States, Europe, or Canada	Immunocompetent: asymptomatic or hepatomegaly and mild LFT elevations Immunocompromised: occasional overt hepatitis	See Chapter 320	See Chapter 320	See Chapter 320	See Chapter 320	See Chapter 320
Leishmania spp	Sand fly bite transmits promastigotes; proliferation in the reticuloendothelial system	Worldwide distribution	Children age 10 and younger and immunocompromised adults Contact with sand flies	Hepatosplenomegaly months to years after infection	See Chapter 319	See Chapter 319	See Chapter 319	See Chapter 319	See Chapter 319
Plasmodium spp	Mosquito (*Anopheles*) bite transmits sporozoites	Multiple regions throughout the world	Exposure to anopheline mosquito bites	Proliferation in hepatocytes causes hepatomegaly, enzyme elevations, and jaundice	See Chapter 316	See Chapter 316	See Chapter 316	See Chapter 316	See Chapter 316
Babesia microti	Tick bite transmits the agent, which parasitizes erythrocytes	Europe	Asplenia is a risk for fatal hepatic failure, especially bovine babesiosis	Mild liver enzyme elevations	See Chapter 324	See Chapter 324	See Chapter 324	See Chapter 324	See Chapter 324
MAJOR HELMINTHS									
Schistosoma spp	Cercaria in fresh water penetrate the skin, travel by the circulation to portal vein radicals	*S. mansoni* found in South America, Africa, and Middle East *S. japonicum* found in Far East (mostly China and Philippines)	Contact with fresh water containing cercaria of schistosomes	Progressive presinusoidal blood flow obstruction, periportal fibrosis, portal hypertension, varices, ascites, splenomegaly	Initial infection presents as itching; later presentations include fever, diarrhea, chills, headaches, or hives Hematemesis from ruptured gastroesophageal varices	Eosinophilia and splenomegaly Seroconversion occurs within 4-6 weeks	Extensive calcification with typical "turtle-back" appearance along portal tracts	Rectal biopsy, liver biopsy, microscopic examination of stool	Praziquantel (single dose of 40 mg/kg for *S. haematobium*, *S. mansoni*, or *S. intercalatum* infections; two divided doses of 60 mg/kg for *S. japonicum* or *S. mekongi* infections) with a second dose 6-12 weeks later if necessary

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

Echinococcus granulosus	Eggs of small (3-7 mm) tapeworms in stool of canid hosts; ingested eggs produce larval oncospheres that migrate to the liver and form cysts in sheep, humans, and other intermediate hosts	Worldwide distribution, found especially in sheep-raising areas (Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand)	Ingestion of food or water fecally contaminated with eggs and human contact with sheepdogs	Initial infection asymptomatic Liver cysts increase in diameter by 1-5 cm yearly and cause variable abdominal pain, hepatomegaly, and variable eosinophilia Occasional cyst rupture, secondary bacterial infection	Enlarged hydatid cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass Mild RUQ pain, urticaria, and episodes of pruritus	Positive Weinberg reaction (false-negative reaction in 38% of cases) or ELISA analysis Eosinophilia seen in ruptured cysts	On US or CT, cysts appear flaky, sometimes showing daughter cysts or peripheral focal calcification; fluid is of variable density	Imaging, Weinberg reaction, or ELISA	Albendazole (15 mg/kg/day, divided into two doses, up to maximum 400 mg, PO bid × 1-3 months; up to 6 months if necessary); cysts without daughter cysts can be drained percutaneously; complicated cysts, including those communicating with the biliary tree, often require surgical treatment
Echinococcus multilocularis	Eggs of small tapeworms in stool of foxes; ingested eggs produce oncospheres in the liver of rodents, humans, and other intermediate hosts	Endemic in Northern hemisphere	Human exposure increasing with growing fox populations	Metacestodes colonize the liver as a tumor-like mass of small vesicles	See Chapter 325	See Chapter 325	See Chapter 325	See Chapter 325	See Chapter 325
Fasciola spp	Leaf-shaped flukes up to 13 × 30 mm derived from ingested cysts; the fluke excysts in the duodenum, migrates directly across the bowel wall into the peritoneal cavity, and burrows directly into the liver (or occasionally out to the skin)	Worldwide distribution	Consumption of freshwater or aquatic plants contaminated by colonized livestock	Adult flukes live in the common and hepatic bile ducts, causing obstruction that leads to thickening of the ducts, dilation, and fibrosis of the proximal biliary tree	Acute: fever, abdominal pain, eosinophilia Chronic: symptomatic biliary obstruction, variable eosinophilia	Serologic tests include hemagglutination, complement fixation, ELISA, and counterimmunoelectrophoresis. Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia are often seen	CT is most useful: liver shows hypodense nodules or tortuous tracks; thickening of the liver capsule, subcapsular hematoma, and parenchymal calcification may also be seen	Serology, stool examination	Triclabendazole, 10 mg/kg PO once or twice
Opisthorchis spp and *Clonorchis sinensis*	Flukes of 8-25 mm derived from ingested cysts; the fluke excysts in the duodenum and migrates into the bile ducts	*Opisthorchis* spp: Southeast Asia, central and eastern Europe (particularly Siberia) *C. sinensis:* China, Japan, Vietnam, and Korea	Consumption of raw, pickled, dried, smoked, or salted freshwater fish or crayfish originating from East Asia or, in the case of *Opisthorchis felineus*, Russia and Eastern Europe	Acute: typically asymptomatic Chronic: abdominal pain, fever, anorexia, tender hepatomegaly, sometimes eosinophilia Late sequelae: intermittent biliary obstruction, cholelithiasis, cholecystitis, cholangitis, secondary bacterial abscesses, cholangiocarcinoma	Chronic infection presents as dyspepsia, abdominal pain, diarrhea, nausea, vomiting, anorexia, weight loss, fevers, hepatomegaly, and urticaria Acute presentation includes serum sickness, intrahepatic pigment stones, and facial edema Other rare complications are cholangitis, pancreatitis, and obstructive jaundice	Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia	US may detect flukes in biliary tree CT shows small hypodense nodules	Serology and stool examination	Praziquantel, 25 mg/kg/day PO tid × 2 days

without permission. Copyright ©2023. Elsevier Inc. All rights reserved.

TABLE 137-2 PARASITIC INFECTIONS INVOLVING THE LIVER—cont'd

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS AND ENDEMIC AREAS	MAJOR HEPATIC MANIFESTATIONS	SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Toxocara spp	Nematode infection disseminates to cause visceral larva migrans after ingestion of soil contaminated with dog or cat feces	Highest prevalence in southeastern United States	Consumption of food contaminated with soil containing eggs; distributed throughout the United States	Often an asymptomatic cause of eosinophilia (exclude *Trichinella, Strongyloides*, filaria, hookworm, schistosomiasis) Hepatomegaly is common, but nonhepatic manifestations dominate the clinical picture	See Chapter 327	See Chapter 327	See Chapter 327	See Chapter 327	See Chapter 327
OTHER HELMINTHS									
Ascaris lumbricoides	Ingested eggs develop into larvae that migrate to the lungs and are coughed and swallowed; develop into roundworms 15-30 mm long in the small intestine	Global distribution with higher prevalence in Africa, South America, India, and the Far East; 20% of the world's population is colonized	Consumption of fecally contaminated food or water, particularly in young children	Colonization is typically asymptomatic with eosinophilia Biliary migration of worms can cause symptomatic biliary obstruction, cholangitis, cholecystitis, and secondary bacterial liver abscess	Sensitized patients during pulmonary phase present with asthma-like symptoms, hemoptysis, chest pain, and cyanosis Urticaria and other allergic reactions sometimes seen Patients in intestinal phase show cognitive and nutritional impairment with abdominal pain, hepatomegaly, cholangitis, and obstructive jaundice	Leukocytosis with eosinophilia Hyperbilirubinemia occasionally seen	Movement of the worms within the biliary tree can sometimes be observed A "bull's-eye" appearance can be seen on cross-sectional imaging	Stool examination, imaging, and ERCP (Video 137-1)	Albendazole, 400 mg PO once
Capillaria hepatica	Ingested eggs develop into larvae in the intestinal mucosa; larvae migrate to the liver by portal blood flow and develop into short-lived roundworms	Human infection is rare	Consumption of food contaminated with rodent feces	Fever, eosinophilia, and hepatomegaly; subsequent foci of liver fibrosis, granulomas, and calcification in involved areas	Persistent fever, eosinophilia, and hepatomegaly most common Splenomegaly, anorexia, nausea, vomiting, night sweats, and altered bowel habits also seen	Anemia, eosinophilia, moderately elevated liver enzymes, increased ESR, and hypergammaglobulinemia	US shows nonspecific hyperechoic areas in the portal spaces	Stool and liver biopsy	Mebendazole, 200 mg PO bid × 20 days
Strongyloides stercoralis	Ingested eggs develop into 1.5- to 2.5-mm nematodes that invade the hepatic vasculature, lymphatics, and biliary tract	Tropical and subtropical areas including southeast United States and southern and eastern Europe	Consumption of food contaminated with soil containing eggs, infection with HTLV-1, and immunocompromised individuals	Hepatic disease in the setting of immunosuppression: jaundice, abdominal pain; eosinophilia is uncommon	Recurrent urticaria, abdominal pain, diarrhea, and cough; mild jaundice and hepatomegaly in the absence of splenomegaly	Eosinophilia and hypoalbuminemia Patients may have elevated liver enzymes	Imaging studies not used in diagnosis	Serology and stool examination	Ivermectin (single dose, 200 µg/kg orally × 1-2 days) or Albendazole (400 mg PO bid × 7 days)

AIDS = acquired immunodeficiency syndrome; AP = alkaline phosphatase; bid = twice daily; CT = computed tomography; ELISA = enzyme-linked immunosorbent assay; ERCP = endoscopic retrograde cholangiopancreatography; ESR = erythrocyte sedimentation rate; HLA = human leukocyte antigen; HTLV = human T-cell lymphotropic virus; LFT = liver function test; MRI = magnetic resonance imaging; PO = orally; RUQ = right upper quadrant; spp = species; tid = three times daily; US = ultrasonography.

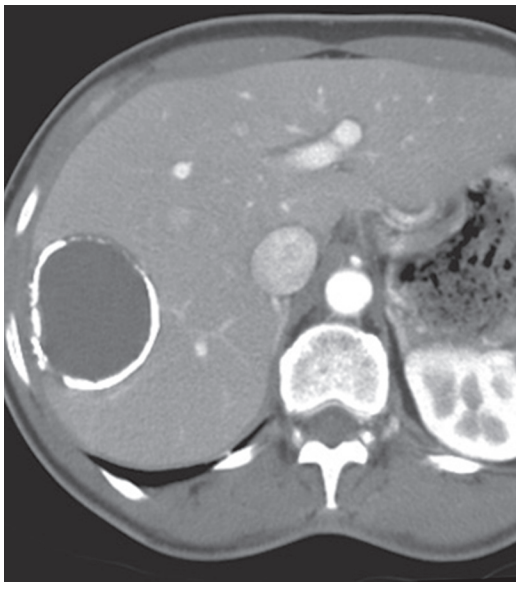

FIGURE 137-4. Computed tomographic scan of a hepatic echinococcal cyst. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

TREATMENT AND PROGNOSIS

Uncomplicated, asymptomatic, inactive cysts can be observed without treatment.[16] Otherwise, however, drug therapy includes the antiparasitic agent albendazole (15 mg/kg/day, divided into two doses, to a maximum 400 mg orally twice daily) for 1 to 3 months, although a 6-month duration has also been used.[17] However, treatment with albendazole alone is not effective, so drainage is essential to the effective treatment of hydatid cysts. Cysts without daughter cysts can be drained percutaneously. Percutaneous drainage consisting of puncture and aspiration, followed by injection and reaspiration of a scolicidal solution is better than needle aspiration[A6] and has fewer side effects than open drainage, provided that patients receive concomitant antihelminthic therapy, such as albendazole starting 1 week before surgery and continuing 4 weeks postoperatively to minimize risk of secondary echinococcosis in the event of spillage. Chlorhexidine, hydrogen peroxide, 80% alcohol, or 0.5% cetrimide are preferred scolicidal agents rather than hypertonic saline or formalin.

Complicated cysts, however, typically require surgery. For example, if the cyst communicates with the biliary tree, injection of scolicidal agents carries an almost universal risk of secondary sclerosing cholangitis and is contraindicated. In such cases, the cyst must be treated surgically, either by cystectomy or hepatic resection.

The prognosis is generally good, with complete cure expected after successful percutaneous or surgical treatment. However, spillage occurs in 2 to 25% of cases, depending on the location of the cyst and the surgeon's experience. The operative mortality rate varies from 0.5 to 4% for the same reasons.

Schistosomiasis

EPIDEMIOLOGY AND PATHOBIOLOGY

Schistosomiasis is an infection of trematodes. *Schistosoma* (Chapter 326) cause periportal fibrosis and liver cirrhosis owing to deposition of eggs in the small portal venules.[18] *S. mansoni* and *S. japonicum* lead to liver disease. Infection with *S. mansoni* is found in parts of South America, Africa, and the Middle East. Infection with *S. japonicum* is found in the Far East, mostly China and the Philippines. Although primary infection does not occur in the United States, 5% of the world's population (200 million people) may be infected, thereby making it a major international health concern and highly prevalent in immigrants.

Humans become infected after contact with water that contains the infective stage (cercaria) of *schistosomes*. After penetration of the skin, the larvae migrate to the lungs and then to the venules of the mesentery, urinary bladder, or ureters. They release eggs in the venules of the mesentery, and the eggs enter the liver through the portal vein, where they become lodged in the terminal branches of the portal venules. The lodged eggs cause a granulomatous inflammation, and the lesions heal by periportal fibrosis. *S. japonicum* is more virulent than *S. mansoni* because its infections produce 10 times more eggs. Hepatic fibrosis may be independent of parasite burden related primarily to the host's inflammatory response.[19]

CLINICAL MANIFESTATIONS

Initial infection is manifested as itching that is caused by skin penetration by larvae. Several weeks later, patients may complain of fever, diarrhea, chills, headaches, or hives. At this time, patients will have eosinophilia. During the next 5 to 15 years, periportal liver fibrosis develops and leads to presinusoidal portal hypertension, splenomegaly (Chapter 154), and gastroesophageal varices (Chapter 124). With *S. japonicum*, however, the progression can be much more rapid, with little interval between the acute and chronic disease. Hepatic function is generally well preserved, and patients generally present with hematemesis from ruptured gastroesophageal varices.

DIAGNOSIS

Schistosomal eggs typically have lateral or terminal spines and are easy to detect on microscopic examination of feces or on a rectal biopsy specimen. Seroconversion occurs within 4 to 8 weeks of infection but cannot distinguish active infection from a history of exposure. Newer, more sensitive and specific molecular and immunodiagnostic techniques (including polymerase chain reaction–enzyme-linked immunosorbent assay systems) for detection of schistosome DNA in feces or serum and plasma have the potential to diagnose schistosomiasis in all stages of clinical disease, not only when the adult worms are producing eggs. Imaging may show extensive calcification with the typical "turtle-back" appearance along the portal tracts reflecting the clustered, calcified eggs along the portal triads. Ultrasound can assess the degree of periportal fibrosis.[20,21] Liver biopsy may demonstrate an egg of *S. mansoni* along with intense granulomatous change in the portal tract (E-Fig. 137-1).

TREATMENT AND PROGNOSIS

Praziquantel (a single dose of 40 mg/kg for *S. haematobium, S. mansoni*, or *S. intercalatum* infections; two divided doses of 60 mg/kg for *S. japonicum* or *S. mekongi* infections), which is the preferred treatment, is effective in 70 to 100% of cases. However, a second dose can be given 6 to 12 weeks later, particularly in patients with eosinophilia, high antibody titers, or persistent symptoms. Despite treatment, 5 to 20% of patients develop significant hepatic fibrosis. Treatment of portal hypertension may be necessary. The mortality is 0.05% with heavy *S. mansoni* infection and 1.8% for severe *S. japonicum* infection. Bleeding from esophageal varices is the most serious complication. Chronic infection can lead to hepatocellular carcinoma.

GRANULOMATOUS DISEASES OF THE LIVER

Granulomas, which are found in up to 15% of liver biopsies, can be an incidental finding or may represent a wide array of liver diseases (Table 137-3). A granuloma is an accumulation of epithelioid cells, including transformed macrophages, mononuclear cells, and other inflammatory cells. Granulomas may have associated necrosis (caseating), as in tuberculosis (Chapter 299), or may be non-necrotizing (noncaseating), as in sarcoidosis (Chapter 83). In addition, fibrin-ring granulomas are characterized by a vacuole encircled by a ring of fibrinoid necrosis and surrounded by lymphocytes and histiocytes, as seen in Q fever.

An incidental granuloma requires minimal further evaluation. Tuberculosis should be excluded. Sarcoidosis also should be considered because it is the most common cause of granulomas in the United States. An antimitochondrial antibody should be obtained to exclude primary biliary cirrhosis (Chapter 139). The use of potentially causative drugs should be stopped (see Table 137-3).

SARCOIDOSIS

Sarcoidosis (Chapter 83), which is the most frequently identified cause of hepatic granuloma in the United States, affects all racial and ethnic groups and occurs at all ages. In patients with sarcoidosis, the liver is the third most commonly involved organ, after the lymph nodes and lung; approximately 20 to 30% of patients with sarcoidosis have noncaseating granulomas on liver biopsy.[22] The classic granuloma is found mainly in the portal triads, with a cluster of large epithelioid cells and often with multinucleated giant cells.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatic involvement of sarcoidosis is often subclinical, and only a minority of patients will present with pruritus, fever, abdominal pain, hepatomegaly,

TABLE 137-3 CAUSES OF GRANULOMATOUS LIVER DISEASE

DIAGNOSIS	SPECIAL AND UNIQUE FEATURES
Sarcoidosis	Evidence of pulmonary sarcoidosis, granulomas found on biopsy of other organs, elevated ACE level
Bacterial infections	
Mycobacterium tuberculosis	Caseating granulomas on biopsy, positive PPD response or interferon-gamma release assay, active pulmonary tuberculosis
Other mycobacteria *(M. avium-intracellulare, M. leprae, M. mucogenicum, M. bovis)*	HIV, exposure history
Other bacteria (brucellosis, listeriosis, melioidosis, tularemia, yersiniosis, Bartonellosis, Q fever, syphilis, psittacosis)	Fever, exposure history
Viral infections (cytomegalovirus, Epstein-Barr virus, hepatitis C, hepatitis B, hepatitis A)	Serology for acute or recent exposure
Fungal infections (histoplasmosis, coccidioidomycosis, blastomycosis, nocardiosis, candidiasis)	Fever, immunocompromised
Parasitic infections (schistosomiasis, *Ascaris lumbricoides*, toxoplasmosis, visceral leishmaniasis)	Travel to endemic regions, positive serologic testing
Primary biliary cirrhosis	Female sex, positive AMA, elevated IgM
Malignant diseases (Hodgkin disease, non-Hodgkin lymphoma, renal cell carcinoma)	Evidence of malignant disease in kidney or bone marrow
Drug reactions (allopurinol, chlorpropamide, phenylbutazone, sulfonamides, carbamazepine, glyburide, quinidine, quinine, diltiazem, hydralazine, rosiglitazone, phenytoin, methyldopa, procainamide, amoxicillin-clavulanic acid, mebendazole, mesalamine, acetaminophen, pyrazinamide, halothane, isoniazid, norfloxacin)	Exposure history
Toxins (beryllium, copper sulfate, Thorotrast)	Previous exposure history
Miscellaneous (talc, Crohn disease, granulomatosis with polyangiitis [formerly Wegener granulomatosis], post-jejunoileal bypass, mineral oil lipogranulomas, hepatic allograft rejection, chronic granulomatous disease)	History of IV drug use, history of liver transplantation, diarrhea

ACE = angiotensin-converting enzyme; AMA = antimitochondrial antibody; HIV = human immunodeficiency virus; IgM = immunoglobulin M; IV = intravenous; PPD = purified protein derivative.

cholestatic jaundice, or portal hypertension.[23] In some patients, the granulomatous injury and destruction of the interlobular bile ducts eventually cause ductopenia and a histologic picture similar to primary biliary cirrhosis (Chapter 141). In other patients, damage to the large bile ducts may lead to a syndrome that mimics primary sclerosing cholangitis (Chapter 141). Other patients may present with focal liver lesions suggestive of malignant neoplasm.

Patients typically have a marked elevation of the serum alkaline phosphatase level. Angiotensin-converting enzyme (ACE) levels also are characteristically elevated but may not be helpful in differentiating sarcoidosis from other chronic liver diseases, such as primary biliary cirrhosis, in which it also may be elevated. The presence of noncaseating granulomas in a patient with clinically suspected sarcoidosis generally establishes the diagnosis. However, granulomas do not correlate with liver function test results or duration of disease.

TREATMENT AND PROGNOSIS

In general, hepatic sarcoidosis does not need to be treated except in patients with other indications for treatment (Chapter 83). Corticosteroids improve liver function test results but do not alleviate portal hypertension, and serial biopsies often show little improvement. Other therapies used in uncontrolled studies include ursodeoxycholic acid, methotrexate, and azathioprine.[24] Sarcoidosis that leads to portal hypertension and fibrosis may ultimately require liver transplantation (Chapter 140), although sarcoidosis may recur in the new organ.

OTHER GRANULOMATOUS LIVER DISEASES

In addition to sarcoidosis, another major cause of granulomatous liver disease is tuberculosis (Chapter 299). Miliary tuberculosis, caused by *Mycobacterium tuberculosis*, commonly results in hepatic granulomas, and patients present with hepatomegaly, abnormal liver function test results, or both. A biopsy revealing caseating granulomas along with a positive PPD (purified protein derivative) response and active pulmonary tuberculosis can help in establishing a diagnosis. Other mycobacteria are also known to cause granulomatous liver disease including *M. avium intracellulare*, *M. genavense*, and *M. scrofulaceum* (Chapter 300).

Other causes of granulomatous liver disease include zoonotic infections such as cat-scratch disease (Chapter 291), Q fever (Chapter 302), and brucellosis (Chapter 286). Cat-scratch disease, which primarily affects children, is caused by *Bartonella henselae*, with cats serving as the main reservoir for the organism. Patients typically present with lymphadenopathy associated with persistent pyrexia of unknown origin, abdominal pain, and weight loss. *B. henselae* can be identified by a Warthin-Starry stain or an imaging study may demonstrate scattered defects in the liver. Q fever is caused by the intracellular gram-negative rickettsial organism *Coxiella burnetii*. Most infections are asymptomatic, but may have self-limited influenza-like symptoms, pneumonia, and hepatitis. A liver biopsy may demonstrate fibrin-ring granulomas (doughnut shaped) in the background of nonspecific reactive hepatitis and steatosis. Brucellosis, which is not common in the United States, is caused by at least four species of *Brucella: B. abortus*, *B. suis*, *B. melitensis*, and *B. canis*. The disease is manifested as recurrent high fevers, drenching sweats, malaise, arthralgia, fatigue, abdominal pain, anorexia, and headaches. Patients often have hepatomegaly. Hepatic biochemical abnormalities are nonspecific and show elevated serum levels of aminotransferases and alkaline phosphatase. The granulomas formed by this infection are typically smaller than those caused by sarcoidosis or tuberculosis, and a definitive diagnosis can be established by serologic testing.

It is important to keep in mind that hepatic granulomas are formed naturally as a consequence of the immune response, so they may be seen in infections with hepatic involvement. Many of the diseases noted above can manifest as granulomatous liver disease (see Table 137-3): listeriosis (Chapter 272), yersiniosis (Chapter 288), candidiasis (Chapter 310), histoplasmosis (Chapter 308), coccidioidomycosis (Chapter 308), and schistosomiasis (Chapter 326). Viral infections (e.g., cytomegalovirus, hepatitis A, hepatitis B, and hepatitis C), primary biliary cirrhosis (Chapter 139), malignancies, and certain drug reactions (Chapter 136) have all been etiologically linked to granulomatous liver disease.

138 ALCOHOLIC AND NONALCOHOLIC STEATOHEPATITIS

NAGA P. CHALASANI AND JACQUELYN MAHER

Alcohol-associated liver disease and nonalcoholic fatty liver disease (NAFLD), which represent two of the most common forms of liver disease, can lead to cirrhosis, liver cancer, liver failure, and death. Although these two conditions have different risk factors and natural histories, in both conditions (Table 138-1) the hepatocytes are characterized by macrovesicular steatosis, which is the accumulation of triglycerides as one large cytoplasmic globule that displaces the nucleus. In microvesicular steatosis, cytoplasmic accumulation of fat occurs as multiple small globules with a central (intact) nucleus.

ALCOHOL-ASSOCIATED LIVER DISEASE

DEFINITION

Excessive alcohol consumption (Chapter 364) causes alcohol-associated liver disease and can significantly worsen other liver disorders, such as viral hepatitis (Chapter 135) and hemochromatosis (Chapter 196). Although most individuals who consume alcohol do not consume it excessively and do not develop any physical or social consequences, some alcoholics consume sufficient alcohol and, presumably because of other predisposing factors, develop alcohol-associated liver disease. Alcohol-associated liver disease is a spectrum of chronic liver diseases ranging from alcoholic fatty liver to acute alcoholic hepatitis and cirrhosis.

Alcohol-associated fatty liver disease will develop in nearly 90% of individuals who consume alcohol heavily (on average, >6 drinks per day), but only a subset of individuals develop the severe conditions of alcoholic hepatitis and alcohol-associated cirrhosis. Genetic predisposition and environmental factors are likely to play a role in the pathogenesis of acute alcoholic hepatitis and alcohol-associated cirrhosis, but such factors have not been well defined. Nearly 50% of the patients with alcoholic hepatitis have preexisting cirrhosis (Chapter 139), and individuals who do not yet have cirrhosis are at high risk for its development, especially if they continue to consume alcohol.

EPIDEMIOLOGY

The true prevalence of alcoholic liver disease is not known, but nearly 1% of North American adults are thought to have alcohol-associated liver disease. Among individuals with alcohol use disorder, the prevalence of alcohol-associated liver disease is about 12%.[1] Even these figures are considered underestimates, however, because milder forms of alcohol-associated liver disease are not associated with symptoms and often are unrecognized. Alcohol-associated liver disease accounts for about 50% of deaths from cirrhosis and 40 to 45% of all deaths from liver disease. Over the last decade, alcohol-associated liver disease was the primary cause of almost one third of liver transplants (Chapter 140) in the United States, thereby replacing hepatitis C virus infection as the leading cause of liver transplantation in the United States. Based on an increase in the frequency of alcohol consumption, especially high-risk drinking, the incidence of alcoholic liver disease in the U.S. population is likely to increase significantly in the future.

PATHOBIOLOGY

The mechanisms underlying alcoholic liver injury can be broadly categorized into those caused by the effects of alcohol directly on hepatocytes and those caused by the effects mediated by Kupffer cells. The hepatocyte-specific mechanisms include the altered redox state induced by alcohol and aldehyde dehydrogenase reactions; the oxidative stress and lipid peroxidation caused by the induction of CYP2E1 enzymes and the mitochondrial electron transfer system; the effects of alcohol upon the nuclear transcription factors AMP kinase and SREBP-1c; protein adduct formation; and altered methionine and folate metabolism with resulting stress on the endoplasmic reticulum. Chronic alcohol consumption increases gut permeability, and the resulting portal endotoxemia activates Kupffer cells. Activated Kupffer cells release a number of proinflammatory mediators. These include tumor necrosis factor-α (TNF-α); transforming growth factor-β1; interleukins 1, 6, 8, and 10; and platelet-derived growth factor. TNF-α has a plethora of biologic effects and causes hepatocyte apoptosis, whereas transforming growth factor-β1 and platelet-derived growth factor play important roles in stellate cell activation, collagen production, and hepatic fibrosis.

Of the known risk factors for the development of alcohol-associated liver disease (Table 138-2), the amount of alcohol consumed is the single most important. For unclear reasons, only 30 to 35% of individuals with heavy and long-term drinking develop alcoholic hepatitis, and fewer than 20% develop cirrhosis. Women are at higher risk; for example, the risk of alcoholic cirrhosis increases after 10 years of alcohol consumption at quantities of more than 60 to 80 g/day in men, whereas in women, it can develop at quantities of only more than 20 g/day. Moreover, the peak incidence of alcohol-associated liver disease in women is approximately a decade earlier than in men. The type of alcoholic beverage consumed may not be as critical, but "spirits" and beer may be more hepatotoxic than wine. Hispanics and American Indians may be predisposed to more significant alcoholic liver injury. Both obesity and protein-calorie malnutrition, in which micronutrients and antioxidant capacity are diminished, also are important predispositions.

Polymorphisms in genes associated with lipid metabolism (*PNPLA3* and *HSD17B13*), alcohol metabolism (alcohol and aldehyde dehydrogenases and cytochrome P-450 enzymes), and dysregulated cytokine production (e.g., *TNF*) may influence susceptibility to alcohol-related liver injury. Candidate genes impacting alcohol-related cirrhosis include *PNPLA3, HSD17B13 TM6SF2* , and *MBOAT7, MARC1* , and *HNRNPUL1*.[2] In patients with other forms of chronic liver disease (e.g., viral hepatitis B or C), concomitant alcohol consumption significantly aggravates liver injury.

CLINICAL MANIFESTATIONS

Patients with alcohol-associated liver disease may have signs and symptoms from underlying alcoholism as well as those caused by liver disease. Stigmata of chronic alcoholism include palmar erythema (see Fig. 132-2), spider nevi, bilateral gynecomastia, testicular atrophy, bilateral parotid enlargement, and Dupuytren contractures (Fig. 138-1). The clinical features of liver disease will depend on the stage of alcohol-associated liver disease, that is, whether a patient has fatty liver or more advanced liver disease, such as alcoholic hepatitis and cirrhosis.

Patients with alcohol-associated fatty liver disease are generally asymptomatic, but some patients may have anorexia, fatigue, right upper quadrant discomfort, and tender hepatomegaly. These patients also may have biochemical

TABLE 138-1 COMMON CAUSES OF MACROVESICULAR AND MICROVESICULAR STEATOSIS

MACROVESICULAR STEATOSIS	MICROVESICULAR STEATOSIS
Obesity, type 2 diabetes, metabolic syndrome, and dyslipidemia (nonalcoholic fatty liver disease)	Reye syndrome
Excessive alcohol consumption	Medications (valproate, antiretroviral medicines, intravenous tetracycline)
Hepatitis C (genotype 3)	Heat stroke
Wilson disease	Acute fatty liver of pregnancy
Lipodystrophy starvation	HELLP syndrome
Jejunoileal bypass	Inborn errors of metabolism (lecithin–cholesterol acyltransferase deficiency, cholesterol ester storage disease, Wolman disease)
Parenteral nutrition	
Medications (amiodarone, methotrexate, tamoxifen, corticosteroids, antipsychotics)	

HELLP = *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets.

MINOR	**MINOR**
Type of beverage	Polycystic ovary syndrome
Binge drinking	Hypothyroidism
Obesity	Obstructive sleep apnea
Hispanic ethnicity	Hypopituitarism
	Hypogonadism

ABSTRACT

Nonalcoholic and alcoholic fatty liver diseases are common chronic liver diseases that can lead to cirrhosis, liver failure, and liver cancer. Alcohol-associated liver disease comprises a spectrum ranging from alcoholic fatty liver to alcoholic hepatitis, alcohol-associated cirrhosis, and related liver failure and cancer. Heavy drinking is obviously the most important risk factor, although malnutrition and genetic factors may play a role in the disease progression and decompensation. Abstinence from drinking is the most important therapeutic option. For nonalcoholic fatty liver disease, the spectrum ranges from fatty liver to steatohepatitis and related cirrhosis, to liver failure, and to cancer. Obesity, type 2 diabetes, and dyslipidemia are the most important risk factors. Weight loss, vitamin E (800 IU/day), and pioglitazone (30 mg/day) are useful treatments.

KEYWORDS

alcoholic hepatitis
alcoholic fatty liver

FIGURE 138-1. Dupuytren contracture. (From Gudmundsson KG, Jonsson T, Arngrimsson R. Guillaume Dupuytren and finger contractures. *Lancet*. 2003;362:165-168.)

evidence of alcoholism and alcohol-associated liver disease with macrocytosis as well as elevated levels of aspartate aminotransferase (AST) and γ-glutamyl transpeptidase. Patients with alcohol-associated fatty liver typically do not have jaundice, ascites, or splenomegaly.

Patients with alcoholic hepatitis may have a more dramatic presentation with severe malaise, fatigue, anorexia, fever, evidence of protein-calorie malnutrition, and features of decompensated liver disease, including jaundice, coagulopathy, ascites, and encephalopathy. However, these classic features are not universally present. Physical examination invariably shows at least some features of chronic alcoholism, and jaundice (see Fig. 132-1), ascites (see Fig. 132-4), and splenomegaly are common. The laboratory examination findings are typically abnormal. Common hematologic abnormalities include leukocytosis with neutrophil predominance, macrocytic anemia (Chapter 150), thrombocytopenia (Chapter 158), and prolonged prothrombin time. Liver biochemistries (Chapter 133) are abnormal with an elevated AST and ratio of AST to alanine aminotransferase (ALT), alkaline phosphatase, γ-glutamyl transpeptidase, and total bilirubin but decreased levels of serum albumin. The AST rarely exceeds 300 IU/L. Serum electrolyte abnormalities, including hypokalemia (Chapter 103), hypomagnesemia (Chapter 105), hypocalcemia (Chapter 227), and hypophosphatemia (Chapter 105), are frequent. Patients with alcoholic cirrhosis have the same clinical features that are common to other types of cirrhosis (Chapter 139) but also with striking features of underlying chronic alcoholism, including gynecomastia in males and significant muscle wasting.

DIAGNOSIS

The diagnosis of alcohol-associated liver disease strongly depends on the history of excessive alcohol consumption and the presence of liver disease.[3,4] Although laboratory abnormalities are not specific for alcohol-associated liver disease, they can be suggestive in the context of excessive alcohol consumption. An AST/ALT ratio of greater than 2 is typical in alcohol-associated liver disease, and ALT values greater than 150 to 200 IU/L are very rare in alcohol-associated liver disease. Serology testing for coexisting chronic viral hepatitis (Chapter 135) is critical. Diagnostic dilemmas arise when a patient denies excessive alcohol consumption in the face of clinical features that are suggestive of alcohol-associated liver disease. Interviewing family members about specific alcohol consumption may be helpful in the accurate ascertainment of alcohol consumption. Serum and urinary levels of ethyl glucuronide and ethyl sulfate are sensitive and specific markers of recent alcohol consumption, but they are not commonly measured in clinical practice. Hepatic imaging by ultrasound, computed tomography, or magnetic resonance imaging will show changes consistent with hepatic steatosis or more advanced forms of liver disease, such as cirrhosis and portal hypertension. Imaging is also important to exclude other forms of liver disease, including malignant disease and biliary obstruction. Imaging findings suggestive of alcohol-associated liver disease include an enlarged caudate lobe, greater visualization of the right posterior hepatic notch, and focal fat sparing or geographic fat distribution.

Because specific treatments for heavy alcohol drinking and alcohol-associated hepatitis may be harmful in patients with other liver diseases, it is important to exclude other predominant or coexisting liver diseases, including chronic viral hepatitis (Chapter 135) and drug-induced liver injury, especially from acetaminophen (Chapter 136), by history, blood tests, and biopsy if needed. Hyperferritinemia generally reflects an acute phase reactant, rather than an iron overload disorder, so it usually will return to normal when the acute liver injury resolves.

Liver biopsy is the key to distinguishing alcohol-associated liver disease from other entities, characterizing the nature of the liver disease, and determining whether a patient has fatty liver or more advanced alcoholic hepatitis. Histologic features of alcohol-associated fatty liver include macrovesicular steatosis that is predominantly centrilobular (zone 3) in nature. In alcoholic hepatitis, the biopsy is more striking and reveals macrovesicular steatosis, lobular neutrophilic infiltration, Mallory hyaline, ballooning degeneration of the hepatocytes, and perivenular fibrosis. In general, patients with alcoholic hepatitis also have histologic evidence of chronic liver injury in the form of more advanced fibrosis (periportal or bridging fibrosis or cirrhosis).

TREATMENT

Total abstinence, which is the most important treatment measure, is mandatory for the improvement of the clinical and histologic features of alcohol-associated liver disease. Its benefits are unequivocal, even in patients with severe decompensation. However, long-term abstinence is difficult to achieve, so a multidisciplinary approach with counseling and medications that promote abstinence should be considered. Disulfiram is not commonly used because of its poor tolerability and hepatotoxicity. Opioid antagonists, such as naltrexone (50 mg/day for up to 6 months or even longer), nalmefene (20 mg/day as maintenance), and acamprosate (333-mg tablets, two tablets three times each day for 1 year), can help promote abstinence when they are used as part of a multidisciplinary approach.

Alcohol-associated fatty liver disease requires no specific treatment other than abstinence. Patients with alcoholic hepatitis, however, have increased short- and long-term mortality and should be considered for therapeutic interventions in addition to mandatory abstinence.[5,6] If a patient's clinical manifestations and/or liver biopsy findings are consistent with alcoholic hepatitis and there is no evidence of other inflammatory liver diseases, such as hepatitis C (Chapter 135), prednisolone (40 mg/day for 4 weeks) should be given to carefully selected patients[7] with severe alcoholic hepatitis who have a score higher than 32 on the Maddrey discriminant function (4.6 × [patient's prothrombin time − control prothrombin time] + total bilirubin level) and encephalopathy but do not have gastrointestinal bleeding or systemic infection. Studies have suggested that a Model for End-Stage Liver Disease (MELD) score (see Table 139-2) higher than 21 can substitute for the Maddrey score to guide the use of prednisolone. Such therapy appears to reduce mortality at 1 month,[A1] but probably not thereafter.[A2] Adding intravenous *N*-acetylcysteine (on day 1 at a dose of 150, 50, and 100 mg/kg of body weight in 250, 500, and 1000 mL of 5% glucose solution during a period of 30 minutes, 4 hours, and 16 hours, respectively; and on days 2 through 5, 100 mg/kg/day in 1000 mL of 5% glucose solution) to prednisolone appears to be superior to prednisolone alone in terms of a significantly lower mortality at 1 month and a somewhat but not significantly lower mortality at 6 months.[A3] Pentoxifylline is not of incremental value when added to corticosteroids.[A4] A variety of newer agents are currently in clinical trials.[8]

All patients with alcoholic hepatitis and alcoholic cirrhosis should be assessed and treated for protein-calorie malnutrition and micronutrient deficiency. Hospitalized patients with severe decompensation should be considered for enteral nutrition (Chapter 198).

Complications such as ascites, spontaneous bacterial peritonitis, encephalopathy, variceal bleeding, hepatorenal syndrome, osteoporosis, and hepatopulmonary syndrome may occur in patients with decompensated alcoholic cirrhosis and must be managed carefully (Chapter 139). Liver transplantation is a reasonable option in patients with decompensated alcoholic cirrhosis, and observational data suggest that early liver transplantation can improve survival in patients with severe, medically refractory alcoholic hepatitis. Although 6 months of abstinence and strong social support are generally required for eligibility (Chapter 140),[9] liver transplantation can be performed with good outcomes in severely ill but highly selected patients with acute alcoholic hepatitis before completing 6 months of abstinence. Patients with alcoholic cirrhosis, especially males, are at risk for hepatocellular carcinoma (Chapter 181) and should be screened with semiannual liver imaging and serum α-fetoprotein levels. They also may be at risk for extrahepatic malignant disease, notably head and neck, lung, and esophageal cancer. For Dupuytren contracture, injection of collagenase *Clostridium histolyticum* can reduce the severity and improve the range of motion significantly.

PROGNOSIS

Alcoholic fatty liver is generally reversible with total abstinence for a few months. The survival of patients with alcoholic hepatitis has improved over the last decade, but about 20% of patients die within 6 months after presentation, and patients with biopsy-documented alcohol-associated liver disease have a five-fold increased risk of death compared with that of the general population.[10]

Predictors of poor outcome include the severity of disease as quantified by approaches such as the MELD score (Chapters 139 and 140), the severity of fibrosis and the neutrophilic infiltration on liver biopsy, and continued alcohol use. Some data also suggest a poorer prognosis in patients who are homozygous for the rs738409:G variant in the *PNPLA3* gene.

NONALCOHOLIC FATTY LIVER DISEASE

DEFINITIONS

On histologic examination, NAFLD resembles alcohol-associated liver disease, but it occurs in individuals without significant alcohol consumption. Average alcohol consumption of more than two drinks per day in men and more than one drink per day in women generally is not consistent with a diagnosis of NAFLD. In addition, the definition of NAFLD excludes patients with a history of exposure to steatogenic medications, such as amiodarone, methotrexate, or tamoxifen.

NAFLD encompasses a spectrum of abnormal liver histologic features, ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis. In simple steatosis, liver histology reveals macrovesicular steatosis without ballooning degeneration of hepatocytes or liver fibrosis. NASH, which is a more advanced form of NAFLD, is histologically characterized by macrovesicular steatosis, ballooning degeneration of the hepatocytes, and sinusoidal fibrosis.

EPIDEMIOLOGY

NAFLD is one of the most common causes of elevated liver enzymes and chronic liver disease in the Western world. Its incidence in adults and children is rising rapidly because of the ongoing epidemics of obesity (Chapter 201), type 2 diabetes mellitus (Chapter 210), and metabolic syndrome. Its prevalence is high in certain populations of patients; for example, nearly 80% of patients with type 2 diabetes and 90% of morbidly obese individuals have imaging evidence of NAFLD, but it also can occur in about 7% of non-obese individuals in the United States and over 15% of non-obese Asians. Nearly one third of adults in westernized countries are estimated to have NAFLD,[11] and about 5% of adults may have NASH.[12] These percentages compare reasonably well with other data suggesting that the prevalence of cirrhosis from NAFLD is about 2%. Hispanics and Whites are at higher risk for NAFLD, whereas its prevalence is intriguingly low in African Americans.

PATHOBIOLOGY

The major risk factors for NAFLD include obesity, type 2 diabetes mellitus (Chapter 210), metabolic syndrome, and dyslipidemia. Other comorbidities associated with NAFLD include polycystic ovary syndrome (Chapter 217), hypothyroidism (Chapter 207), hypopituitarism (Chapter 205), hypogonadism (Chapter 216), and sleep apnea (Chapter 374).

Two fundamental but related defects in NAFLD are insulin resistance/hyperinsulinemia and excessive levels of circulating nonesterified fatty acids, which are released from adipose tissue and taken up by hepatocytes.[13] An excessive influx of nonesterified fatty acids into hepatocytes results in macrovesicular steatosis, which is predominantly centrilobular in location.

In addition, patients with NAFLD have increased de novo lipogenesis in the liver. Although patients with NAFLD robustly esterify free fatty acids into neutral triglycerides, free fatty acids that remain unesterified within hepatocytes are considered the primary mediators of cell injury (lipotoxicity). In the background of hepatic steatosis, factors that promote cell injury, inflammation, and fibrosis include oxidative stress, endoplasmic reticulum stress, apoptosis, adipocytokines, and stellate cell activation. The sources of oxidative stress include mitochondria and microsomes. Adipocytokines that play an important role in the pathogenesis of NAFLD include adiponectin and TNF-α. It is unclear why some patients with NAFLD exhibit NASH, whereas other patients with a comparable risk factor profile have only simple steatosis. There is a consistent and significant relationship between *PNPLA3* genetic polymorphisms and the severity of steatosis and other histologic features of NAFLD. Other polymorphisms that correlate positively with NAFLD are formed in *GCKR, TM6SF2* , and *MBOAT7*. Conversely, a polymorphism in *HSD17B13* offers protection against NAFLD and its severity.

CLINICAL MANIFESTATIONS

NAFLD is often asymptomatic but may rarely cause fatigue and right upper quadrant pain. Physical examination may reveal hepatomegaly, palmar erythema (see Fig. 132-2), and spider nevi. If liver disease is advanced, the features of liver failure, such as ascites, encephalopathy, and abdominal collateral vessels, are present. Simple steatosis is benign with a minimal risk of cirrhosis, whereas NASH is progressive and can lead to cirrhosis (Chapter 139) and liver failure (Chapter 140). In up to 20% of patients with NASH, liver histologic features will worsen and cirrhosis will develop during a 10- to 15-year period. Severe obesity, advancing age, and diabetes are thought to be risk factors for disease progression. Progressive disease during the early phase can be identified by a repeat liver biopsy or by noninvasive imaging tests, such as vibration-controlled transient elastography or magnetic resonance elastography. In later stages, however, the signs and symptoms of portal hypertension (e.g., abdominal collateral vessels and low platelet count) indicate the development of cirrhosis. Patients with NASH-induced cirrhosis are at risk for development of hepatocellular carcinoma (Chapter 181). Patients with NAFLD have several metabolic risks that predispose them to atherosclerosis, and coronary artery disease is the most common cause of death in patients with NAFLD.

DIAGNOSIS

NAFLD is generally suspected when aminotransferase levels are asymptomatically elevated in an individual with metabolic risk factors (obesity, diabetes, or the metabolic syndrome) or when liver imaging (ultrasound, computed tomography, or magnetic resonance imaging) obtained for another reason shows fatty infiltration (Fig. 138-2).[14] The diagnosis of NAFLD requires that there is no history of previous or ongoing significant alcohol consumption, no exposure to steatogenic medications, and no evidence of other causes of liver disease, such as viral hepatitis B or C. Elevated levels of aminotransferases, although common, are not required for the diagnosis of NAFLD. In contrast to alcohol-associated liver disease, ALT levels are higher than AST levels, but they rarely exceed 250 IU/L. In general, AST and ALT levels do not have diagnostic or prognostic significance. Mild hyperferritinemia is common and should not be confused with hereditary hemochromatosis (Chapter 196). Similarly, low-grade autoantibody (antinuclear antibody, anti–smooth muscle antibody) positivity is not uncommon and should not be confused with autoimmune liver disease (Chapter 135). Because steatosis is common in patients with Wilson disease (Chapter 195), serum ceruloplasmin levels should be obtained as part of the diagnostic evaluation in individuals who are younger than age 45 years.

Fatty liver on ultrasonography has a positive predictive value of only 77% and a negative predictive value of only 67% compared with liver biopsy. Abdominal magnetic resonance imaging is more accurate, but its high cost limits its usefulness in routine practice. Because neither of these imaging tests can differentiate simple steatosis from NASH or identify cirrhosis until hepatic fibrosis has caused nodular liver or overt portal hypertension, liver biopsy is required to establish the presence of NASH or cirrhosis. Common indications for a percutaneous liver biopsy in patients with NAFLD include persistently high aminotransferase levels, inability to exclude a competing or a coexisting cause (e.g., iron overload or autoimmune liver disease), and clinical suspicion of NASH and advanced fibrosis. In patients with NASH, liver histology shows steatosis, inflammation, ballooning, and fibrosis (Fig. 138-3).[15] However, liver histology alone cannot reliably distinguish NASH

from alcoholic hepatitis because these two entities have remarkably similar microscopic features. Vibration controlled transient elastography, which now can be performed as a point-of-care test, can provide an estimate of liver fibrosis in NAFLD in clinical practice.

TREATMENT

Lifestyle modification with dietary restriction and regular exercise is the first choice of treatment for NAFLD.[16,17] Weight reduction, a low refined-sugar diet, and increased physical activity reduce liver fat, improve glucose control and insulin sensitivity, and improve histopathologic features.[A5,A6] It is generally recommended that patients with NAFLD lose 10% of their body weight in a gradual fashion, but this goal is difficult to achieve. If resources are available, a multidisciplinary approach with behavioral therapy, dietary advice, and monitoring by a professional nutritionist and an exercise expert is more successful than a prescriptive approach (Chapter 201). Weight loss via bariatric surgery in obese patients (Chapter 201) has been reported to resolve liver biopsy finding in about 80% of patients, with a progressive reduction in fibrosis.[18]

Pharmacotherapy options[19–21] include vitamin E (800 IU of α-tocopherol administered daily for 2 years), which can significantly improve liver enzymes and histologic findings in NASH and NAFLD.[A7] Statins (e.g., atorvastatin 20 mg daily) with or without vitamins C and E can improve liver test results and reduce subsequent NAFLD.[A8] Liraglutide (a glucagon-like peptide-1 agonist at 1.8 mg daily subcutaneously) can safely lead to a histologic resolution of NASH.[A9,A10] Semaglutide (subcutaneously daily at 0.4 mg for 72 weeks) also has been highly effective in resolving steatohepatitis but does not significantly improve fibrosis in individuals with NASH and clinically significant fibrosis.[A11] Lanifibranor (a peroxisome proliferator-activated receptor agonist at 1200 mg daily) can improve the inflammatory components of NASH and may reduce fibrosis.[A12]

Thiazolidinedione insulin sensitizers (pioglitazone and rosiglitazone) improve steatosis, inflammation, ballooning, and perhaps fibrosis, but with the side effect of an average gain of nearly 10 pounds.[A13] Unfortunately, the weight gain that is common with thiazolidinediones may offset the histologic benefits that they offer.

Supplemental omega-3 polyunsaturated fatty acids have shown promise in small controlled trials.[A14] Treatment with pentoxifylline (400 mg three times daily) may improve liver enzymes and liver histologic findings in individuals with NASH.

Obeticholic acid (an FXR agonist) has shown some histologic efficiency,[A15] but longer-term studies are awaited. An engineered fibroblast growth factor 19 (FGF19) administered over 12 weeks has shown dramatic improvement in hepatic fat in a proof-of-concept study in adults with NASH.[A16,A17] Inhibition of dihydroceramide desaturase 1 is a potential target for treating hepatic steatosis.[22] Another potential agent is resmetirom, a selective thyroid hormone receptor-β agonist (80 mg orally twice daily).[A18]

Patients with NAFLD often have dyslipidemia that puts them at excessive risk for coronary artery disease; their dyslipidemia (Chapter 190) should be treated aggressively with statins and other lipid-lowering agents, which can be safely administered to patients with NAFLD and NASH. In morbidly obese individuals with NASH and other significant metabolic comorbidities, foregut bariatric surgery can lead to significant improvement in hepatic histologic features,[A19] but the physician must exclude the presence of portal hypertension before offering this type of surgery. Carefully selected patients with decompensated cirrhosis due to NASH can be treated with liver transplantation (Chapter 140), but recurrence during the post-transplantation period is common.[23]

PREVENTION

The measures to prevent NAFLD include maintaining optimal body weight, exercising regularly, and treating any associated metabolic comorbidities such as diabetes and dyslipidemia. Avoidance of saturated fat, high fructose intake, and alcohol consumption may reduce the development of NAFLD.

PROGNOSIS

Steatosis alone is generally benign, whereas steatohepatitis is often progressive. Liver fibrosis on biopsy is also independently associated with long-term liver failure and mortality.[24,25] One third of NAFLD patients may have remission within 7 years, mostly depending on modest weight reduction. Otherwise, however, data are sparse regarding the risk and risk factors for the progression of NAFLD and NASH to cirrhosis and liver failure.

Because NAFLD often coexists with one or more components of the metabolic syndrome, its presence reflects guarded long-term overall prognosis. The long-term complications in patients with simple steatosis generally result from cardiovascular disease and atherosclerosis, not from liver failure (Chapter 140).[26]

Patients with NASH also are at risk for liver failure and liver cancer (Chapter 181),[27] in addition to their significantly increased risk of cardiovascular disease. For example, among patients with NASH on their initial biopsy, one third or more develop progressive fibrosis during a mean follow-up interval of about 5 years. Older age, diabetes, and ballooning and fibrosis on liver biopsy are important predictors of progression. In the United States, NAFLD is now second only to alcohol-associated liver disease as a cause of being listed for liver transplantation.

139 CIRRHOSIS AND ITS SEQUELAE

GUADALUPE GARCIA-TSAO

DEFINITION

Cirrhosis, which can be the final stage of any chronic liver disease, is a diffuse process characterized by fibrosis and conversion of normal architecture to structurally abnormal nodules (Fig. 139-1). These "regenerative" nodules lack normal lobular organization and are surrounded by fibrous tissue. The process involves the whole liver and generally is considered irreversible. Although cirrhosis is histologically an "all-or-nothing" diagnosis, it can be classified clinically by its status as compensated or decompensated. Decompensated cirrhosis is defined by the presence of ascites, variceal bleeding, encephalopathy, or jaundice, which are complications that result from the main consequences of cirrhosis: portal hypertension and liver insufficiency.

EPIDEMIOLOGY

Because many patients with cirrhosis are asymptomatic until decompensation occurs, it is difficult to assess the real prevalence and incidence of cirrhosis in the general population. The prevalence of chronic liver disease or cirrhosis worldwide is estimated to be 100 (range, 25 to 400) per 100,000 subjects, but it varies widely by country and by geographic region.

Cirrhosis is an important cause of morbidity and mortality worldwide and in the United States. According to the latest Global Burden of Diseases study, cirrhosis annually causes more than 1.32 million deaths worldwide and about 45,000 deaths in the United States, making it the 11th leading cause of death overall.[1] Importantly, chronic liver disease and cirrhosis mainly affect individuals between 25 and 64 years of age. As chronic liver disease affects people in their most productive years of life, it has a significant impact on the economy as a result of premature death, illness, and disability.

Any chronic liver disease can lead to cirrhosis (Table 139-1). The main causes of cirrhosis in Western and industrialized countries are alcohol-related (Chapter 138) and nonalcoholic steatohepatitis (Chapter 138),[2,3] whereas viral hepatitis B (Chapter 135) is the primary cause in China and other Asian countries. Hepatitis C (Chapter 135) was the most common cause of cirrhosis in the United States until effective antiviral therapy became available. Other causes of cirrhosis include autoimmune liver diseases, such as primary biliary cholangitis (Chapter 135), primary sclerosing cholangitis (Chapter 135), autoimmune hepatitis (Chapter 135), and metabolic diseases such as hemochromatosis (Chapter 196) and Wilson disease (Chapter 195). Heterozygous carriage of the alpha1-antitrypsin Pi*Z variant, which is present in up to 10% of persons of European descent, increases the risk of liver cirrhosis in patients with liver disease or alcohol abuse (Chapter 138). When all potential causes have been investigated and excluded, cirrhosis is considered "cryptogenic." Many cases of cryptogenic cirrhosis are now thought to be due to nonalcoholic steatohepatitis (Chapter 138).

PATHOBIOLOGY

Liver Fibrosis and Cirrhosis

The key pathogenic feature underlying liver fibrosis and cirrhosis is activation of hepatic stellate cells. Hepatic stellate cells, which are known as *Ito cells* or *perisinusoidal cells*, are located in the space of Disse between hepatocytes and sinusoidal endothelial cells. Normally, hepatic stellate cells are quiescent and serve as the main storage site for retinoids (vitamin A). In response to injury, hepatic stellate cells become activated, as a result of which they lose their vitamin A, proliferate, develop a prominent rough endoplasmic reticulum, and secrete extracellular matrix (collagen types I and III, sulfated proteoglycans, and glycoproteins). In addition, they become contractile myofibroblasts.

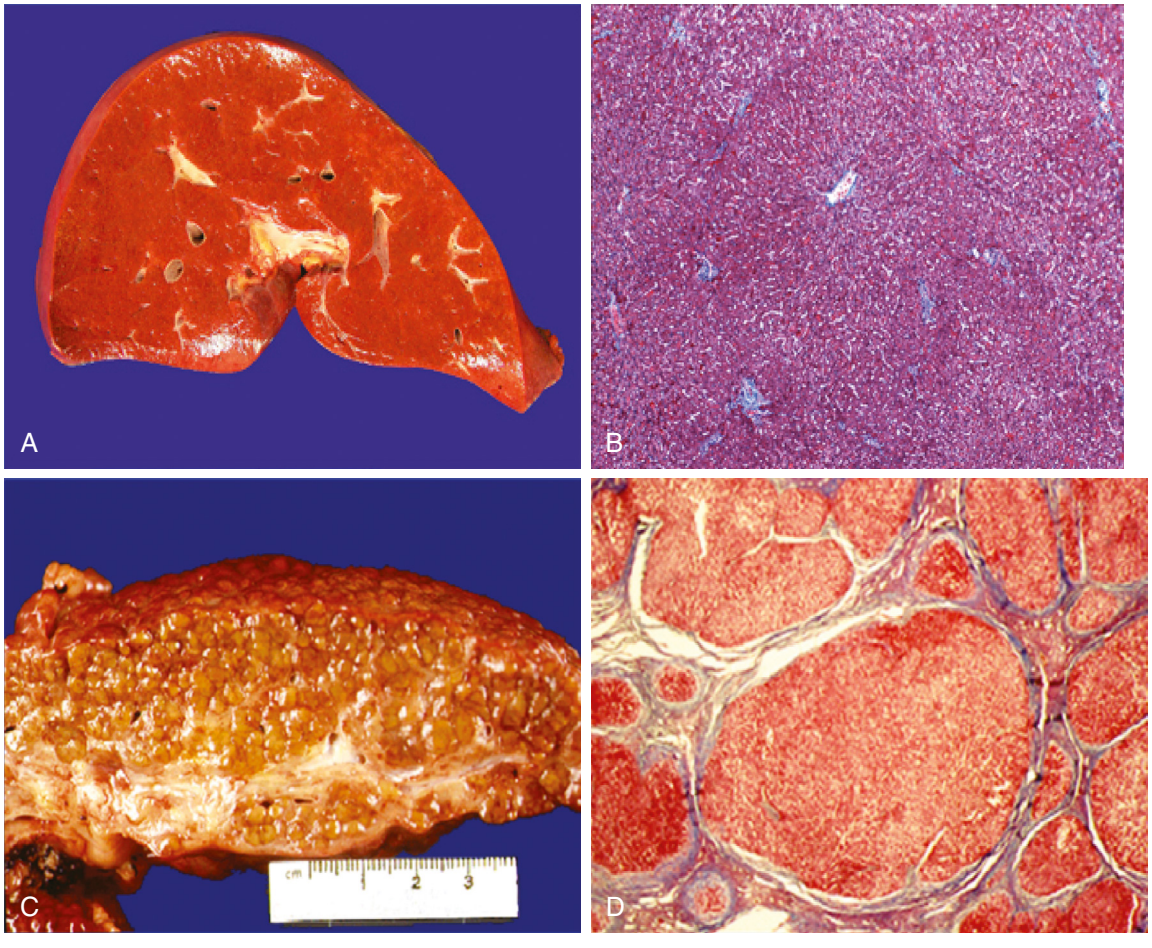

FIGURE 139-1. Gross and microscopic images of a normal and cirrhotic liver. A, Gross image of a normal liver with a smooth surface and homogeneous texture. **B,** On microscopic examination, liver sinusoids are organized, and vascular structures are normally distributed. **C,** Gross image of a cirrhotic liver. The liver has an orange-tawny color with an irregular surface and a nodular texture. **D,** On microscopic examination, the architecture is disorganized, and there are regenerative nodules surrounded by fibrous tissue.

ABSTRACT

Cirrhosis is the end stage of any chronic liver disease. It is classified in two main prognostic stages—compensated and decompensated. Decompensated cirrhosis is defined by the development of ascites, variceal hemorrhage, encephalopathy, or jaundice, all of which are consequences of portal hypertension (and the hyperdynamic circulatory state) and/or liver insufficiency. Stages and substages of cirrhosis are not only prognostically significant but have different predominant pathophysiologic mechanisms and therefore are managed differently.

KEYWORDS

cirrhosis
portal hypertension
ascites
encephalopathy
variceal hemorrhage

TABLE 139-1 CAUSES OF CIRRHOSIS

MAIN FACTORS CAUSING CIRRHOSIS
Alcoholic liver disease
Nonalcoholic fatty liver disease
Chronic hepatitis B
OTHER CAUSES OF CIRRHOSIS (<2% OF ALL CASES)
Chronic hepatitis C
Cholestatic and autoimmune liver diseases
Primary biliary cirrhosis
Primary sclerosing cholangitis
Autoimmune hepatitis
Intrahepatic or extrahepatic biliary obstruction
Mechanical obstruction
Biliary atresia
Cystic fibrosis
Metabolic disorders
Hemochromatosis
Wilson disease
α_1-Antitrypsin deficiency
Glycogen storage diseases
Abetalipoproteinemia
Porphyria
Hepatic venous outflow obstruction
Budd-Chiari syndrome
Veno-occlusive disease
Right-sided heart failure
Drugs and toxins
Intestinal bypass
Indian childhood cirrhosis

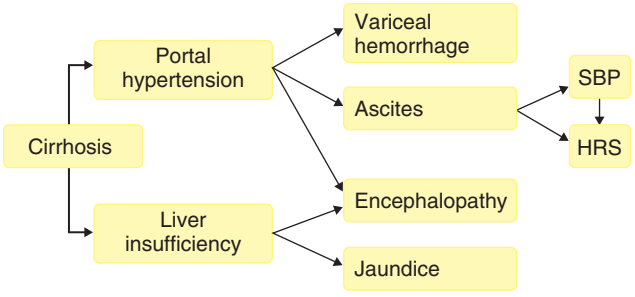

FIGURE 139-2. Complications of cirrhosis result from portal hypertension or liver insufficiency. Varices and variceal hemorrhage are a direct consequence of portal hypertension. Ascites results from sinusoidal portal hypertension and can be complicated by infection (spontaneous bacterial peritonitis [SBP]) or renal dysfunction (hepatorenal syndrome [HRS]). Hepatic encephalopathy results from portosystemic shunting (i.e., portal hypertension) and liver insufficiency. Jaundice results solely from liver insufficiency.

A number of genetic polymorphisms have been associated with a higher risk of cirrhosis related to alcohol or obesity,[4] but their clinical utility remains unclear.

Unlike other capillaries, normal hepatic sinusoids lack a basement membrane. The sinusoidal endothelial cells themselves contain large fenestrae (100 to 200 nm in diameter) that permit the passage of large molecules with molecular masses up to 250,000 daltons. Collagen deposition in the space of Disse, as occurs in cirrhosis, leads to defenestration of the sinusoidal endothelial cells ("capillarization" of the sinusoids), thereby altering exchange between plasma and hepatocytes and resulting in a decreased sinusoidal diameter that is further exacerbated by the contraction of stellate cells.

Complications of Cirrhosis

The two main consequences of cirrhosis are portal hypertension, with the accompanying hyperdynamic circulatory state, and liver insufficiency (Fig. 139-2). The development of varices and ascites is a direct consequence of portal hypertension and the hyperdynamic circulatory state, whereas jaundice occurs as a result of an inability of the liver to excrete bilirubin (i.e., liver insufficiency). Encephalopathy is the result of both portal hypertension and liver insufficiency. Ascites, in turn, can become complicated by infection, which is called *spontaneous bacterial peritonitis*, and by functional renal failure, which is called *hepatorenal syndrome*.

Portal Hypertension and the Hyperdynamic Circulatory State

In cirrhosis, portal hypertension results from both an increase in resistance to portal flow and an increase in portal venous inflow.[5] The initial mechanism is increased sinusoidal vascular resistance (Fig. 139-3) secondary to (1) deposition of fibrous tissue and subsequent compression by regenerative nodules (fixed component), which could theoretically be amenable to antifibrotic agents and could be ameliorated by resolving the underlying etiologic process, and (2) active vasoconstriction (functional component), which is amenable to the action of vasodilators such as nitroprusside and is caused by a deficiency in intrahepatic nitric oxide (NO), as well as enhanced activity of vasoconstrictors.

Early in the portal hypertensive process, the spleen grows and sequesters platelets and other formed blood cells, thereby leading to hypersplenism. In addition, vessels that normally drain into the portal system, such as the coronary vein, reverse their flow and shunt blood away from the portal system to the systemic circulation. These portosystemic collaterals are insufficient to decompress the portal venous system and offer additional resistance to portal flow. As collaterals develop, an increase in portal blood inflow, which results from splanchnic vasodilation, maintains the portal hypertensive state. Splanchnic arteriolar vasodilation is, in turn, secondary to increased production of NO. Thus, the paradox in portal hypertension is that a deficiency of NO in the intrahepatic vasculature leads to vasoconstriction and increased resistance, whereas overproduction of NO in the extrahepatic circulation leads to vasodilation and increased portal flow.

In addition to splanchnic vasodilation, there is systemic vasodilation, which by causing a decreased *effective* arterial blood volume leads to activation of neurohumoral systems (renin-angiotensin-aldosterone system), retention of sodium, expansion of plasma volume, and development of a hyperdynamic circulatory state. This hyperdynamic circulatory state maintains portal hypertension, thereby leading to the formation and growth of varices, and plays an important role in the development of all other complications of cirrhosis.

Varices and Variceal Hemorrhage

The complication of cirrhosis that results most directly from portal hypertension is the development of portal-systemic collaterals, the most relevant of which are those that form through dilation of the coronary and gastric veins and constitute gastroesophageal varices. The initial formation of esophageal collaterals depends on a threshold portal pressure, clinically established by a hepatic venous pressure gradient of 10 to 12 mm Hg, below which varices do not develop.

Development of a hyperdynamic circulatory state leads to further dilation and growth of varices and eventually to their rupture and variceal hemorrhage, one of the most dreaded complications of portal hypertension. Tension in a varix determines variceal rupture and is directly proportional to variceal diameter and intravariceal pressure and inversely proportional to variceal wall thickness.

Ascites and Hepatorenal Syndrome

Ascites, which is the accumulation of intraperitoneal fluid, in cirrhosis is secondary to sinusoidal hypertension and retention of sodium. Cirrhosis leads to sinusoidal hypertension by blocking hepatic venous outflow both anatomically by fibrosis and regenerative nodules and functionally by increased postsinusoidal vascular tone. Similar to the formation of esophageal varices, a threshold hepatic venous pressure gradient of 12 mm Hg is needed for the formation of ascites. In addition, retention of sodium replenishes the intravascular volume and allows the continuous formation of ascites. Retention of sodium results from vasodilation that is mostly due to an increase in the production of NO. With progression of cirrhosis and portal hypertension, vasodilation is more pronounced, thereby leading to further activation of the renin-angiotensin-aldosterone and sympathetic nervous systems and resulting in further sodium retention (refractory ascites), water retention (hyponatremia), and renal vasoconstriction (hepatorenal syndrome).[6]

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis, an infection of ascitic fluid, occurs in the absence of perforation of a hollow viscus or an intra-abdominal inflammatory focus, such as an abscess, acute pancreatitis, or cholecystitis. Bacterial translocation, or the migration of bacteria from the intestinal lumen to mesenteric lymph nodes and other extraintestinal sites, is the main mechanism implicated in spontaneous bacterial peritonitis. Impaired local and systemic immune defenses are a major element in promoting bacterial translocation and, together with shunting of blood away from the hepatic Kupffer cells through portosystemic collaterals, allow a transient bacteremia to become more prolonged, thereby colonizing ascitic fluid. Spontaneous bacterial peritonitis occurs in patients with reduced ascites defense mechanisms, such as a low

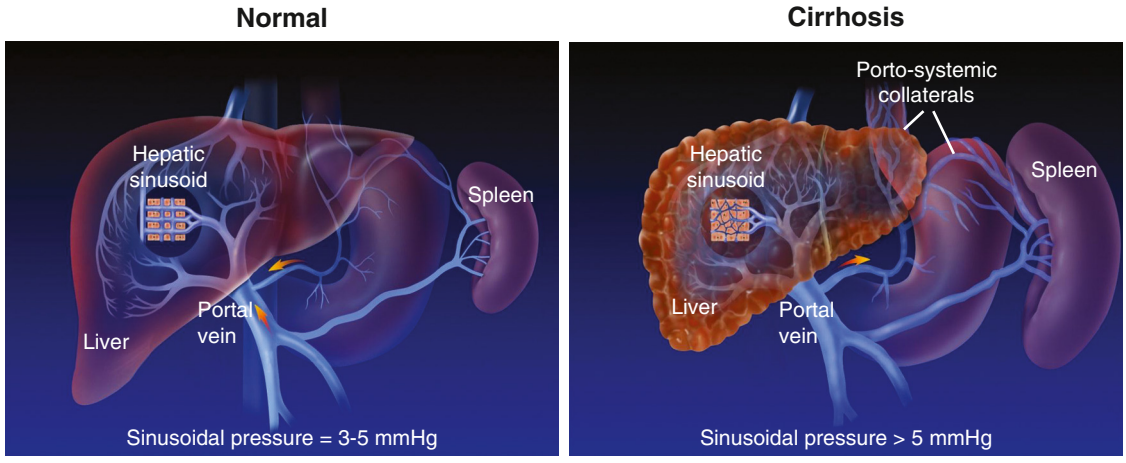

FIGURE 139-3. Hepatic sinusoidal pressure is increased in cirrhosis. In the normal liver (*left*), the intrahepatic vasculature is compliant, and the hepatic venous pressure gradient, which is a measure of sinusoidal pressure, is 5 mm Hg or lower. In the cirrhotic liver (*right*), the sinusoidal architecture is distorted by regenerative nodules and fibrosis that lead to increased intrahepatic resistance, portal hypertension, splenomegaly, and portosystemic collaterals; the hepatic venous pressure gradient is above 5 mm Hg. Complications of cirrhosis develop after the gradient increases above 10 to 12 mm Hg.

complement level in ascitic fluid. Another factor that promotes bacterial translocation in cirrhosis is intestinal bacterial overgrowth attributed to a decrease in small bowel motility and intestinal transit time. Infections, particularly from gram-negative bacteria, can precipitate renal dysfunction through worsening of the hyperdynamic circulatory state.

Encephalopathy

Hepatic encephalopathy is brain dysfunction caused by liver insufficiency, portosystemic shunting, or both.[7] Ammonia, a toxin normally removed by the liver, plays a key role in its pathogenesis. In cirrhosis, ammonia accumulates in the systemic circulation because of shunting of blood through portosystemic collaterals and decreased liver metabolism (i.e., liver insufficiency). The presence of large amounts of ammonia in the brain damages supporting brain cells or astrocytes and leads to structural changes characteristic of hepatic encephalopathy (Alzheimer type II astrocytosis). Ammonia results in upregulation of astrocytic peripheral-type benzodiazepine receptors, the most potent stimulants of neurosteroid production. Neurosteroids are the major modulators of γ-aminobutyric acid, which results in cortical depression and hepatic encephalopathy. Other toxins, such as manganese, also accumulate in the brain, particularly the globus pallidus, where they lead to impaired motor function. Other yet-to-be-elucidated toxins may also be involved in the pathogenesis of encephalopathy.

Jaundice

Jaundice (Chapter 133) in cirrhosis results from the inability of the liver to excrete bilirubin and is therefore the result of liver insufficiency. However, in cholestatic diseases leading to cirrhosis (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, vanishing bile duct syndrome), jaundice is more likely due to biliary damage than to liver insufficiency. Other indicators of liver insufficiency, such as the presence of encephalopathy or prolongation of the international normalized ratio, help determine the most likely contributor to hyperbilirubinemia (Chapter 133).

Cardiopulmonary Complications

The hyperdynamic circulatory state eventually results in high-output heart failure with decreased peripheral utilization of oxygen, a complication that has been referred to as *cirrhotic cardiomyopathy*. Vasodilation at the level of the pulmonary circulation leads to arterial hypoxemia, the hallmark of hepatopulmonary syndrome. Normal pulmonary capillaries are 8 μm in diameter, and red blood cells (slightly less than 8 μm) pass through them one cell at a time, thereby facilitating oxygenation. In *hepatopulmonary syndrome*, the pulmonary capillaries are dilated up to 500 μm, so passage of red cells through the pulmonary capillaries may be many cells thick. As a result, a large number of red cells are not oxygenated, which causes the equivalent of a right-to-left shunt.

Conversely, *portopulmonary hypertension*[8] occurs when the pulmonary bed is exposed to vasoconstrictive substances that may be produced in the splanchnic circulation and bypass metabolism by the liver; the initial result is reversible pulmonary hypertension. However, because these factors result in endothelial proliferation, vasoconstriction, in situ thrombosis, and obliteration of vessels, irreversible pulmonary hypertension ensues.

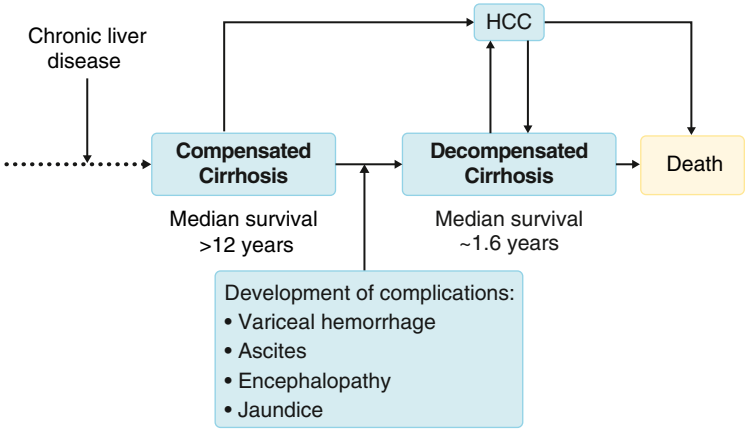

FIGURE 139-4. Natural history of cirrhosis. Any chronic liver disease will lead to cirrhosis. Initially, cirrhosis will be compensated (median survival, >12 years), but once complications (ascites, variceal hemorrhage, encephalopathy, jaundice) develop, it becomes decompensated (median survival, 1.6 years). Hepatocellular carcinoma (HCC) can develop at any stage and precipitate decompensation and death.

CLINICAL MANIFESTATIONS

The clinical manifestations of cirrhosis range widely, depending on the stage of cirrhosis, from an asymptomatic patient with no signs of chronic liver disease to a patient who is confused and jaundiced with severe muscle wasting and ascites. The natural history of cirrhosis is characterized by an initial phase, termed *compensated* cirrhosis, followed by a rapidly progressive phase marked by the development of complications of portal hypertension or liver dysfunction (or both), termed *decompensated* cirrhosis (Fig. 139-4).[9] In the compensated phase, liver synthetic function is mostly normal, and portal pressure, although increased, is below the threshold level required for the development of varices or ascites. As the disease progresses, portal pressure increases and liver function worsens, thereby resulting in the development of ascites, portal hypertensive gastrointestinal bleeding, encephalopathy, and jaundice.[10] The development of any of these clinically detectable complications marks the transition from a compensated to a decompensated phase. Progression to death may be accelerated by the development of other complications, such as recurrent gastrointestinal bleeding, renal impairment (refractory ascites, hepatorenal syndrome), hepatopulmonary syndrome, and sepsis (spontaneous bacterial peritonitis). The development of hepatocellular carcinoma (Chapter 181) may accelerate the course of the disease at any stage (see Fig. 139-4). Transition from a compensated to a decompensated stage occurs at a rate of approximately 5 to 7% per year. The median time to decompensation, or the time at which half the patients with compensated cirrhosis will become decompensated, is about 6 years.

Compensated Cirrhosis

In this stage, cirrhosis is mostly asymptomatic and is diagnosed either during the evaluation of chronic liver disease or fortuitously during routine physical examination, biochemical testing, imaging for other reasons, endoscopy showing gastroesophageal varices, or abdominal surgery in which a nodular liver is detected. Nonspecific fatigue, weight loss, decreased muscle mass, decreased libido, or sleep disturbances may be the only complaints. About 40% of patients with compensated cirrhosis have esophageal varices. Nonbleeding gastroesophageal varices are asymptomatic, and their presence (without bleeding) does not denote decompensation.

Decompensated Cirrhosis

At this stage, there are signs of decompensation: ascites, variceal hemorrhage, jaundice, hepatic encephalopathy, or any combination of these findings. Ascites, which is the most frequent sign of decompensation, is present in 80% of patients with decompensated cirrhosis.

Variceal Hemorrhage

Gastroesophageal varices are present in approximately 50% of patients with newly diagnosed cirrhosis. The prevalence of varices correlates with the severity of liver disease and ranges from 40% in Child A cirrhotic patients (Table 139-2) to 85% in Child C cirrhotic patients.

Both the development of varices and the growth of small varices occur at a rate of 7 to 8% per year. The incidence of a first variceal hemorrhage in patients with small varices is about 5% per year, whereas medium and large varices bleed at a rate of approximately 15% per year. Large varices, severe liver disease, and red wale markings on varices are independent predictors of variceal hemorrhage. Bleeding from gastroesophageal varices can be manifested as overt hematemesis, melena, or both (Chapter 121).

Ascites and Hyponatremia

Ascites is the most common cause of decompensation in cirrhosis and occurs at a rate of 7 to 10% per year. The most frequent symptoms associated with ascites are increased abdominal girth, which is often described by the patient as tightness of the belt or garments around the waist, and recent weight gain. When it is present in small to moderate amounts, ascites can be identified on examination by bulging flanks, flank dullness, and shifting dullness (Chapter 132).

Hyponatremia, which is defined as a serum sodium concentration <130 mEq/L (Chapter 102), is present in about 25% of patients with cirrhosis and ascites. However, patients with cirrhosis do not usually have the neurologic manifestations of hyponatremia, presumably because it typically develops gradually. Nevertheless, hyponatremia is a marker of the severity of cirrhosis and is associated with poorer quality of life and the development of hepatic encephalopathy.

Hepatorenal syndrome is a type of prerenal kidney injury that occurs in patients with cirrhosis and ascites.[11] It represents the extreme of the spectrum of abnormalities that lead to cirrhotic ascites and is the result of maximal peripheral vasodilation, as well as maximal activation of hormones that cause the retention of sodium and water and intense vasoconstriction of the renal arteries. Hepatorenal syndrome is divided into two types based on clinical characteristics and prognosis. Type 1 hepatorenal syndrome (now called hepatorenal syndrome–acute kidney injury) is rapidly progressive *acute* kidney injury in which the rise in serum creatinine concentration occurs within a 2-week period. Type 2 hepatorenal syndrome (now called hepatorenal syndrome–non-acute kidney injury) is more slowly progressive and associated with ascites that is refractory to diuretics. Patients with hepatorenal syndrome usually have tense ascites that responds poorly to diuretics, but no specific symptoms or signs typify this entity.

Spontaneous Bacterial Peritonitis

About one third of patients with cirrhosis are admitted for bacterial infection or acquire a bacterial infection during hospitalization, the most common being spontaneous bacterial peritonitis. The two most important predictors of the development of bacterial infection are the severity of liver disease and admission for gastrointestinal hemorrhage. The most frequent clinical manifestations of spontaneous bacterial peritonitis are fever, jaundice, and abdominal pain. On physical examination, there is typically abdominal tenderness, with or without rebound tenderness, or ileus (or both). However, up to one third of patients with spontaneous bacterial peritonitis initially may have no abdominal symptoms or symptoms of infection[12] and may present instead with encephalopathy, acute kidney injury, or evidence of shock.

Hepatic Encephalopathy

Hepatic encephalopathy, which is the neuropsychiatric manifestation of cirrhosis, occurs at a rate of approximately 2 to 3% per year. Hepatic encephalopathy associated with cirrhosis is of gradual onset and rarely fatal. It is manifested as a wide spectrum of neurologic and psychiatric abnormalities ranging from subclinical alterations to coma. Clinically, it is characterized by alterations in consciousness and behavior ranging from inversion of the sleep-wake pattern and forgetfulness (grade 1); to confusion, bizarre behavior, and disorientation (grade 2); to lethargy and profound disorientation (grade 3); to coma (grade 4). On physical examination, early stages may demonstrate only a distal tremor, but the hallmark of overt hepatic encephalopathy is the presence of asterixis. In addition, patients with hepatic encephalopathy may have sweet-smelling breath, a characteristic termed *fetor hepaticus*.

Pulmonary Complications

Hepatopulmonary syndrome is associated with exertional dyspnea, which can lead to extreme debilitation. Clubbing of the fingers, cyanosis, and vascular spiders may be seen on physical examination. Hepatopulmonary syndrome is present in approximately 5 to 10% of patients awaiting liver transplantation.

Portopulmonary hypertension is manifested as exertional dyspnea, syncope, and chest pain.[13] On examination, an accentuated second sound and right ventricular heave are prominent (Chapter 69).

TABLE 139-2 THE TWO MOST COMMONLY USED SCORING SYSTEMS IN CIRRHOSIS

1. CHILD-TURCOTTE-PUGH (CTP) SCORE (RANGE, 5-15)

	POINTS ASCRIBED		
Parameters	**1**	**2**	**3**
Ascites	None	Grade 1-2 (or easy to treat)	Grade 3-4 (or refractory)
Hepatic encephalopathy	None	Grade 1-2 (or induced by a precipitant)	Grade 3-4 (or spontaneous)
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds > control) or INR	<4 <1.7	4-6 1.7-2.3	>6 >2.3

CTP classification: Child A: score of 5-6; Child B: score of 7-9; Child C: score of 10-15

2. MODEL OF END-STAGE LIVER DISEASE (MELD) SCORE (RANGE, 6-40)

$[0.957 \times \text{LN (creatinine in mg/dL)} + 0.378 \times \text{LN (bilirubin in mg/dL)} + 1.12 \times \text{LN (INR)} + 0.643] \times 10$

MELD-Na is calculated first by determining the traditional MELD ($\text{MELD}_{(0)}$); if the initial $\text{MELD}_{(i)}$ score is 12 or greater, the score is adjusted by incorporating the serum sodium value

$$[\text{MELD}_{(0)} + 1.32 \times (137\text{-Na}) - [0.033 \times \text{MELD(i)} \times (137\text{-Na})]$$

INR = international normalized ratio; LN = natural logarithm.

DIAGNOSIS

The diagnosis of cirrhosis should be considered in any patient with chronic liver disease. In asymptomatic patients with *compensated cirrhosis*, typical signs of cirrhosis may not be present, and the physical examination and laboratory test findings may be entirely normal. The diagnosis may often require histologic confirmation by liver biopsy, which is the "gold standard" for the diagnosis of cirrhosis. However, liver biopsy is an invasive procedure subject to sampling error, and the presence of cirrhosis can often be confirmed noninvasively by a combination of serum biomarkers, imaging techniques, and measurements of liver stiffness.

Physical Examination

On physical examination, stigmata of cirrhosis consist of muscle atrophy, mainly involving the bitemporal muscle regions and the thenar and hypothenar eminences; spider angiomas, mostly on the trunk, face, and upper limbs; and palmar erythema involving the thenar and the hypothenar eminences and the tips of the fingers. Although muscle atrophy is a marker of liver insufficiency, spider angiomas and palmar erythema are markers of vasodilation and a hyperdynamic circulation. Men may have hair loss on the chest and

abdomen, gynecomastia, and testicular atrophy. Petechiae and ecchymoses may be present as a result of thrombocytopenia or a prolonged prothrombin time. Dupuytren contracture, which is a thickening of the palmar fascia, occurs mostly in alcoholic cirrhosis. A pathognomonic feature of cirrhosis is the finding on abdominal examination of a small right liver lobe, with a span of less than 7 cm on percussion, and a palpable left lobe that is nodular with increased consistency. Splenomegaly may also be present and is indicative of portal hypertension. Collateral circulation on the abdominal wall (caput medusae) may also develop as a consequence of portal hypertension. Absence of any of these physical findings does not exclude cirrhosis.

Laboratory Tests

Laboratory test results suggestive of cirrhosis include even subtle abnormalities in serum levels of albumin or bilirubin or elevation of the international normalized ratio. The most sensitive and specific laboratory finding suggestive of cirrhosis in the setting of chronic liver disease is a low platelet count (<150,000/μL), which occurs as a result of portal hypertension and hypersplenism. Other serum markers that are often abnormal include levels of aspartate aminotransferase, γ-glutamyl transpeptidase, hyaluronic acid, α_2-macroglobulin, haptoglobin, tissue metalloproteinase inhibitor 1, and apolipoprotein A. Combinations of these tests have been used to predict the presence of cirrhosis, but they are not as accurate as imaging studies.

Imaging Studies

Confirmatory imaging tests include computed tomography, ultrasound, and magnetic resonance imaging. Findings consistent with cirrhosis include a nodular contour of the liver, a small liver with or without hypertrophy of the left or caudate lobe, splenomegaly, and, in particular, identification of intra-abdominal collateral vessels indicative of portal hypertension (Fig. 139-5). With increasing fibrosis, the liver becomes stiff, and this stiffness can be measured by ultrasound (transient elastography, acoustic radiation force impulse imaging), or magnetic resonance imaging. Measurement of liver stiffness, a new noninvasive technique, appears to be useful in the diagnosis of cirrhosis and in excluding its presence. These tests are becoming more widely available, and typical findings on any of these imaging studies, together with a compatible clinical picture, are indicative of the presence of cirrhosis. A liver biopsy then would not be required unless the degree of inflammation or other features require investigation.

In *decompensated cirrhosis*, detection of ascites, variceal bleeding, or encephalopathy in the setting of chronic liver disease essentially establishes the diagnosis of cirrhosis, so a liver biopsy is not necessary to establish the diagnosis. Patients with decompensated cirrhosis often exhibit malnutrition, more severe muscle wasting, more numerous vascular spiders, and hypotension and tachycardia as a result of the hyperdynamic circulatory state.

Portal Pressure Measurements

Direct measurements of portal pressure involve catheterization of the portal vein, are cumbersome, and may be associated with complications. Hepatic vein catheterization with measurement of wedged and free pressure is the simplest, safest, most reproducible, and most widely used method to indirectly measure portal pressure. Portal pressure measurements are expressed as the hepatic venous pressure gradient: the gradient between wedged hepatic venous pressure, which is a measure of sinusoidal pressure, and free hepatic or inferior vena cava pressure, which is used as an internal zero reference point. In a patient with clinical evidence of portal hypertension (e.g., varices), the hepatic venous pressure gradient is useful in the differential diagnosis of the cause of portal hypertension: it will be normal (3 to 5 mm Hg) in prehepatic causes of portal hypertension, such as portal vein thrombosis, and in intrahepatic but presinusoidal causes, such as schistosomiasis (Chapter 326); but it will be abnormal (≥6 mm Hg) in sinusoidal causes of portal hypertension, such as cirrhosis, and in postsinusoidal causes, such as veno-occlusive disease. In patients with compensated viral or alcoholic cirrhosis, a hepatic venous pressure gradient of 10 mm Hg or greater ("clinically significant" portal hypertension) predicts the development of decompensation, and its reduction with pharmacologic therapy predicts a favorable outcome in patients with cirrhosis. In patients with variceal hemorrhage, a hepatic venous pressure gradient of more than 20 mm Hg predicts recurrent variceal hemorrhage and may portend death. Measurements of liver stiffness correlate with hepatic venous pressure measurements and can help stratify patients with compensated cirrhosis, regardless of etiology, into those with and without clinically significant portal hypertension.

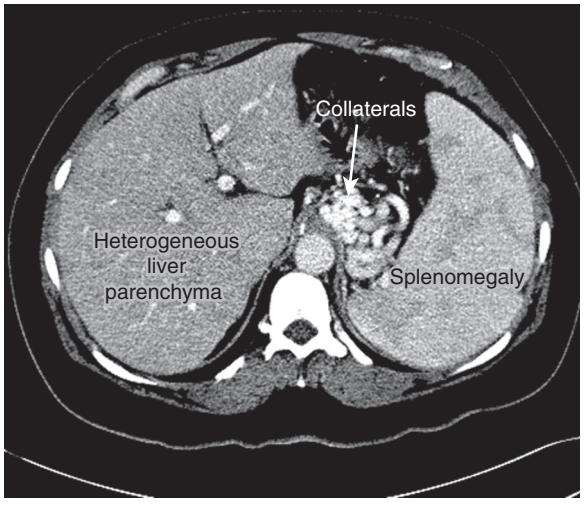

FIGURE 139-5. Computed tomography in a patient with compensated cirrhosis. The liver parenchyma is heterogeneous, there is splenomegaly, and, importantly, there are portosystemic collaterals.

Complications of Cirrhosis

Varices and Variceal Hemorrhage

Upper gastrointestinal endoscopy (Chapter 120) remains the main method for diagnosis of varices and variceal hemorrhage. Varices are classified as small (straight, minimally elevated veins above the esophageal mucosal surface), medium (tortuous veins occupying less than one third of the esophageal lumen), or large (occupying more than one third of the esophageal lumen). The diagnosis of variceal hemorrhage is made when diagnostic esophagogastroduodenoscopy shows one of the following: active bleeding from a varix, a "white nipple" overlying a varix, clots overlying a varix, or varices with no other potential source of bleeding.

Ascites

The most common cause of ascites is cirrhosis, which accounts for 80% of cases. Peritoneal malignant disease (e.g., peritoneal metastases from gastrointestinal tumors or ovarian cancer), heart failure (Chapter 45), and peritoneal tuberculosis (Chapter 299) together account for another 15% of cases. The initial, most cost-effective, and least invasive method to confirm the presence of ascites is abdominal ultrasonography.

Diagnostic paracentesis is a safe procedure that should be performed in every patient with new-onset ascites, even in those with coagulopathy. Ultrasound guidance should be used in patients in whom percussion cannot locate the ascites or in whom a first paracentesis attempt does not yield fluid. The fluid in a patient with new-onset ascites should always be evaluated for albumin (with simultaneous estimation of serum albumin), total protein, and polymorphonuclear (PMN) blood cell count, and bacteriologic cultures and cytology should be performed. The PMN cell count and bacteriologic culture are useful to exclude infection (either spontaneous or secondary bacterial peritonitis), and cytologic evaluation is needed if peritoneal carcinomatosis is suspected. Depending on the clinical setting, additional tests can be performed on the fluid: glucose and lactate dehydrogenase levels (if secondary bacterial peritonitis is suspected), smear and culture for acid-fast bacilli (if peritoneal tuberculosis is suspected), and amylase level (if pancreatic ascites is suspected).

The serum-ascites albumin gradient and ascites protein levels are useful in the differential diagnosis of ascites (Table 139-3). The serum-ascites albumin gradient correlates with sinusoidal pressure and will therefore be elevated (>1.1 g/dL) in patients in whom the source of ascites is the hepatic sinusoid (e.g., cirrhosis or cardiac ascites). Protein levels in ascitic fluid are an indirect marker of the integrity of the hepatic sinusoids: normal sinusoids are permeable structures that "leak" protein, whereas sinusoids in cirrhosis are "capillarized" and do not leak as much protein. The three main causes of ascites—cirrhosis, peritoneal malignant disease or tuberculosis, and heart failure—can easily be distinguished by combining the results of both the serum-ascites albumin gradient and ascites total protein content. Cirrhotic ascites typically has a high serum-ascites albumin gradient and low protein, cardiac ascites has a high serum-ascites albumin gradient and high protein, and ascites secondary to peritoneal malignant disease typically has a low serum-ascites albumin gradient and high protein. A high serum B-type natriuretic peptide has a high diagnostic accuracy in the diagnosis of ascites due to heart failure.

TABLE 139-3 USING THE SERUM-ASCITES ALBUMIN GRADIENT AND THE ASCITES TOTAL PROTEIN LEVEL TO DIAGNOSE THE CAUSE OF ASCITES

CONDITION	SERUM-ASCITES ALBUMIN GRADIENT*	ASCITES TOTAL PROTEIN LEVEL†
Cirrhosis	High	Low
Malignant ascites	Low	High
Cardiac ascites	High	High

*High is more than 1.1 g/dL; low is less than 1.1 g/dL.
†High is more than 2.5 g/dL; low is less than 2.5 g/dL.

Hepatorenal Syndrome

Hepatorenal syndrome is a diagnosis of exclusion, but patients typically have ascites that is unresponsive to diuretics, and most have hyponatremia. The differential diagnosis of acute kidney injury in cirrhosis includes conditions that worsen vasodilation, such as sepsis, the use of vasodilators, and large-volume paracentesis not accompanied by albumin infusion; conditions that decrease effective arterial blood volume, such as gastrointestinal hemorrhage, overdiuresis, or diarrhea (often induced by overdoses of lactulose); conditions that induce renal vasoconstriction, such as nonsteroidal anti-inflammatory drugs; and nephrotoxic insults, such as from aminoglycosides. As a result, the diagnosis of hepatorenal syndrome can only be made after diuretics have been discontinued, any condition that leads to worsening of the hemodynamic status of the cirrhotic patient has been excluded or treated, and intravascular volume has been expanded with albumin.

Spontaneous Bacterial Peritonitis

A high index of suspicion and early diagnosis are key in the management of spontaneous bacterial peritonitis. Diagnostic paracentesis should be performed in any patient with symptoms or signs of spontaneous bacterial peritonitis, including unexplained encephalopathy and renal dysfunction. Because spontaneous bacterial peritonitis is often asymptomatic and frequently community acquired, diagnostic paracentesis should be performed when any patient with cirrhosis is admitted to the hospital, regardless of the cause for admission.

The diagnosis of spontaneous bacterial peritonitis is established by an ascitic fluid PMN count >250/μL. Bacteria can be isolated from ascitic fluid in only 40 to 50% of cases, even with sensitive methods such as inoculation directly into a blood culture bottle. Spontaneous bacterial peritonitis is mostly a non-bacterial infection, usually with a gram-negative enteric organism. However, the widespread use of antibiotic prophylaxis in cirrhosis has led to an increased prevalence of infections with multidrug-resistant organisms. Anaerobes and fungi very rarely cause spontaneous bacterial peritonitis; their presence, as well as a polymicrobial infection, should raise suspicion of secondary bacterial peritonitis.

Hepatic Encephalopathy

The diagnosis of overt hepatic encephalopathy is mainly clinical and based on a history and physical examination that shows alterations in consciousness and behavior as well as the presence of asterixis. Ammonia levels are unreliable, and there is poor correlation between the grade of hepatic encephalopathy and ammonia blood levels. High levels (>150 μmol/L) are, however, indicative of hepatic encephalopathy and can be useful in the evaluation of a patient with neurocognitive disturbances of unknown origin. Psychometric tests and an electroencephalogram, which typically shows generalized slow waves and the presence of triphasic waves, are commonly used in research but are not generally used for clinical diagnosis. Minimal or subclinical hepatic encephalopathy, which is present in up to 80% of patients with cirrhosis, is diagnosed solely on the basis of abnormal results of psychometric and neuropsychological tests of attention (e.g., number connection test, digit symbol test) and psychomotor function (e.g., grooved pegboard). Screening of patients with cirrhosis for minimal hepatic encephalopathy is not widely recommended because diagnostic tests are not standardized and the benefits of treatment are uncertain.

Hepatopulmonary Syndrome and Portopulmonary Hypertension

The diagnostic criteria for hepatopulmonary syndrome are arterial hypoxemia with a PaO_2 of less than 80 mm Hg or an alveolar arterial oxygen gradient of greater than 15 mm Hg, along with evidence of pulmonary vascular shunting on contrast echocardiography (Chapter 43) or a ^{99m}Tc-labeled macroaggregated albumin scan demonstrating abnormal shunting of radioactivity to the brain. Portopulmonary hypertension is diagnosed by the presence of mean pulmonary arterial pressure higher than 25 mm Hg on right-sided heart catheterization, provided pulmonary capillary wedge pressure is less than 15 mm Hg.

TREATMENT

Treatment of cirrhosis should ideally be aimed at interruption or reversal of fibrosis. Although antifibrotic drugs have not been shown to reverse fibrosis consistently or to improve outcomes in patients with cirrhosis, eradication of the hepatitis C or the hepatitis B virus has been associated with regression of fibrosis. Treatment of compensated cirrhosis is currently directed at preventing the development of decompensation by (1) treating the underlying liver disease (e.g., antiviral therapy for hepatitis C or B) to reduce fibrosis and to prevent decompensation; (2) avoiding factors that could worsen liver disease, such as alcohol, hepatotoxic drugs, and superimposed viral infections; (3) lowering portal pressure by the use of nonselective β-adrenergic blockers (e.g., carvedilol, propranolol) that have been shown to prevent variceal hemorrhage and decompensation in patients with compensated cirrhosis; and (4) screening for hepatocellular carcinoma (so it can be treated at an earlier stage) (Fig. 139-6).[14] Treatment of decompensated cirrhosis focuses on specific decompensating events and the option of liver transplantation. Increasingly, data reveal that different therapies for the same complication may be applicable to patients with different risk profiles, mainly based on severity of the disease (see Table 139-2).

Varices and Variceal Bleeding

Reducing portal pressure decreases the risk for the development of varices and variceal hemorrhage, as well as the risk for ascites and death. Nonselective β-adrenergic blockers (propranolol, nadolol) reduce portal pressure by producing splanchnic vasoconstriction and decreasing portal venous inflow. In patients with cirrhosis and medium or large varices that have never bled, nonselective β-blockers significantly reduce the risk for first variceal hemorrhage.[A1] In patients who have compensated cirrhosis with no or small varices, nonselective β-blockers significantly reduce the risk of decompensation.[A2] Carvedilol (a nonselective β-blocker with vasodilating properties) is more effective than other β-blockers for lowering portal pressure[A3] and also reduces decompensation and death in patients who have compensated cirrhosis with significant portal hypertension.[A4] Therefore, carvedilol at a dose of 3.125 to 12.5 mg/day is now recommended to prevent decompensation.[15] In patients who cannot tolerate or have contraindications to nonselective β-blockers, endoscopic variceal ligation (see Fig. 125-3), a therapy that aims to obliterate varices by placing rubber rings on variceal columns, is at least as useful as traditional nonselective β-blockers to prevent a first variceal hemorrhage but will not prevent ascites. Ligation has no effect on portal pressure and can lead to hemorrhage from ligation-induced ulcers. Among patients who have cirrhosis, screening endoscopy should be repeated every 2 to 3 years in patients with no varices, every 1 to 2 years in patients with small varices, and sooner in patients with decompensated disease so that ligation can be instituted before the varices grow in size and bleed.

Patients with cirrhosis and variceal hemorrhage require resuscitation in an intensive care unit. However, over-transfusion should be avoided because it can precipitate rebleeding. Hemoglobin values should be maintained at about 8 g/dL. Prophylactic antibiotics should be used in this setting not only to prevent bacterial infections but also to decrease rebleeding and death. The recommended antibiotic is ceftriaxone at a dose of 1 g/day for 5 to 7 days.

The most effective specific therapy for the control of active variceal hemorrhage is the combination of a vasoconstrictor with endoscopic therapy. Safe vasoconstrictors include terlipressin, somatostatin, and the somatostatin analogues octreotide and vapreotide; they can be initiated at admission to the hospital and continued for 2 to 5 days. The vasoconstrictor currently available in the United States is octreotide, which is used as a 50-μg intravenous bolus followed by an infusion at 50 μg/hour. The preferred endoscopic therapy to control variceal hemorrhage is esophageal variceal ligation.[A5] In cases in which bleeding continues despite vasoconstrictors and ligation, an esophageal stent appears to be more effective as a bridge to a more definitive therapy and is safer than balloon tamponade, although it may not reduce mortality.[A6]

The transjugular intrahepatic portosystemic shunt (TIPS) is generally recommended for patients who fail to respond to standard therapy (Fig. 139-7). In patients at high risk of failure, Child C (score 10 to 13) patients and Child B patients who have actively bleeding varices at endoscopy, preemptive TIPS placement (24 to 48 hours after admission) is associated with a reduced failure rate and a significant improvement in survival. Therefore, preemptive "early" TIPS should be considered in high-risk subpopulations of patients with variceal hemorrhage.[A7–A9] Even though patients with cirrhosis and coagulopathy (prolonged international normalized ratio or decreased platelet count) have a higher risk of not responding to hemostasis for variceal hemorrhage or bleeding from procedures (ligation, paracentesis, TIPS, surgery), neither recombinant factor VII nor eltrombopag has proved beneficial in randomized trials, and neither is recommended.

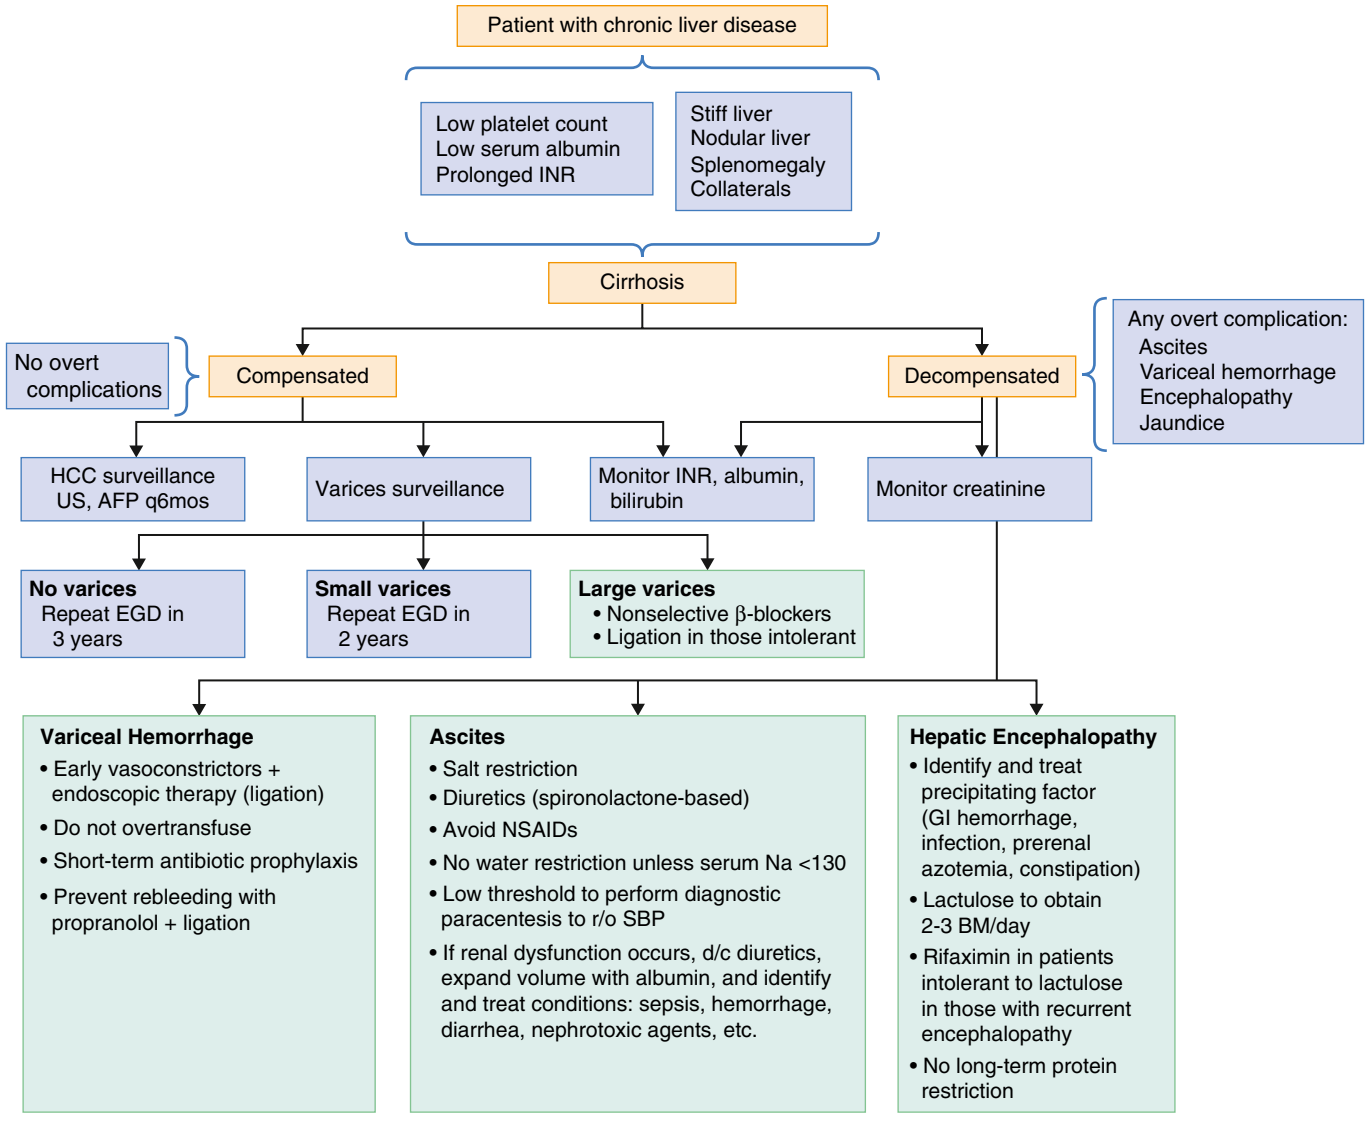

FIGURE 139-6. **Summary of the management of compensated and decompensated cirrhosis.** AFP = α-fetoprotein; BM = bowel movement; d/c = discontinue; EGD = esophagogastroduodenoscopy; GI = gastrointestinal; HCC = hepatocellular carcinoma; INR = international normalized ratio; Na = sodium; NSAIDs = nonsteroidal anti-inflammatory drugs; r/o = rule out; SBP = spontaneous bacterial peritonitis; US = ultrasound.

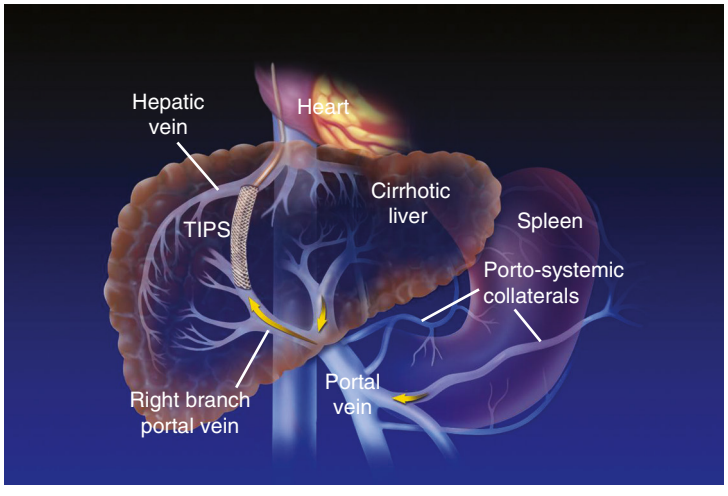

FIGURE 139-7. **Transjugular intrahepatic portosystemic shunt (TIPS).** This shunt is performed by interventional radiologists and consists of an expandable metal stent (most often coated with polytetrafluoroethylene) that connects a branch of the portal vein (high-pressure vein) to a branch of the hepatic vein (low-pressure vein). The shunt decompresses the portal system and portosystemic collaterals, and therefore it is used in the treatment of selected patients with cirrhosis and variceal hemorrhage. The shunt also decompresses the hepatic sinusoids and therefore is also used in the treatment of refractory ascites.

After control of hemorrhage, the 1-year recurrence of hemorrhage without treatment is high, at about 60%. Therefore, therapy to prevent rebleeding should be instituted before the patient is discharged. The recommended therapy is a combination of nonselective β-blockers (propranolol or nadolol) and endoscopic variceal ligation.[A10] The dose of β-blockers should be the maximum dose that is tolerated, and endoscopic variceal ligation should be repeated every 2 to 4 weeks until the varices are obliterated. Patients who had TIPS placed during the episode of acute variceal hemorrhage do not require β-blockers or ligation but do require periodic Doppler examination of the shunt to assess its patency.

Shunt therapy, either surgical or through radiologic placement of a TIPS, should be used in patients whose variceal bleeding has persisted or recurred despite combined pharmacologic and endoscopic therapy. Both types of shunts are equally effective, and the choice will depend on local expertise. Although the uncovered TIPS frequently occludes, polytetrafluoroethylene-covered stents are associated with lower occlusion rates and lower rates of hepatic encephalopathy. In a randomized trial, covered stents were more effective than β-blockers in preventing variceal rebleeding in patients with cirrhosis, but they produced slightly more adverse events without increasing survival time or quality of life.[A11]

Ascites

Salt restriction and diuretics constitute the mainstay of management of ascites.[16] Dietary sodium intake should be restricted to 2 g/day. A more restrictive diet is not recommended and may compromise nutritional status.

Spironolactone, which is more effective than loop diuretics, should be started at a dose of 100 mg/day (once a day in the morning). The dose should be adjusted every 3 to 4 days to a maximal effective dose of 400 mg/day. Furosemide, at an escalated dose from 40 to 160 mg/day, can be started concurrently with

spironolactone if ascites is tense or added subsequently if weight loss is inadequate or if hyperkalemia develops with spironolactone alone. The goal is weight loss of 1 kg in the first week and 2 kg/week subsequently. However, diuretics should be reduced if the rate of weight loss is more than 0.5 kg/day in patients without peripheral edema or more than 1 kg/day in patients with peripheral edema. Side effects of diuretic therapy include hypovolemic hyponatremia, hyperkalemia, renal dysfunction, encephalopathy, and, with spironolactone, painful gynecomastia.

In the acute setting, albumin infusion alone appears to be of no benefit and can increase the risk of pulmonary edema.[A12] However, the addition of long-term human albumin (40 g twice weekly for 2 weeks, then 40 g weekly) to spironolactone and furosemide can significantly reduce recurrent ascites[A13] and improve 18-month survival.[A14]

In the 10 to 20% of patients with ascites who are refractory to diuretics, large-volume paracentesis, aimed at removal of all or most of the fluid, plus albumin at a dose of 6 to 8 g intravenously per liter of ascites removed, particularly when more than 5L is removed at once, is a reasonable approach. The frequency of large-volume paracentesis is dictated by the rapidity at which the ascites reaccumulates. TIPS with uncovered stents is more effective than large-volume paracentesis plus albumin in preventing recurrent ascites but is associated with a higher rate of encephalopathy. In patients requiring frequent large-volume paracentesis (more than twice per month), a polytetrafluoroethylene-covered TIPS can improve survival.[A15] A peritoneovenous shunt, with use of a subcutaneously placed silicone tube that transfers ascites from the peritoneal cavity to the systemic circulation, can be used in patients who are not candidates for TIPS or liver transplantation. Automated flow pumps to move ascitic fluid to the bladder can reduce the need for large-volume paracentesis and improve quality of life in patients with medically untreatable ascites, but they require surgical placement and are at risk for infection.[A16]

Hyponatremia

Fluid restriction to 1.5 liters daily is recommended for severe hyponatremia (serum sodium concentration <130 mEq/L), but adherence with this recommendation is poor. Although V2-receptor antagonists such as tolvaptan are sometimes effective at increasing free water excretion and raising the serum sodium level in hyponatremic cirrhotic patients, they have no overall effect on survival and are not approved for this use because of potential hepatotoxicity. Because hyponatremia is a marker of neurologic dysfunction and increased mortality, short-term use of tolvaptan (15 mg/day, increased to 30 to 60 mg/day if needed) may be indicated only as a bridge to liver transplantation in patients in whom transplantation is imminent (Chapter 140).

Hepatorenal Syndrome

Hepatorenal syndrome is a functional kidney injury that results from hemodynamic abnormalities owing to end-stage liver disease and severe portal hypertension, and it is associated with a high mortality despite specific therapy. As a result, documented hepatorenal syndrome in the absence of prerenal azotemia or acute tubular necrosis represents a priority for transplantation (Chapter 140). Specific therapies for hepatorenal syndrome that have been used to "bridge" a patient to transplantation include vasoconstrictors (terlipressin, norepinephrine, octreotide plus midodrine) plus albumin, TIPS, and extracorporeal albumin dialysis, which is an experimental hemofiltration dialysis method that uses an albumin dialysate. The largest experience is with the use of terlipressin, which at a dose of 0.5 to 2.0 mg intravenously every 4 to 6 hours leads to a higher reversal rate of hepatorenal syndrome compared with placebo.[A17] However, terlipressin can also cause adverse effects, such as respiratory failure, and must be used with caution.

Spontaneous Bacterial Peritonitis

Empirical antibiotic therapy with an intravenous third-generation cephalosporin (e.g., cefotaxime 2 g intravenously every 12 hours or ceftriaxone 2 g intravenously every 24 hours) should be initiated as soon as the diagnosis is established and before culture results are available; the minimal duration of therapy should be 5 days. Response to recommended empirical antibiotics is significantly lower in patients with health care–associated infections (i.e., infections that occur in patients who have been in a health care facility within the prior 3 months) and particularly low in nosocomial infections (i.e., infections that occur >48 hours after hospitalization) because more infections are caused by multidrug-resistant organisms. In these settings, broader-spectrum antibiotics (e.g., vancomycin-tazobactam, imipenem, ertapenem [Chapter 94]) should be given initially and then modified after culture results and antibiotic sensitivities are obtained. Aminoglycosides should be avoided because of the high incidence of renal toxicity in cirrhotic patients.

Repeated diagnostic paracentesis should be performed 2 days after antibiotics are started, by which time the number of PMN neutrophils in ascitic fluid should have decreased by more than 25% from baseline. Lack of response should prompt further investigations to exclude secondary peritonitis. The renal dysfunction associated with spontaneous bacterial peritonitis can be prevented by the intravenous administration of albumin, particularly in patients who have any evidence of renal dysfunction (blood urea nitrogen >30 mg/dL or creatinine >1 mg/dL, or both) or serum bilirubin concentration higher than 4 mg/dL at the time of diagnosis. Albumin at a dose of 1.5 g per kilogram of body weight at diagnosis, repeated on the third day at an intravenous dose of 1 g per kilogram of body weight, can reduce the risk of renal failure and acute mortality. However, this dosing is empirical, should not exceed 100 g per dose, and does not reduce 3-month mortality in cirrhotic patients with infections other than spontaneous bacterial peritonitis.[A18]

The administration of nonabsorbable (or poorly absorbable) antibiotics can prevent the development of spontaneous bacterial peritonitis and other infections in cirrhosis by selectively eliminating gram-negative organisms in the gut.[17] However, norfloxacin, which was used for this purpose, was withdrawn from the U.S. market in 2014. Reasonable alternatives include oral ciprofloxacin 500 mg every day or rifaximin 600 mg twice daily.[18] Long-term antibiotic prophylaxis may be justified only in two groups: patients who have recovered from a previous episode of spontaneous bacterial peritonitis and patients who have an ascites protein level of less than 1 g/L with advanced liver and circulatory dysfunction as evidenced by the presence of jaundice, hyponatremia, or renal dysfunction.

Hepatic Encephalopathy

Treatment of overt hepatic encephalopathy starts by exclusion of alternative causes of altered mental status. Once the diagnosis of hepatic encephalopathy has been made, treatment involves identifying and treating the precipitating factor and reducing the ammonia level. Precipitating factors include infections, overdiuresis, gastrointestinal bleeding, high oral protein load, and constipation. Narcotics and sedatives contribute to hepatic encephalopathy by directly depressing brain function. TIPS is a common precipitant of hepatic encephalopathy, and shunt reduction or occlusion may be required. Among agents aimed at decreasing ammonia production in the gut, lactulose (15 to 30 mL orally twice daily adjusted to obtain two or three soft bowel movements per day) is the first choice for the treatment of episodic overt encephalopathy.[19] Polyethylene glycol 3350-electrolyte solution (4 L orally or by nasogastric tube over 4 hours), however, may lead to a more rapid clinical response. Other agents include orally administered nonabsorbable antibiotics, such as rifaximin (550 mg two times per day),[A19] neomycin (500 mg to 1 g three times per day), and metronidazole (250 mg two to four times per day). Drugs that may increase ammonia fixation in the liver, such as L-ornithine-L-aspartate, benzoate, and glycerol phenylbutyrate, are being studied.

Once an episode of overt encephalopathy has resolved, secondary prophylaxis with lactulose is recommended. If a precipitating factor has been identified and is well controlled or when liver function or nutritional status has improved, prophylactic therapy may be discontinued. In patients with recurrent encephalopathy, rifaximin together with lactulose is useful in preventing further recurrence. Switching dietary protein from an animal source to a vegetable source may be beneficial in recurrent or persistent encephalopathy, but protein restriction is not necessary and should not be used chronically. Experimental approaches can engineer gut microbiota to reduce urease activity in mice, but whether this approach can be extended to humans is unknown.

Pulmonary Complications

Hepatopulmonary syndrome rarely resolves spontaneously, and medical therapy is disappointing.[20] TIPS is not generally recommended. The only viable treatment is liver transplantation (Chapter 140).

By comparison, liver transplantation is indicated only in a subset of patients with portopulmonary hypertension. In fact, a mean pulmonary arterial pressure higher than 45 mm Hg is an absolute contraindication to liver transplantation. The use of vasodilators should be considered in these patients (Chapter 69).

Surgical Therapy

Liver Transplantation

Orthotopic liver transplantation (Chapter 140), which is the definitive therapy for cirrhosis, is indicated when the risk for dying of liver disease is greater than the risk for dying of transplantation, as determined by a Child-Pugh score of 7 or higher (see Table 139-2) or a Model for End-Stage Liver Disease (MELD) score of 15 or higher. MELD and MELD-Na (see Table 139-2), which estimate the risk for 3-month mortality, are used to determine the priority for liver transplantation. The number of available deceased donor organs is lower than the number of patients awaiting liver transplantation; as a result, 15 to 20% of patients awaiting liver transplantation in the United States die before an organ becomes available.

PREVENTION

Treatment of the underlying liver disease, before the development of cirrhosis, is a primary prevention strategy. Because the major causes of cirrhosis are related to lifestyle choices such as injection drug use (Chapter 365), alcohol consumption (Chapter 364), obesity, and unprotected sex, primary prevention programs that focus on encouraging alcohol abstinence, reducing high-risk behavior for hepatitis virus infection, weight reduction, and vaccination for hepatitis B are even better prevention strategies.

PROGNOSIS

The outcome of cirrhosis depends on the patient's stage. Patients with compensated cirrhosis die of liver disease only after transition to a decompensated stage. The 10-year survival rate of patients who remain in a compensated stage is approximately 90%, whereas their likelihood of decompensation is 50% at 10 years. Inception cohort studies of patients with compensated cirrhosis show a median survival of all patients, including those in whom decompensation develops over time, of about 10 years. Overall, the median survival after decompensation is about 2 years.[21] Survival is even lower in patients with refractory ascites, hyponatremia, or recurrent variceal hemorrhage and is lowest in patients who are hospitalized with an acute decompensating event, in whom 28-day mortality is about 30% and correlates with the number of organ failures present. Hepatocellular carcinoma develops at a fairly constant rate of 3% per year and is associated with a worse outcome at whatever stage it develops.

Predictors of survival are somewhat different in compensated and decompensated patients. Parameters of portal hypertension (varices, splenomegaly, platelet count, γ-globulin) assume greater importance in compensated patients, whereas renal dysfunction, hemorrhage, and hepatocellular carcinoma are important predictive factors in patients with decompensated cirrhosis. In clinical practice, the Child-Pugh score is applicable to all cirrhotic patients, and the MELD score is used in decompensated patients to determine priority for liver transplantation (see Table 139-2).

140 LIVER FAILURE AND TRANSPLANTATION

ROBERT J. FONTANA

LIVER FAILURE

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute liver failure, which is a rare disorder seen in 2000 to 3000 U.S. patients each year, is defined as a severe acute liver injury that precipitates the sudden onset of encephalopathy and coagulopathy (international normalized ratio [INR] > 1.5).[1] By definition, acute liver failure results from an insult within the prior 6 months. Acute-on-chronic liver failure is defined when liver injury of longer duration worsens and causes liver failure or other complications of portal hypertension.[2]

Nearly 50% of all cases of acute liver failure are caused by acetaminophen hepatotoxicity (Chapters 96 and 136), whereas idiosyncratic drug-induced liver injury (Chapter 136), autoimmune hepatitis (Chapter 135), acute hepatitis B (Chapter 134), and shock liver (Chapter 92) account for more than a quarter of cases.[3]

Acute-on-chronic liver failure can sometimes be precipitated by the same acute insults that cause acute liver failure. More commonly, however, acute-on-chronic liver failure occurs when cirrhosis (Chapter 139) decompensates because of a comparatively minor insult superimposed on serious but compensated underlying liver disease, or when ongoing alcoholic liver disease (Chapter 138), fatty liver disease (Chapter 138), or a metabolic liver disease (e.g., hemochromatosis [Chapter 196] or Wilson disease [Chapter 195]) causes severe progressive injury.

Liver failure results in loss of the liver's ability to synthesize coagulation factors and metabolize ammonia. The rapid loss of hepatocytes results in a massive release of cytokines, thereby leading to tissue hypoxia and lactic acidosis. The encephalopathy of acute liver failure is mediated by cerebral edema, not by the portosystemic shunting and portal hypertension of cirrhosis (Chapter 139).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of liver failure are the same as the manifestations of severe cirrhosis (Chapter 139). Hepatic encephalopathy and coagulopathy are the dominant features, but ascites, hepatorenal syndrome, hepatopulmonary syndrome, and portopulmonary hypertension typically occur. Variceal bleeding is more common in acute-on-chronic liver failure.

Patients with acute liver failure typically have the rapid onset of the encephalopathy and coagulopathy (INR > 1.5), but the onset can be slower in patients who have acute-on-chronic liver failure.[4] The severity of acute liver failure and the adequacy of tissue perfusion (e.g., serum pH and lactate level) can be assessed by measuring blood levels of markers that are synthesized by the liver (e.g., the INR, factor V level, and serum albumen level) or processed by the liver (e.g., serum arterial ammonia level and bilirubin level) and then monitoring them serially. Because factor V is the coagulation factor with the shortest half-life, it is the most sensitive biomarker to detect trends over time. The patient's grade of encephalopathy should be assessed on a scale of 1 (subtle, minimal change in consciousness), 2 (disoriented, inappropriate), 3 (somnolent but arousable), or 4 (comatose).

TREATMENT

Patients who have acute liver failure should be stabilized in an intensive care unit, where any neurologic, respiratory, hemodynamic, infectious, and renal complications should be addressed.[5] *N*-acetylcysteine (a 140 mg/kg loading dose followed by 70 mg/kg every 4 hours) should be administered immediately to all patients with suspected acetaminophen hepatotoxicity (Chapter 136). Based on limited data that raise the possibility of its potential benefit, N-acetylcysteine is also commonly recommended in acute liver failure caused by idiosyncratic drug-induced liver injury, hepatitis B, and autoimmune hepatitis, as well as acute liver failure of indeterminate cause, especially in patients who have grade 1 or 2 encephalopathy.[6]

Removal of the offending agent for idiosyncratic drug-induced liver injury (Chapter 136), nucleos(t)ide analogues for acute hepatitis B (Chapter 134), acyclovir for herpes simplex virus (Chapter 345), copper chelation and

140 LIVER FAILURE AND TRANSPLANTATION

ROBERT J. FONTANA

LIVER FAILURE

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute liver failure, which is a rare disorder seen in 2000 to 3000 U.S. patients each year, is defined as a severe acute liver injury that precipitates the sudden onset of encephalopathy and coagulopathy (international normalized ratio [INR] > 1.5).[1] By definition, acute liver failure results from an insult within the prior 6 months. Acute-on-chronic liver failure is defined when liver injury of longer duration worsens and causes liver failure or other complications of portal hypertension.[2]

Nearly 50% of all cases of acute liver failure are caused by acetaminophen hepatotoxicity (Chapters 96 and 136), whereas idiosyncratic drug-induced liver injury (Chapter 136), autoimmune hepatitis (Chapter 135), acute hepatitis B (Chapter 134), and shock liver (Chapter 92) account for more than a quarter of cases.[3]

Acute-on-chronic liver failure can sometimes be precipitated by the same acute insults that cause acute liver failure. More commonly, however, acute-on-chronic liver failure occurs when cirrhosis (Chapter 139) decompensates because of a comparatively minor insult superimposed on serious but compensated underlying liver disease, or when ongoing alcoholic liver disease (Chapter 138), fatty liver disease (Chapter 138), or a metabolic liver disease (e.g., hemochromatosis [Chapter 196] or Wilson disease [Chapter 195]) causes severe progressive injury.

Liver failure results in loss of the liver's ability to synthesize coagulation factors and metabolize ammonia. The rapid loss of hepatocytes results in a massive release of cytokines, thereby leading to tissue hypoxia and lactic acidosis. The encephalopathy of acute liver failure is mediated by cerebral edema, not by the portosystemic shunting and portal hypertension of cirrhosis (Chapter 139).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of liver failure are the same as the manifestations of severe cirrhosis (Chapter 139). Hepatic encephalopathy and coagulopathy are the dominant features, but ascites, hepatorenal syndrome, hepatopulmonary syndrome, and portopulmonary hypertension typically occur. Variceal bleeding is more common in acute-on-chronic liver failure.

Patients with acute liver failure typically have the rapid onset of the encephalopathy and coagulopathy (INR > 1.5), but the onset can be slower in patients who have acute-on-chronic liver failure.[4] The severity of acute liver failure and the adequacy of tissue perfusion (e.g., serum pH and lactate level) can be assessed by measuring blood levels of markers that are synthesized by the liver (e.g., the INR, factor V level, and serum albumen level) or processed by the liver (e.g., serum arterial ammonia level and bilirubin level) and then monitoring them serially. Because factor V is the coagulation factor with the shortest half-life, it is the most sensitive biomarker to detect trends over time. The patient's grade of encephalopathy should be assessed on a scale of 1 (subtle, minimal change in consciousness), 2 (disoriented, inappropriate), 3 (somnolent but arousable), or 4 (comatose).

TREATMENT

Patients who have acute liver failure should be stabilized in an intensive care unit, where any neurologic, respiratory, hemodynamic, infectious, and renal complications should be addressed.[5] *N*-acetylcysteine (a 140 mg/kg loading dose followed by 70 mg/kg every 4 hours) should be administered immediately to all patients with suspected acetaminophen hepatotoxicity (Chapter 136). Based on limited data that raise the possibility of its potential benefit, N-acetylcysteine is also commonly recommended in acute liver failure caused by idiosyncratic drug-induced liver injury, hepatitis B, and autoimmune hepatitis, as well as acute liver failure of indeterminate cause, especially in patients who have grade 1 or 2 encephalopathy.[6]

Removal of the offending agent for idiosyncratic drug-induced liver injury (Chapter 136), nucleos(t)ide analogues for acute hepatitis B (Chapter 134), acyclovir for herpes simplex virus (Chapter 345), copper chelation and

ABSTRACT

Liver transplantation is a life-saving treatment for acute and acute-on-chronic liver failure caused by alcoholic liver disease, nonalcoholic steatohepatitis, viral hepatitis, autoimmune disorders, certain hepatic malignancies, and some genetic conditions. Pre-transplantation management of the acute liver failure is key. Most transplants are from deceased donors, with priority assigned based on the severity of illness and ABO compatibility. However, living donor transplants are increasingly performed. Postoperative issues include surgical complications, management of immunosuppressive agents, and prophylaxis and treatment of infections.

plasmapheresis for Wilson disease (Chapter 195), corticosteroids for autoimmune hepatitis (Chapter 135), delivery of the infant for pregnancy-related liver disease (Chapter 221), and a continuous heparin infusion for Budd-Chiari syndrome (Chapter 129) should be implemented.

The management of varices and variceal bleeding, ascites, hyponatremia, hepatorenal syndrome, and the hepatopulmonary syndrome is as recommended for cirrhosis. Although coagulopathy is inherent to acute liver failure, routine transfusions of plasma and platelets are not recommended because the excess volume can exacerbate cerebral and pulmonary edema without significant benefit.

To prevent intracranial hypertension, the head of the bed should be elevated above 30 degrees from horizontal, and efforts should be taken to minimize movement and Valsalva maneuvers. All sedative and psychotropic drugs should be avoided because of their delayed clearance. For acute kidney injury, continuous renal replacement therapy is preferred over hemodialysis and may help improve outcomes by reducing systemic ammonia levels.[7] When patients develop grade 3 encephalopathy, their respiratory status should be carefully monitored so that they can be electively intubated with a target P_{CO_2} of 28 to 30 mm Hg to facilitate intracerebral vasoconstriction.[8]

Invasive intracranial pressure (ICP) monitoring using intraparenchymal devices should be considered to guide medical therapy in nonresponsive patients with grade 3 or 4 encephalopathy because other signs of worsening neurologic function (e.g., posturing, dilated pupils, abnormalities on a brain computed tomographic scan) are frequently not present. Placement of an ICP monitor carries a 10 to 20% risk of intracranial bleeding, so all patients should receive desmopressin (20 μg) plus individualized doses of recombinant factor VIIa, fresh frozen plasma, or plasma factor concentrate under expert supervision to lower the risk of hemorrhage to less than 5%.[9] Surges in ICP that reduce cerebral perfusion pressure may be treated with an intravenous bolus of hypertonic saline (1 to 4 mL/kg of 3 to 10% saline over 30 minutes) or mannitol (0.5 to 1 mg/kg IV), with concomitant monitoring of serum sodium and osmolarity levels. Pentobarbital (100 to 150 mg bolus followed by 1 to 3 mg/kg/hour) can be used in patients who have refractory cerebral edema. Moderate hypothermia to 32° to 33° C via external cooling blankets may be helpful, but data are currently insufficient to recommend its routine use.

Serious bacterial infections are documented in about 80% of patients with acute liver failure, including fungal infections in about 20%. Any fever requires comprehensive evaluation (Chapters 259 and 260), with a low threshold for starting empirical broad-spectrum antibiotics while awaiting culture results if patients suffer from clinical deterioration.

PROGNOSIS

The likelihood of spontaneous recovery from acute liver failure without liver transplant can be estimated by knowing its cause, the initial severity of hepatic encephalopathy, the need for vasopressor or ventilatory support, and the laboratory parameters (e.g., the INR and bilirubin level) and vital organ function over time. Acute liver failure that is pregnancy-related or caused by acetaminophen, ischemia, or hepatitis A has a higher rate of spontaneous liver recovery (50 to 70%) compared with other causes of acute liver failure (20 to 50%). Hypophosphatemia is suggestive of liver regeneration and is a positive prognostic sign.

Patients who have a predicted transplant-free survival of less than 80% (see https://appadvice.com/app/acute-liver-failure-prognostic) should be considered for early transfer to a liver transplant center for further evaluation. Even if patients initially are at lower risk, however, they may require emergency liver transplantation if they exhibit no signs of liver recovery and regeneration, despite disease-specific interventions and general supportive care. Qualifying patients should be placed on the liver transplant waiting list with the highest priority, known as status 1A. With emergency surgery, patients in acute liver failure can achieve a 2-year survival as high as 92% with excellent neurologic and clinical outcomes. However, only 30% of listed patients who have acute liver failure undergo transplantation because of either spontaneous improvement or the development of a contraindication to liver transplantation. As a result, acute liver failure accounts only for 3 to 5% of annual liver transplants in the United States.

When patients with decompensated cirrhosis (Chapter 139) develop acute-on-chronic liver failure with variceal hemorrhage, ascites, and/or hepatic encephalopathy, they should be referred for evaluation for a liver transplant because of their increased risk of short-term mortality.[10,11,12] Adult patients with compensated cirrhosis have a median survival of 12 years and typically do not require referral for a possible liver transplant unless they have a Sodium-Model for End-Stage Liver Disease (Na-MELD) score above 15 (see Table 139-2), progressive protein calorie malnutrition, or severe clinical symptoms (e.g., muscle wasting, severe pruritus, recurrent encephalopathy, ascites, or gastrointestinal bleeding) that will improve with liver transplant. Patients who have the hepatopulmonary syndrome or portopulmonary hypertension (Chapter 139) may qualify for a higher priority on the waiting list via Na-MELD exception scores.

LIVER TRANSPLANTATION

Liver transplantation is a life-saving therapy for selected patients who have severe acute or chronic liver failure, as well as patients who have certain genetic, metabolic, and intrahepatic neoplastic disorders. In the United States, over 150 liver transplant centers perform nearly 9000 liver transplants annually. Deceased donors account for about 95% of transplanted livers, whereas about 5% are from living donors (Fig. 140-1).[13] At any given time, approximately 13,000 patients are on the liver transplant waiting list. The size of the deceased organ donor pool has gradually increased owing to the use of livers from deceased donors who are elderly or have hepatic steatosis, chronic hepatitis C, or prior hepatitis B infection. Nevertheless, the pre-transplant mortality rate for patients on the waiting list remains 7 to 12 deaths per 100 waiting list-years. By comparison, the 1- and 5-year recipient survival rates are now about 93 and 82%, respectively (Fig. 140-2).

INDICATIONS FOR LIVER TRANSPLANTATION

Chronic alcohol-related liver disease (Chapter 138), is now the most common underlying indication for liver transplant (Fig. 140-3) because of the success of antiviral therapies for treating chronic hepatitis C (Chapter 135). Nonalcoholic fatty liver disease (Chapter 138) is another increasing indication for liver transplant because of the obesity epidemic in the United States and other developed and even developing countries (Chapter 201).

Acute or Acute-on-Chronic Liver Failure

Liver transplantation is reserved for patients who have acute or acute-on-chronic liver failure with a high 90-day risk of death, as well as patients who

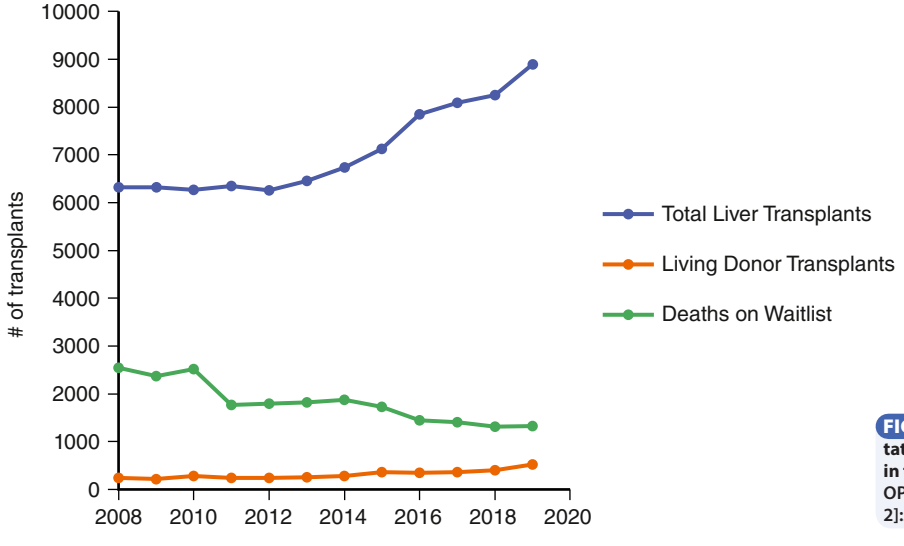

FIGURE 140-1. Annual number of patients undergoing liver transplantation, living donor liver transplantation, and dying on the waiting list in the United States. FIGURE 140-3. Leading indications for adult liver transplantation in the United States (Based on data from Kwong AJ, Kim WR, Lake JR, et al. OPTN/SRTR 2019 annual data report: liver. *Am J Transplant*. 2021;21[Suppl 2]:208-315. Courtesy of Jason Pan, MD.)

have metabolic, genetic, and neoplastic diseases that may be cured with liver transplantation.[14] When a patient with progressive cirrhosis experiences hepatic decompensation (e.g., ascites, variceal hemorrhage, portal vein thromboses, hepatic encephalopathy), progressive protein calorie malnutrition, or deteriorating laboratory indices, the patient should be referred for liver transplant evaluation. Most patients who have cirrhosis and a Na-MELD score of 15 or higher (Table 139-2) are likely to have a survival benefit with transplantation. Patients who have unique qualifying complications of portal hypertension (e.g., hepatopulmonary syndrome or refractory hepatic hydrothorax) may also receive high priority.[15]

Hepatobiliary Cancer

Hepatocellular carcinoma is the primary indication for 10 to 20% of adult liver transplants in the United States. To qualify for transplant independently of their Na-MELD score, patients must have: no evidence of extrahepatic disease or vascular invasion; one lesion that is less than 5 cm in size, or two or three lesions, each less than 3 cm in size; and a serum α-fetoprotein level less than 1000 ng/mL. Hepatocellular carcinoma patients who meet these criteria have a 5-year post-transplant survival approaching 80%.[16] If locoregional therapy, radiation, or chemoembolization (Chapter 181) reduces the size of the tumor(s), patients who do not meet these criteria may be downstaged, become eligible for transplantation, and do as well as patients who met transplantation criteria without downstaging.

Selected patients with locally advanced perihilar cholangiocarcinoma may also qualify for transplantation, regardless of their Na-MELD score if they have unresectable disease or have underlying liver disease that would make them poor candidates for resection surgery. Before transplantation, such patients should receive neoadjuvant chemotherapy and radiation (Chapter 181) and then undergo operative staging to ensure that they have no lymphatic, intrahepatic, or extrahepatic metastases. In eligible patients, the 5-year recurrence-free survival with neoadjuvant therapy and liver transplant is about 65%. Other uncommon indications for liver transplantation include hemangioendotheliomas and metastatic neuroendocrine and carcinoid tumors to the liver (Chapter 213).

Metabolic Disorders

Inborn errors of metabolism, such as primary hyperoxaluria, urea cycle disorders, and organic acidemias (Chapter 189) do not cause parenchymal liver disease or fibrosis.[17] However, liver transplantation can correct the enzymatic defects by lowering ammonia levels in urea cycle disorders and organic acidemia, lowering oxalate levels in primary hyperoxaluria, and providing normal protein in patients with familial amyloid polyneuropathy (Chapter 174). Liver transplantation also can prevent progression of systemic manifestations of these diseases but does not typically reverse preexisting systemic clinical manifestations, such as the intellectual deficits in the urea cycle disorders and organic acidemias or advanced neurologic symptoms and cardiac disease in familial amyloidosis or in patients with Wilson disease.

SELECTION FOR TRANSPLANTATION

Liver transplant candidates should be carefully evaluated by a multidisciplinary team to ensure that they have severe enough disease to warrant transplantation but also will be able to tolerate the surgery and associated immunosuppression with a favorable 5-year outcome. The presence of severe cardiopulmonary disease, active use of illicit substances or alcohol, frailty, and nonadherence with medical care are contraindications to transplantation (Table 140-1). A patient's eligibility for transplantation may vary over time and should be reassessed

TABLE 140-1 CONTRAINDICATIONS TO LIVER TRANSPLANTATION

Relapsing illicit substance or alcohol use
Inadequate social support
Severe or untreated psychiatric disease or behavioral concerns
Severe cardiopulmonary disease
Active extrahepatic malignancy
Uncontrolled sepsis or other severe infections
Active HIV infection with AIDS-defining illness
Irreversible neurologic disease
Anatomic anomalies or extensive vascular thromboses that are prohibitive to transplant
Severe malnutrition and frailty

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

whenever they undergo a clinical change, hospitalization, or a decompensating liver-related event.

Preoperative Medical Assessment

The pre-transplant evaluation process initially involves confirming the cause of the liver disease and determining whether any treatment other than transplantation may be effective. Then an assessment of the patient's severity of disease, operative risk, and nutritional and functional status is undertaken. Patients should complete age- and gender-appropriate cancer screenings (e.g., head and neck examination, skin examination, colonoscopy, mammography, pelvic examination, prostate-specific antigen determination). Blood typing is needed to ensure proper matching with potential donors, but matching by human leukocyte antigen (HLA) type is not required.

Liver transplantation surgery places significant stress on the heart and lungs, so patients with heart failure, inadequately treated coronary artery disease, severe valvular disease, or moderate to severe pulmonary hypertension are frequently excluded from consideration. All transplant candidates should have an electrocardiogram, a transthoracic echocardiogram with Doppler and bubble study to exclude intrapulmonary shunting, and a chest radiograph to screen for cardiopulmonary disease. Patients at risk for coronary artery disease should undergo formal cardiac stress testing with follow-up coronary angiography as indicated (Chapters 44 and 56).[18] Patients who have smoked or have underlying lung disease should undergo pulmonary function tests (Chapter 73) and pulse oximetry. Patients who have stage IV or V chronic kidney disease (Chapter 116) or who have been on hemodialysis for more than 90 days may be considered for combined liver and kidney transplantation.

Because of the need for lifelong immunosuppression, recipients of liver transplants are at risk for both bacterial and opportunistic infections. A careful dental examination is important to exclude an oral source of chronic infection. Latent pathogens such as tuberculosis (Chapter 299), Epstein-Barr virus (Chapter 348), cytomegalovirus (Chapter 347), toxoplasma (Chapter 320), and hepatitis B (Chapter 135) may reactivate in the setting of immunosuppression, so patient's prior exposure must be assessed before transplantation to plan for proper prophylaxis. Vaccinations against hepatitis A, hepatitis B, influenza, pneumococcus, herpes zoster, and COVID-19 infection (Chapter 15) are recommended before transplantation whenever possible. Patients with well-controlled human immunodeficiency virus (HIV) on stable antiretroviral therapy (Chapter 357) may undergo liver transplantation at specialized centers with good outcomes. However, patients with uncontrolled HIV infection or acquired immunodeficiency syndrome are excluded from liver transplantation because their outcomes are poor.

Patients who have severe malnutrition (Chapter 198), frailty (Chapter 24), morbid obesity (Chapter 201), or are older than age 70 years must be carefully assessed on an individual basis because they are at higher risk for postoperative complications and poor allograft function. Preoperative contrast-enhanced computed tomographic (CT) or magnetic resonance (MR) imaging of the liver is recommended in most centers for surgical planning and to evaluate for portal vein thromboses and atherosclerosis of the major vessels.

Preoperative Psychosocial Assessment

Successful liver transplantation requires long-term adherence to medication regimens, laboratory monitoring, and outpatient follow-up, as well as continued lifelong abstinence from alcohol, tobacco, and other illicit substances. Poor adherence may arise from a lack of motivation, poor social support, inability to maintain insurance coverage, and severe or untreated psychiatric conditions or substance use disorders. Long-term (≥6 months) preoperative abstinence from alcohol is desirable, in part to determine whether liver function may improve, but is not as predictive of the likelihood of recidivism as are factors such as social isolation, underlying psychiatric conditions, and family support. For example, selected patients with severe alcoholic hepatitis and a first episode of hepatic decompensation that is refractory to corticosteroids may do well after emergent liver transplantation combined with intensive post-transplantation treatment of the alcohol use disorder.[19]

A multidisciplinary team that involves hepatologists, social workers, psychiatrists, and psychologists may best identify and address any potential barriers to transplantation. In addition, liver transplantation candidates are typically screened with periodic toxicology testing, such as a serum phosphatidylethanol level, urine toxicology, urine ethyl glucuronide, and urine cotinine levels. Formal pre-transplantation education instructs patients, their families, and caregivers about the process of transplantation and the need for lifelong abstinence from illicit substances and compliance with medical treatments.

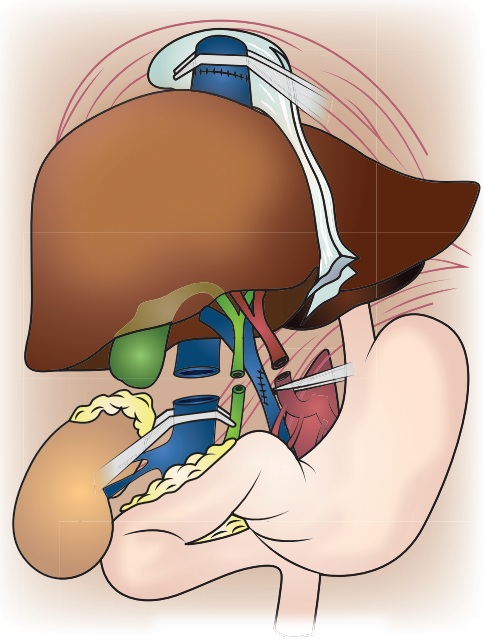

FIGURE 140-4. The four major anastomoses created during a standard liver transplant operation. The recipient's main portal vein is typically sewn to the donor's portal vein in an end-to-end manner. The venous outflow can be created via direct insertion of the individual hepatic veins onto the recipient vena cava or via a side-to-side cavocavostomy. Hepatic artery blood flow is established via an end-to-end arterial anastomosis. (From Karp SJ, Alexopoulous S. Liver transplantation. In: Townsend CM Jr, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery,* 21st ed. St. Louis, MO: Elsevier; 2022: 614-626.)

Listing for Liver Transplantation

Once an adult patient is medically, psychosocially, and financially approved to be added to the liver transplant waiting list, their priority is determined by their calculated Na-MELD score (Table 139-2), which is correlated with the likelihood of dying in the next 3 months without liver transplantation. The minimal Na-MELD score required to be listed for liver transplantation varies by center, but the usual requirement is a score of at least 15 points or evidence of complications of portal hypertension or progressive protein calorie malnutrition. Once on the list, organs are generally offered to ABO-identical or compatible patients who have the highest laboratory Na-MELD score, but critically ill adults may be upgraded to a higher priority if they are in an intensive care unit with fulminant liver failure, have acutely decompensated Wilson disease, or have acute failure of a previously transplanted liver.[20]

THE TRANSPLANTATION PROCEDURE

Liver transplant surgery entails three phases that requires 3 vascular and 1 biliary anastomoses: removal of the native liver, the anhepatic state, and engraftment (Fig. 140-4). Significant intra-operative bleeding typically requires large volumes of blood products and procoagulants.

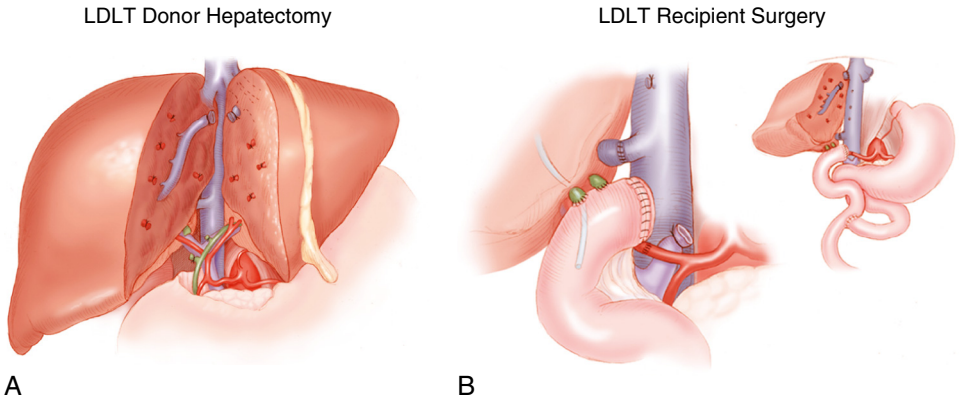

FIGURE 140-5. Living related donor hepatectomy (A) and orthotopic implantation of the right lobe graft (B). LDLT = living donor liver transplantation. (From Everson GT. Hepatic failure and liver transplantation. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine,* 26th ed. Philadelphia: Elsevier; 2020:998-1004.)

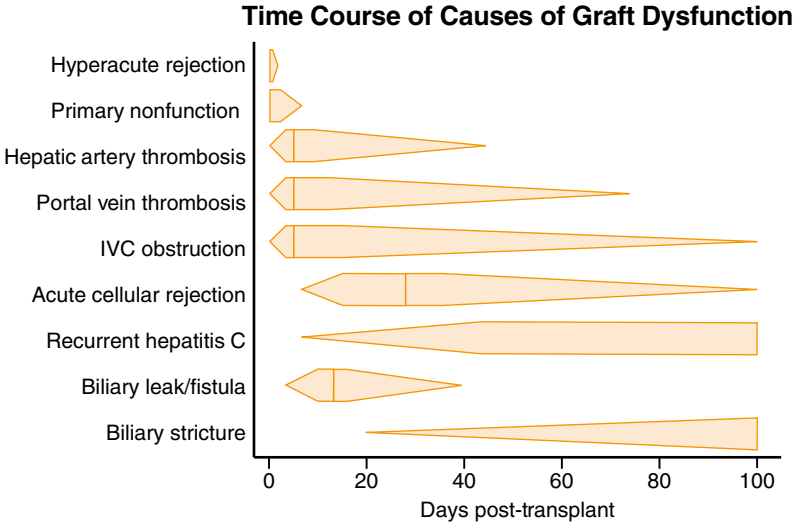

FIGURE 140-6. Time course of causes of graft dysfunction. Hyperacute rejection is rare (ABO incompatibility) but occurs in the first few hours to days. Primary nonfunction, vascular thrombosis, and biliary leaks are early events, and acute rejection episodes occur after the first 7 days. Recurrent hepatitis C may begin early but typically is manifested after the first 2 or 3 weeks after transplantation. Biliary strictures evolve more slowly and tend to be later events. IVC = inferior vena cava. (From Everson GT. Hepatic failure and liver transplantation. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine,* 26th ed. Philadelphia: Elsevier; 2020:998-1004.)

In the United States, approximately 95% of adult liver transplants use organs from deceased donors. Most deceased donor livers are procured from individuals who have experienced brain death due to head trauma, intracranial bleeding, or prolonged anoxia. However, about 8% are from critically ill patients who do not meet criteria for brain death (Chapter 373) but who may still qualify to be a liver donor after controlled withdrawal of life support. Livers from these latter donors have a higher risk of complications, such as ischemic cholangiopathy and primary non-function, because of prolonged warm ischemia following withdrawal of life-support. Cold ischemia time, which is the time between removal of the organ from the donor and implantation into the recipient, typically ranges from 4 to 8 hours. Advanced techniques for hypothermic[A1] and for normothermic[A2,21] perfusion can maintain the integrity of the graft during cold ischemia and may help expand the donor pool. Due to concerns of excessive travel time, livers from deceased donors over age 70 years or whose livers were harvested after cardiac death are offered to local liver transplantation programs.

Living donor liver transplantation can expedite liver transplantation and improve survival. Living donor liver transplantation is generally reserved for outpatients who have cirrhosis, liver tumors, or metabolic defects and who are not of high enough priority to qualify for a cadaveric liver (Fig. 140-5).[22] A portion of the larger right liver lobe (segments 5 to 8, which weigh 600 to 1000 grams) is typically used in an adult-to-adult transplantation (see Fig. 140-5).

POST-TRANSPLANTATION COMPLICATIONS AND CARE

Early post-transplantation complications (Fig. 140-6) related to the surgery include intra-abdominal bleeding, primary nonfunction of the graft, small-for-size syndrome, hepatic artery thrombosis, and bile leaks.[23,24] Subacute complications, which occur 1 to 3 months after surgery, include strictures of the biliary anastomosis, acute cellular rejection, and opportunistic infections. Late complications beyond 1 year include post-transplant lymphoproliferative disorder (Chapter 348), de novo malignancy, and recurrence of the original liver disease. Cardiovascular disease and malignancy are the leading causes of death after 1 year.

Surgical Complications

Primary nonfunction of the graft is the most serious perioperative complications but fortunately occurs in only 2 to 4% of recipients. Primary nonfunction is characterized by high aminotransferase levels, an elevated INR, lactic acidosis, and renal failure. Patients with primary nonfunction within 7 days of transplantation are highest priority for another transplant.

Hepatic artery thrombosis, which develops in less than 5% of patients and typically manifests with high levels of aminotransferases, coagulopathy, acidosis, or bile leaks early on and cholangiopathy later, can be diagnosed by liver ultrasound with Doppler. If surgical or radiologic interventions are not possible or successful, patients with hepatic artery thrombosis within 7 days after transplantation are highest priority for re-transplantation.

Biliary complications, such as bile leaks, biliary anastomotic strictures, and ischemic cholangiopathy, occur in 20 to 30% of recipients. Bile leaks tend to occur within days of the transplant. Ischemic cholangiopathy typically results in multiple, diffuse intrahepatic strictures that present clinically at 1 to 6 months after transplantation and may require percutaneous transhepatic cholangiography or re-transplantation for definitive management.

Infectious Complications

In the days after surgery, patients are prone to wound and surgical site infections, ventilator-associated pneumonia, catheter-associated bloodstream infections, and infections of non-anatomic fluid collections that arose during surgery (e.g., biloma, hematoma). In the first month after transplantation, high levels of immunosuppression raise the risk of infection with opportunistic pathogens (Fig. 140-7). Patients are typically prescribed trimethoprim-sulfamethoxazole[25] (usually one double strength tablet three times a week) to prevent *Pneumocystis* infections (see Table 313-2) and oral antifungal agents (e.g., fluconazole 100 mg per day) for 3 to 6 months after transplantation. The risk for cytomegalovirus is highest when the donor is anti-cytomegalovirus

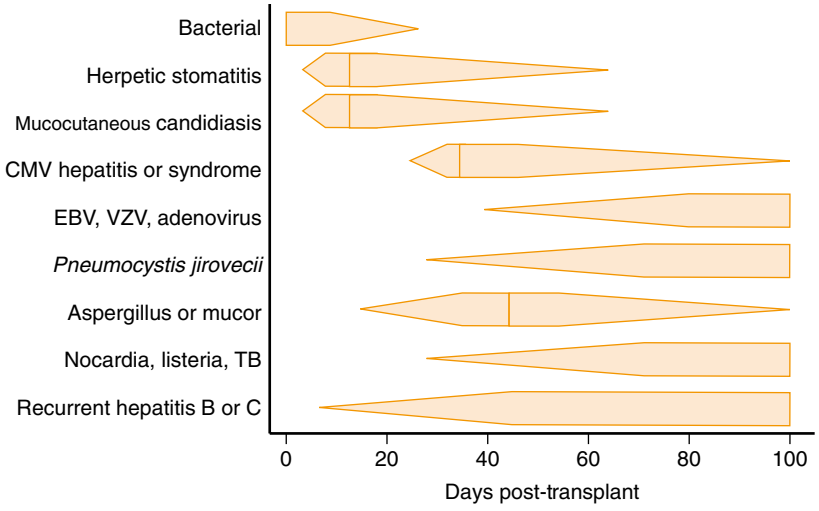

FIGURE 140-7. Time course for infectious complications. Bacterial and mucocutaneous viral or candidal infections occur early, and most of the others occur after the first 2 or 3 weeks after transplantation. CMV = cytomegalovirus (Chapter 347); EBV = Epstein-Barr virus (Chapter 348); TB = tuberculosis (Chapter 299); VZV = varicella-zoster virus (Chapter 346). (From Everson GT. Hepatic failure and liver transplantation. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:998-1004.)

bid = twice daily; CBC = complete blood count; GI = gastrointestinal; mTOR = mammalian target of rapamycin.

IgG positive and the recipient is anti-cytomegalovirus IgG negative; in this situation, antiviral prophylaxis with valganciclovir (900 mg per day) is recommended. Beyond 6 months, patients remain at-risk for community-acquired bacterial and viral infections. When patients with hepatitis B infection undergo liver transplantation, post-transplantation oral nucleoside analogues (such as entecavir or tenofovir, see Chapter 135) are required to suppress viral replication along with hepatitis B immunoglobulins in selected individuals based on their virological profile at the time of transplantation. Recipients with detectable hepatitis C RNA can usually be cleared of infection with a 12-week course of pangenotypic, combination oral direct-acting antiviral agents (see Table 135-5).

Immunosuppression and Rejection

Immunosuppressive medications and associated prophylactic agents are generally managed by the patient's liver transplant team, but all clinicians should be familiar with the general approach and common toxicities (Table 140-2).[26] The initial immunosuppression for adult liver transplant recipients typically consists of high-dose intraoperative corticosteroids followed by tacrolimus, mycophenolate mofetil, and a steroid taper over 3 to 6 months. As early as 6 to 12 months after liver transplantation, healthy and uncomplicated liver transplant recipients may be tapered to a single calcineurin inhibitor (e.g., cyclosporine or tacrolimus).[A3] Some patients are also treated with mammalian target of rapamycin (mTOR) inhibitors (sirolimus or everolimus) combined with a low-dose calcineurin inhibitor in an effort to minimize nephrotoxicity. The target trough level of the calcineurin inhibitors and mTORs can generally be reduced over time if the patient has stable allograft function and evidence of immunologic tolerance.

Because calcineurin inhibitors and mTOR inhibitors are metabolized by cytochrome P-450 3A4/5, commonly used antifungal agents (e.g., azoles, caspofungin), some antibiotics (e.g., macrolides), non-dihydropyridine

calcium-channel blockers, amiodarone, and other agents that are also metabolized by CYP3A4 must be carefully dosed and monitored to be sure that their blood levels do not increase or result in dangerous levels of immunosuppressants. Conversely, St. John's wort, rifampin, and some anticonvulsants (e.g., carbamazepine, phenytoin) can induce P-450 levels and reduce blood levels of immunosuppressive agents.

Acute T-cell–mediated rejection of the liver is most common during the first 10 days, and over 50% of cases of acute rejection occur in the first 90 days. Acute rejection should be suspected whenever the patient has unexplained allograft dysfunction or elevations in liver biochemistries.[27,28] The gold standard for the diagnosis is liver biopsy, which demonstrates variable degrees of portal inflammation, bile duct injury, and vascular endothelial inflammation (E-Fig. 140-1). The majority of patients with acute rejection will respond to a short course of intravenous corticosteroids and an increased dose of their maintenance immunosuppression under expert care. Repeated episodes of acute rejection can also lead to chronic ductopenic rejection, which is associated with obliteration of the bile ducts. Affected patients are slower to improve and may merit consideration for re-transplantation.

Antibody-mediated rejection may arise in a small proportion of recipients due to the development of donor-specific antibodies. In such cases, an increase in immunosuppression and/or plasmapheresis or IV immunoglobulin may be required under expert care.

Post-transplant lymphoproliferative disorders typically present in the first 12 to 18 months, but they can develop in up to 5% of recipients over their lifetimes. Post-transplant lymphoproliferative disorders usually occur when a patient has uncontrolled replication of Epstein-Barr virus (Chapter 348) because they are overly immunosuppressed. The diagnosis is confirmed by biopsy of a suspicious lymph node, solid organ, or bone marrow. About 50% of patients respond to a 25 to 50% reduction in immunosuppression within 1 month. Second- and third-line treatments include antiviral agents, rituximab, and chemoradiation therapy (see Chapter 348).

Long-Term Management

Beyond the first year, recipients of liver transplants are at increased risk for accelerated atherosclerosis, obesity, chronic kidney disease, and malignancy compared with age and gender-matched controls. Cardiovascular disease risk factors (e.g., hypertension [Chapter 64], hyperlipidemia [Chapter 190], diabetes [Chapter 210], obesity [Chapter 201]) should be aggressively managed with medications and diet. Patients who are on long-term immunosuppression should undergo screening and surveillance for cancer, including annual skin examinations by a dermatologist due to the high incidence of squamous cell and basal cell carcinomas (Chapter 188). Metabolic bone disease and vitamin D deficiency are frequent, so patients should receive oral calcium, vitamin D, and bisphosphonates (Chapter 225) to reduce the risk of bone fractures. Recurrent liver disease includes primary sclerosing cholangitis (Chapter 141), primary biliary cholangitis (Chapter 141), fatty liver disease (Chapter 138), and autoimmune hepatitis (Chapter 135).

Vaccination against herpes zoster reactivation, influenzae, pneumococcus, and COVID-19 are recommended in all recipients of liver transplants (Chapter 15). However, live virus vaccines should be avoided.

141 DISEASES OF THE GALLBLADDER AND BILE DUCTS

EVAN L. FOGEL AND STUART SHERMAN

GALLBLADDER

Gallstones

EPIDEMIOLOGY

Gallstone disease is one of the most common and costly digestive diseases, with an estimated annual direct cost of $15 billion in the United States. Newly diagnosed gallstone disease occurs in more than 1 million people annually in the United States, and more than 750,000 cholecystectomies are now performed annually. The prevalence of gallstones is about 10 to 15% in American and European adults, with women affected about twice as often as men. Cholesterol gallstones are uncommon in individuals younger than 20 years, but a sharp increase is noted with each decade up to approximately the age of 70 years, particularly in women. About 20% of women and 10% of men have gallstones by 60 years of age. Together, approximately 12% of Americans, or 36 million men and women, harbor gallstones.

In the United States, the prevalence of stones is highest in Mexican American women (26%), followed by White women (17%) and African American women (14%). The prevalence of gallstones is extremely high in Native Americans, especially in women. In Chileans and Bolivians of Indian ancestry, gallstones are also common, and gallstone-associated cancer is the most common gastrointestinal cancer in these countries.

Environmental factors and genetic predisposition are likely to play an interactive role in gallstone formation. Pregnancy may contribute to the predominance of cholesterol stones in younger women because it is associated with progesterone-induced impaired gallbladder emptying and estrogen-mediated increased cholesterol saturation of bile. The prevalence of gallbladder stones in nulliparous women is approximately one tenth of that noted in multiparous women (1.3 vs. 13%). Exogenous estrogen administration in the form of hormone replacement therapy and oral contraceptives is also associated with stone formation. Other medications, including somatostatin analogues, ceftriaxone, and clofibrate, have been associated also with an increased incidence of gallbladder stones.

Obesity is a major risk factor for the development of cholesterol stones. Obese individuals have an increase in biliary cholesterol secretion relative to bile acid and lecithin secretion, thereby resulting in bile supersaturation. However, rapid weight loss is also associated with an increased risk for gallstones. Diminished ileal absorption of bile acids, due to surgical resection or bypass or to active inflammation (e.g., Crohn disease), may also lead to an increased likelihood of gallstones. Adherence to a modified Mediterranean diet (Fig. 13-1) or Dietary Approaches to Stop Hypertension (DASH) diet (Table 13-4) is associated with lower risk of symptomatic gallstone disease.[1]

PATHOBIOLOGY

Gallstone Formation

Gallstones represent a failure to maintain certain biliary solutes, primarily cholesterol and calcium salts, in a solubilized state. Gallstones are classified by their cholesterol content as either cholesterol or pigment stones. Pigment stones are further classified as either black or brown. Most cholesterol stones contain calcium salts in their core, and pure cholesterol gallstones are uncommon (10%). In most American populations, 70 to 80% of gallstones are cholesterol,[2] and black pigment stones account for most of the remaining 20 to 30%. Potential genetic susceptibility loci for gallstone disease include a common variant (p.D19H) of the hepatic and intestinal cholesterol transporter ABCG5/G8 and loss-of-function mutations in the ABCB4 transporter.[3]

In normal bile, cholesterol is soluble in the form of mixed micelles with optimal concentration of bile salts and phospholipids. With disproportionate

141 DISEASES OF THE GALLBLADDER AND BILE DUCTS

EVAN L. FOGEL AND STUART SHERMAN

GALLBLADDER

Gallstones

EPIDEMIOLOGY

Gallstone disease is one of the most common and costly digestive diseases, with an estimated annual direct cost of $15 billion in the United States. Newly diagnosed gallstone disease occurs in more than 1 million people annually in the United States, and more than 750,000 cholecystectomies are now performed annually. The prevalence of gallstones is about 10 to 15% in American and European adults, with women affected about twice as often as men. Cholesterol gallstones are uncommon in individuals younger than 20 years, but a sharp increase is noted with each decade up to approximately the age of 70 years, particularly in women. About 20% of women and 10% of men have gallstones by 60 years of age. Together, approximately 12% of Americans, or 36 million men and women, harbor gallstones.

In the United States, the prevalence of stones is highest in Mexican American women (26%), followed by White women (17%) and African American women (14%). The prevalence of gallstones is extremely high in Native Americans, especially in women. In Chileans and Bolivians of Indian ancestry, gallstones are also common, and gallstone-associated cancer is the most common gastrointestinal cancer in these countries.

Environmental factors and genetic predisposition are likely to play an interactive role in gallstone formation. Pregnancy may contribute to the predominance of cholesterol stones in younger women because it is associated with progesterone-induced impaired gallbladder emptying and estrogen-mediated increased cholesterol saturation of bile. The prevalence of gallbladder stones in nulliparous women is approximately one tenth of that noted in multiparous women (1.3 vs. 13%). Exogenous estrogen administration in the form of hormone replacement therapy and oral contraceptives is also associated with stone formation. Other medications, including somatostatin analogues, ceftriaxone, and clofibrate, have been associated also with an increased incidence of gallbladder stones.

Obesity is a major risk factor for the development of cholesterol stones. Obese individuals have an increase in biliary cholesterol secretion relative to bile acid and lecithin secretion, thereby resulting in bile supersaturation. However, rapid weight loss is also associated with an increased risk for gallstones. Diminished ileal absorption of bile acids, due to surgical resection or bypass or to active inflammation (e.g., Crohn disease), may also lead to an increased likelihood of gallstones. Adherence to a modified Mediterranean diet (Fig. 13-1) or Dietary Approaches to Stop Hypertension (DASH) diet (Table 13-4) is associated with lower risk of symptomatic gallstone disease.[1]

PATHOBIOLOGY

Gallstone Formation

Gallstones represent a failure to maintain certain biliary solutes, primarily cholesterol and calcium salts, in a solubilized state. Gallstones are classified by their cholesterol content as either cholesterol or pigment stones. Pigment stones are further classified as either black or brown. Most cholesterol stones contain calcium salts in their core, and pure cholesterol gallstones are uncommon (10%). In most American populations, 70 to 80% of gallstones are cholesterol,[2] and black pigment stones account for most of the remaining 20 to 30%. Potential genetic susceptibility loci for gallstone disease include a common variant (p.D19H) of the hepatic and intestinal cholesterol transporter ABCG5/G8 and loss-of-function mutations in the ABCB4 transporter.[3]

In normal bile, cholesterol is soluble in the form of mixed micelles with optimal concentration of bile salts and phospholipids. With disproportionate

concentrations, bile becomes supersaturated, and the excess cholesterol precipitates as monohydrate crystals. These crystals become embedded in gallbladder mucin gel with bilirubinate to form biliary sludge, which may eventually aggregate into a gallbladder stone.

Black pigment stones make up a small proportion of gallstones. These stones consist of polymerized calcium bilirubinate, precipitated as a result of exceeding the solubility of calcium and unconjugated bilirubin. In addition to increasing age, the formation of black pigment stones is more common in individuals who have conditions that create an excessive amount of unconjugated bilirubin (e.g., chronic hemolysis in hemoglobinopathies, cirrhosis, ineffective erythropoiesis), who are being fed by total parenteral nutrition (Chapter 198), or who have ileal diseases. Black pigment stones are typically tarry, are usually not associated with infected bile, and are located almost exclusively in the gallbladder.

By contrast, brown pigment stones are coarse in texture and are primarily formed in the bile duct as a result of bacterial infection that releases β-glucuronidase to hydrolyze glucuronic acid from bilirubin. Phospholipid hydrolysis also increases, thereby leading to precipitation of calcium, bilirubin, and free fatty acids and also resulting in the formation of brown pigment stones. Brown pigment stones account for 30 to 90% of gallstones in Asian populations, may also occur throughout the entire biliary tree, and are frequently associated with pyogenic cholangiohepatitis.

Gallbladder contractility is impaired in some patients with gallstones. Although gallbladder dysfunction can be the consequence of gallstone disease or of excessive cholesterol infiltration into the gallbladder's smooth muscle, evidence suggests that gallbladder stasis itself can lead to gallbladder stone formation. A normal gallbladder ejects 10 to 20% of its contents into the duodenum in response to enteric nervous stimulation. The presence of postprandial intestinal fat further increases gallbladder contractility, which is mediated by the enteric nervous system and cholecystokinin. Gallbladder stasis is frequently evident in patients with risk factors for forming gallstones, including obesity, pregnancy, rapid weight loss, and prolonged fasting (Table 141-1). Somatostatin analogues may predispose to gallstone formation by decreasing gallbladder emptying. Furthermore, gallbladder dysmotility is an independent risk factor for recurrent gallstones in patients who have been treated with extracorporeal shock wave lithotripsy.

Acute Calculous Cholecystitis

The most common complication of gallstone disease is acute cholecystitis, which occurs in 15 to 20% of symptomatic patients. Acute cholecystitis results when a stone becomes lodged at the gallbladder–cystic duct junction, where it impairs gallbladder outflow and drainage. The extent of inflammation and the progression of acute cholecystitis are related to the duration and degree of obstruction. In the most severe cases, this process can lead to ischemia and necrosis of the gallbladder wall. More often, the stone spontaneously dislodges, and the inflammation gradually resolves. Acute cholecystitis is primarily an inflammatory rather than an infectious process, but about 50% of patients with acute cholecystitis have secondary bacteriobilia, most commonly with *Escherichia coli*.

CLINICAL MANIFESTATIONS

The clinical spectrum of cholelithiasis ranges from the asymptomatic state to fatal complications. Among patients with asymptomatic gallstones, approximate annual risks are 1% for biliary pain, 0.3% for acute cholecystitis, 0.2% for symptomatic choledocholithiasis, and 0.04 to 1.5% for gallstone pancreatitis. However, these low individual percentages represent a huge population-wide number of symptomatic patients, given the frequency of gallstones. Overall, about 1 to 2% of asymptomatic individuals with gallstones develop serious symptoms or complications each year related to their gallstones.

The majority of gallstones are asymptomatic and are discovered on imaging studies performed for other indications. In such individuals, the gallbladder fills and empties normally, and the gallstones remain in the gallbladder and do not obstruct the cystic duct. Over time, however, asymptomatic gallstones can become symptomatic and be manifested as biliary colic due to impaction of a gallstone at the neck of the gallbladder or cystic duct. Although the pain is commonly termed biliary colic, the majority of patients actually note constant pain due to obstruction of the cystic duct and a progressive increase in gallbladder wall tension, rather than the paroxysmal pain of typical colic. The pain usually is located in the right upper quadrant or epigastrium and frequently radiates to the back and right scapula. Although biliary colic classically occurs after fatty meals, an association with meals is present in only 50% of patients, and the pain often develops more than 1 hour after eating. The duration of pain is typically 1 to 5 hours, but it may persist up to 24 hours. Pain persisting beyond 24 hours suggests that acute inflammation or cholecystitis is present. Episodes of biliary colic are usually less frequent than one episode per week. Other symptoms, such as nausea and vomiting, accompany each episode in 60 to 70% of cases. Bloating and belching are also present in 50% of patients. Fever and jaundice occur much less frequently with simple biliary colic. Although some patients with gallstones have continuous pain, predominantly in the back or the left upper quadrant, rather than episodic pain, alternative causes should be considered in such patients.

Acute Calculous Cholecystitis

Patients with acute cholecystitis typically present with right upper quadrant pain similar to biliary colic.[3] In acute cholecystitis, however, the pain is usually unremitting, may last several days, and is often associated with nausea, emesis, anorexia, and fever. On physical examination, patients usually have a low-grade fever, with localized right upper quadrant tenderness and guarding. The presence of a Murphy sign, an inspiratory arrest during deep palpation of the right upper quadrant, is the classic physical finding of acute cholecystitis. A palpable right upper quadrant mass is appreciated in one third of patients and usually represents omentum that has migrated to the area around the gallbladder in response to the inflammation. Mild jaundice (bilirubin level <6 mg/dL) may be present. Significant jaundice is rare with acute cholecystitis but when present suggests the presence of common bile duct stones, cholangitis, or obstruction of the common hepatic duct by severe pericholecystic inflammation because of the impaction of a large stone in the Hartmann pouch, which mechanically obstructs the bile duct (i.e., Mirizzi syndrome; Fig. 141-1). Mirizzi syndrome, which occurs in about 0.1% of patients with gallstones and 0.7 to 4% of patients after cholecystectomy, may lead to chronic inflammation, compression of the bile duct associated with clinical jaundice (Mirizzi type A), necrosis, and fibrosis. Ultimately, a cholecystocholedochal fistula may occur (Mirizzi type B). High fever suggests ascending cholangitis, often with bacterial infection (Fig. 141-2). Acute cholecystitis may coexist with choledocholithiasis or its complications of acute cholangitis and gallstone pancreatitis.

TABLE 141-1 RISK FACTORS ASSOCIATED WITH GALLSTONE FORMATION

NONMODIFIABLE FACTORS	MODIFIABLE FACTORS
Increasing age	Pregnancy and parity
Female gender	Obesity
Ethnicity	Low-fiber, high-calorie diet
Genetics, family history	Prolonged fasting
	Medications: clofibrate, estrogens, octreotide
	Low-level physical activity
	Rapid weight loss
	Hypertriglyceridemia, low high-density lipoprotein
	Metabolic syndrome
	Gallbladder stasis
	Terminal ileal disease or resection
	Total parenteral nutrition, fasting state

DIAGNOSIS

Transabdominal ultrasound is the radiologic procedure of choice to identify gallstones (Fig. 141-3). Because the ultrasound waves cannot penetrate the stones, acoustic shadowing is seen posterior to the stones, thereby facilitating diagnosis. Free-floating gallbladder stones will also move to a dependent position when the patient is repositioned during scanning. If both of these features are present, the positive predictive value of ultrasound approaches 100%. Nonshadowing echoes alone, however, may be caused by gallbladder polyps. Gallstones may be missed because of a lack of contrasting bile around the stones, as may occur with an impacted cystic duct stone or when the gallbladder is filled with stones. Small gallstones may not cast an acoustic shadow. An ileus with increased abdominal gas, as can occur with acute cholecystitis or pancreatitis (Chapter 130), may limit visualization of the gallbladder. Overall, the false-negative rate of ultrasound for detection of gallstones is less than 5% but may increase to 15% with acute cholecystitis. Ultrasound may also demonstrate dilation of the intrahepatic and extrahepatic bile ducts. Dilated ducts may signify obstruction due to stones in the common bile duct, distal strictures, or malignant obstruction (Chapters 180 and 181).

ABSTRACT

Gallstone disease is one of the most common and costly digestive diseases, with an estimated annual direct cost of $15 billion in the United States. The prevalence is about 10 to 15% of American and European adults, but age, gender, nationality, environmental, genetic, and other demographic features alter this prevalence. Gallstones can be diagnosed by a variety of abdominal imaging tests, but transabdominal ultrasound remains a highly sensitive, specific, simple, low-cost technology for the diagnosis. Cholecystectomy is the most frequently performed operation in the United States. Although gallstones may remain silent for years and often are found incidentally, nearly 750,000 people in the United States undergo gallbladder surgery on an annual basis for symptomatic gallstone disease, complications thereof, acute acalculous cholecystitis, or a functional gallbladder disorder. Patients whose gallstones do not cause symptoms rarely require cholecystectomy. However, patients with or without symptomatic gallstones should undergo cholecystectomy if they are found to have a porcelain gallbladder or anomalous pancreaticobiliary union. Cholecystectomy should be considered for patients who are undergoing liver transplantation or bariatric surgery, have sickle cell disease, or have gallstones larger than 3 cm in diameter. Disorders of the bile ducts may lead to chronic cholestasis, liver damage, or acute and potentially life-threatening consequences. In this chapter, we discuss benign and malignant diseases of the gallbladder and bile ducts, with an emphasis on epidemiology, pathobiology, clinical manifestations, diagnosis, and treatment of these disorders.

KEYWORDS

gallstones
cholecystitis
gallbladder cancer
choledocholithiasis
cholangitis
biliary strictures
ampullary tumors

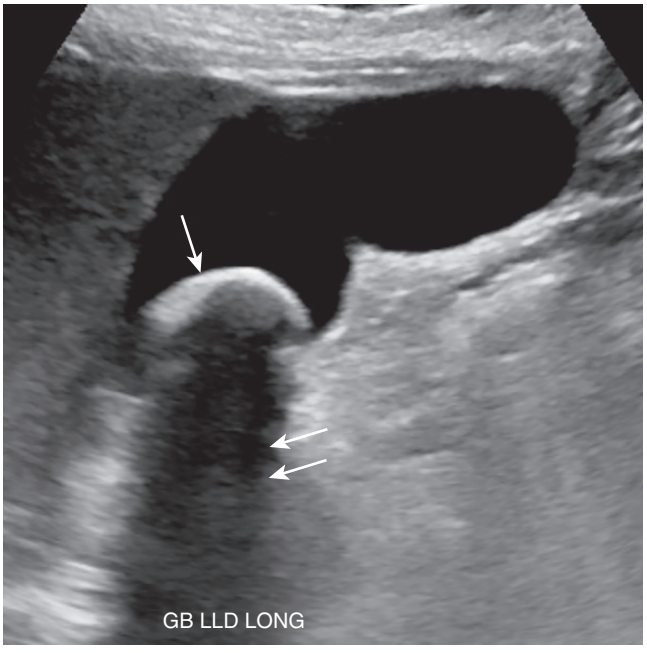

FIGURE 141-3. **Ultrasound image of the long axis of the gallbladder.** The image shows a dependent gallstone *(single arrow)* and acoustic shadow *(double arrows).*

FIGURE 141-2. **Endoscopic image of pus exiting the biliary orifice in this patient who presented with ascending cholangitis secondary to choledocholithiasis (note several small stones in duodenum).**

Ultrasound has a sensitivity and specificity of 85% and 95%, respectively, for the diagnosis of acute cholecystitis. In addition to the presence of gallstones, findings suggestive of acute cholecystitis include thickening of the gallbladder wall (>4 mm) and the presence of pericholecystic fluid. Focal tenderness directly over the gallbladder (sonographic Murphy sign) also is suggestive of acute cholecystitis.

Cholescintigraphy provides a noninvasive, anatomic, and functional evaluation of the liver, gallbladder, bile duct, and duodenum, although it has generally been superseded by ultrasound for this purpose, except in certain situations, such as identification of a suspected occult bile leak after cholecystectomy or a functional gallbladder disorder (see later). In this procedure, technetium 99 m (^{99m}Tc)–labelled iminodiacetic acid derivatives are injected intravenously, taken up by the liver, and excreted into the bile. These hepatobiliary iminodiacetic acid (HIDA) scans provide functional information about the liver's ability to excrete radiolabelled substances into a nonobstructed biliary tree. The tracer should be taken up by the liver, gallbladder, common bile duct, and duodenum within 1 hour. Nonvisualization of the gallbladder 1 hour after the injection of the radioisotope with filling of the bile duct and duodenum indicates an obstructed cystic duct and in the acute clinical setting is highly sensitive (95%) and specific (95%) for acute cholecystitis, although false-positive results are often seen in the setting of gallbladder stasis (e.g., critically ill patients, total parenteral nutrition). Slow uptake of the tracer by the liver suggests hepatic parenchymal disease. Filling of the gallbladder and bile duct with delayed or absent filling of the intestine may suggest an obstruction at the level of the major papilla.

Abdominal computed tomography (CT) is less sensitive than ultrasound for the diagnosis of gallstones and is primarily indicated for the diagnosis of complications of gallstone disease, such as acute cholecystitis, choledocholithiasis, pancreatitis, and gallbladder cancer. By comparison, *plain abdominal radiographs* are of little value in the evaluation of gallbladder disease because only 15% of gallstones contain sufficient calcium to appear radiopaque. Plain films can be useful, however, for the diagnosis of other causes of acute abdominal pain (e.g., perforated viscus, bowel obstruction). Rarely, abdominal films may show a calcified gallbladder wall (Fig. 141-4) in chronic cholecystitis or findings such as pneumobilia or gallstone-associated ileus in acute cholecystitis.

A CT scan also is frequently performed to evaluate an acutely ill patient with abdominal pain. The CT scan can detect gallstones, gallbladder wall thickening, pericholecystic fluid and edema, and air in the gallbladder or gallbladder wall (emphysematous cholecystitis), but it is generally much less sensitive than ultrasonography for finding these conditions.

Magnetic resonance imaging is highly sensitive for the diagnosis of both gallstones and common duct stones, but stones smaller than 3 mm may be missed. Endoscopic ultrasound provides excellent imaging of the gallbladder and biliary tree but is rarely the primary imaging modality for detection of a gallbladder stone. Endoscopic collection of bile for crystal analysis may serve as a surrogate for microlithiasis not seen on transabdominal ultrasound.

With cholecystitis, laboratory evaluation can show a mild leukocytosis, with a white blood cell count of 12,000 to 15,000 cells/μL. However, many patients have a normal white blood cell count. Leukocytosis greater than 20,000 cells/μL should suggest further complications of cholecystitis, such as gangrene, perforation, or cholangitis. Mild elevations in serum bilirubin, alkaline phosphatase, aminotransferase, and amylase levels may also be seen with acute cholecystitis.

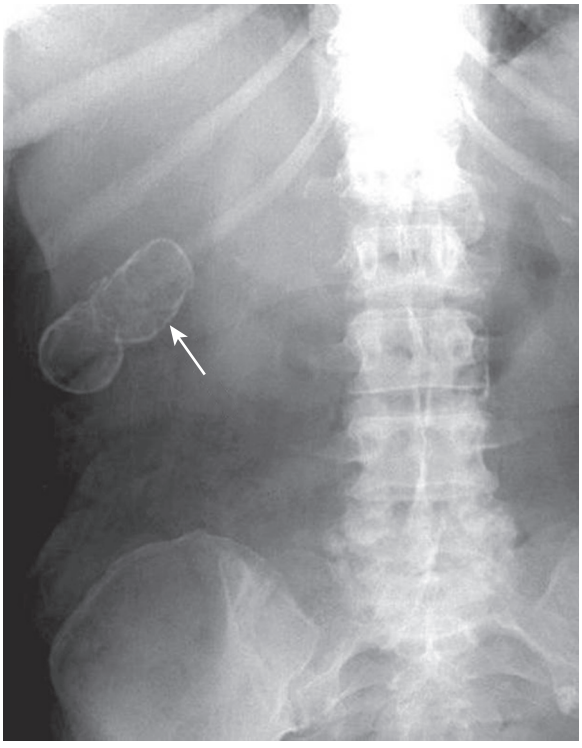

FIGURE 141-4. Plain abdominal radiograph illustrating a porcelain gallbladder. Note the calcified gallbladder wall.

TREATMENT

The treatment approach to gallstones depends on symptoms, complications, and whether there are stones in the common bile duct (Fig. 141-5).

Silent Gallstones

The longer that stones remain silent, the less likely they are to cause symptoms. In one large series, 20% of patients with initially silent gallstones developed events (8% uncomplicated, 12% complicated) at a median of 17 years. Risks were higher in women and in patients with multiple stones or a stone larger than 10 mm. Almost all patients will develop symptomatic disease before developing one of the serious complications of gallstones. Therefore, prophylactic cholecystectomy is not generally indicated in patients with asymptomatic gallstones.

In select groups of patients, however, prophylactic cholecystectomy should be considered, even when gallbladder stones are absent. A porcelain gallbladder with a calcified gallbladder wall is associated with a 5% or higher risk for malignant transformation, high enough to justify cholecystectomy. Patients with a long common channel between the bile and pancreatic ducts (i.e., anomalous pancreaticobiliary duct junction; see later) also are at significant risk for gallbladder cancer and should undergo prophylactic cholecystectomy. Acute cholecystitis is a potentially life-threatening condition in immunosuppressed patients, so prophylactic cholecystectomy is generally recommended before or at the time of major organ transplantation. Data also support cholecystectomy in patients undergoing bariatric weight loss surgery even in the absence of gallstones because of their nearly 30% risk for developing gallstones and requiring cholecystectomy during rapid weight loss in the first year after surgery. Prophylactic cholecystectomy adds minimal morbidity and mortality risks to most bariatric operations[4] and is clearly indicated in patients with gallstones. Some patients with silent gallbladder stones may also benefit from prophylactic cholecystectomy. In patients with sickle cell disease (Chapter 149), for example, cholecystitis can precipitate a crisis with substantial operative risks. Large gallstones (>3 cm) are more frequently associated with acute cholecystitis and gallbladder carcinoma. Because gallbladders containing stones that are larger than 3 cm in diameter have a 10-fold greater risk for developing malignancy than do those containing stones that are smaller than 1 cm, prophylactic cholecystectomy may also be indicated in these patients.

Symptomatic Gallstones in Outpatients

Although initial conservative management followed by elective surgery is reasonable in patients with mild symptoms,[A1] early surgery within 24 hours is generally preferred for patients with uncomplicated biliary colic. If patients do not have severe pain that lasts for >15 minutes, is located in the epigastrium or right upper quadrant, radiates to the back, and responds to simple analgesics, a conservative strategy of delaying surgery may be a reasonable alternative.[A2]

Day surgery is as safe and effective as an overnight stay.[A3] More than 95% of cholecystectomies are performed laparoscopically, with about 3% of elective procedures converted to an open procedure in the operating room. Contraindications to laparoscopic surgery include significant bleeding and Child class C cirrhosis (Chapter 139). Some patients with severe chronic obstructive pulmonary disease or heart failure may not tolerate the pneumoperitoneum required for laparoscopic surgery, and the prior upper abdominal surgery may increase the difficulty of or preclude laparoscopic cholecystectomy. Serious complications of laparoscopic cholecystectomy are rare, with a reported incidence of 0.6 to 1.5% for any bile duct leaks and 0.3 to 0.6% for a major bile duct injury. Although these risks are higher than for open surgery, the overall mortality rate (<0.3%) is lower for laparoscopic surgery, and the postoperative recovery is much easier. Outcomes for laparoscopic cholecystectomy are comparable among low- and high-volume centers. Robotic-assisted cholecystectomy appears to be as effective as laparoscopic cholecystectomy but is associated with a significant increase in complications and costs.[5]

Inpatient Acute Calculous Cholecystitis

In patients with an acute attack of cholecystitis warranting hospital admission, medical stabilization with intravenous fluids as needed, broad-spectrum antibiotics (e.g., piperacillin-tazobactam 3.375 g every 6 hours; or ceftriaxone 1 to 2 g once daily, plus metronidazole 500 mg every 6 hours; or levofloxacin, 500 mg once daily, plus metronidazole) and parenteral analgesics are indicated (see Table 26-4 in Chapter 26). The duration of antibiotic therapy is tailored to clinical improvement.

Early laparoscopic cholecystectomy within 2 days of the onset of symptoms is the treatment of choice for acute cholecystitis unless there are contraindications.[A4] Such surgery significantly reduces morbidity,[6] length of hospital stay,[A5] and time to return to work compared with open surgery. However, the conversion rate to an open procedure is about 25% compared with a rate of about 3% for elective laparoscopic surgery. If the bilirubin level is less than 4 mg/dL with no signs of cholangitis (i.e., intermediate risk for the presence of a bile duct stone), initial cholecystectomy with intraoperative cholangiography results in a shorter length of stay and fewer bile duct investigations compared with sequential common duct endoscopic assessment followed by subsequent surgery, without increasing morbidity. Laparoscopic fenestrating or reconstituting subtotal cholecystectomy is a safe "bailout" procedure in difficult operative situations.[7] Reconstituting subtotal cholecystectomy, which retains a small remnant gallbladder, may have better outcomes, but these techniques depend on intraoperative findings and surgical expertise.[A6]

In high-risk patients whose medical conditions preclude cholecystectomy, endoscopic gallbladder drainage is preferred over percutaneous cholecystostomy so as to allow prompt gallbladder drainage.[A7,A8] In expert hands, endoscopic retrograde cholangiopancreatography (ERCP)–guided stent drainage may be possible if contrast and a subsequent guidewire can be passed through the cystic duct, thereby allowing access to the gallbladder via the major papilla. Placement of a metal stent between the gallbladder and alimentary tract using endoscopic ultrasound is an alternative that does not depend on a patent cystic duct. Both techniques have success rates higher than 90%, with improved pain scores and lower reintervention rates than percutaneous drainage.[8]

If such drainage and appropriate antibiotics do not lead to clear improvement within 24 hours, however, laparotomy is indicated because failure to improve after percutaneous drainage is usually caused by gangrene of the gallbladder or perforation. If cholecystostomy is successful and the acute episode resolves, the patient can electively undergo either cholecystectomy or percutaneous stone extraction and removal of the cholecystostomy tube. Ideal timing of cholecystectomy after cholecystostomy is uncertain,[9,10] and nearly two thirds of patients may not proceed to cholecystectomy within the same calendar year.

Nonsurgical options for the treatment of gallstone disease are rarely used today because of their limited efficacy and the widespread application of laparoscopic cholecystectomy. Oral dissolution therapy (e.g., ursodeoxycholic acid, 15 mg/kg/day) may be considered in patients who have cholesterol gallstones, but it completely dissolves stones in only 40% of patients, and stones recur in up to 50% of patients within 5 years after therapy is stopped. Lifelong therapy, therefore, may be necessary. The direct infusion of organic solvents (methyl *tert*-butyl ether) into the gallbladder also is efficacious only for cholesterol gallstones, and the recurrence rate is similar to that of oral dissolution therapy. Extracorporeal shock wave lithotripsy can be considered for a single radiopaque stone that is 0.5 to 2 cm in diameter, regardless of its type, but only a small percentage of symptomatic patients fit these criteria. As a result, this therapy is limited to an extremely select group of patients.

PREVENTION

Moderate physical activity and dietary management (high fiber intake, avoidance of saturated fatty acids) may lower the risk for gallstone disease. Daily administration of cholecystokinin (3.5 μg) in patients receiving prolonged total parenteral nutrition may prevent formation of gallbladder sludge. Oral ursodeoxycholic acid (15 mg/kg/day) is beneficial to prevent gallstone disease during rapid weight loss and in patients who need long-term somatostatin

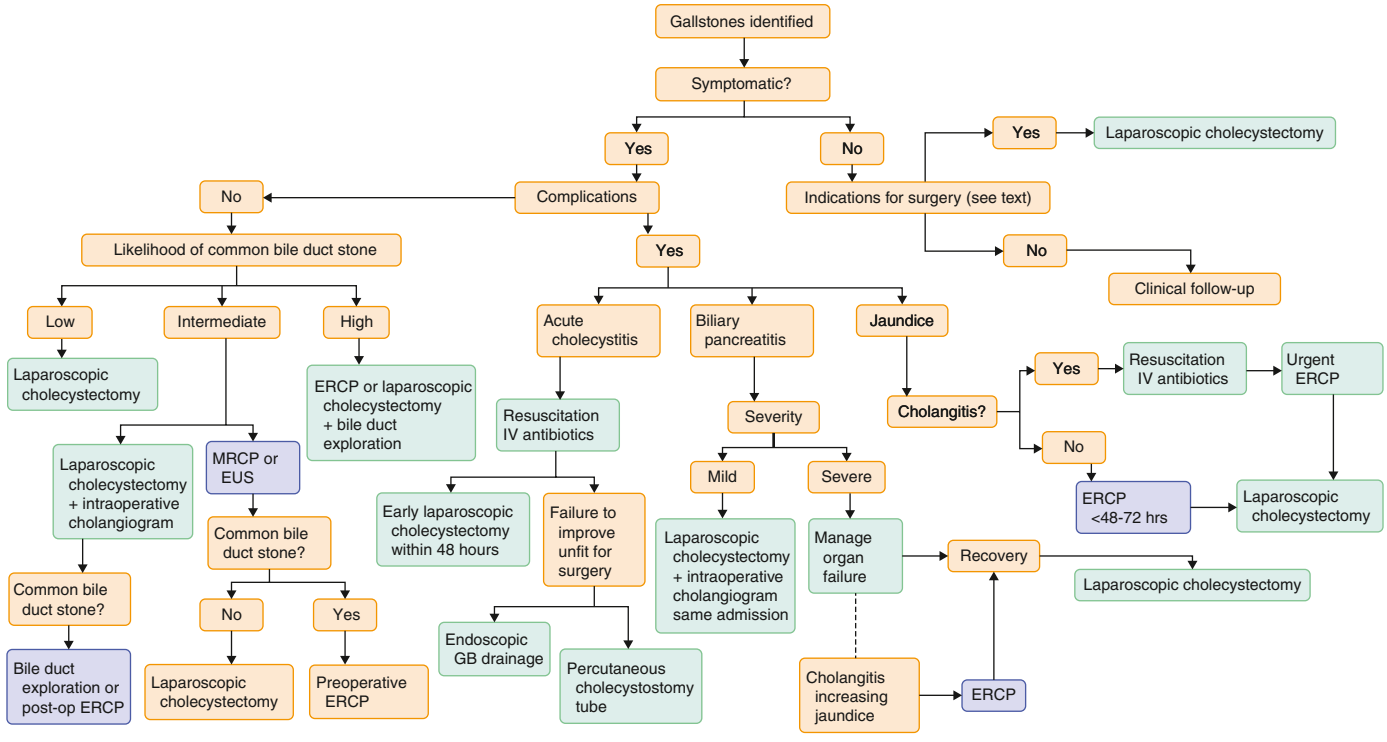

FIGURE 141-5. Algorithm for the treatment of gallstones. ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; GB = gallbladder; IV = intravenous; MRCP = magnetic resonance cholangiopancreatography.

therapy. For secondary prevention (i.e., in patients with gallstones already present), there are insufficient data to support the use of any medical therapy.

Complications of Acute Calculous Cholecystitis

Several complications of acute cholecystitis include empyema of the gallbladder, emphysematous cholecystitis, and gangrene leading to gallbladder perforation. Each of these complications can be associated with significant morbidity and mortality and therefore requires prompt surgical intervention. In 1 to 2% of patients with acute cholecystitis, the gallbladder will perforate into an adjacent hollow viscus, thereby creating a cholecystenteric fistula; the duodenum (79%) and the hepatic flexure of the colon (17%) are the most common sites. The episode of acute cholecystitis generally resolves as the gallbladder spontaneously decompresses after the fistula forms. If a large gallstone passes from the gallbladder into the small intestine, a mechanical bowel obstruction, termed gallstone ileus, may result. Gallstone ileus occurs in 10 to 15% of patients with a cholecystenteric fistula. Patients with gallstone ileus present with signs and symptoms of intestinal obstruction—nausea, vomiting, and abdominal pain. Abdominal films will demonstrate small bowel distention and air-fluid levels and may give additional clues to the source of the obstruction (pneumobilia or a calcified gallstone distant from the gallbladder). The initial management of gallstone ileus includes relieving the obstruction. Most frequently, this goal can be achieved by removing the gallstone through an enterotomy, although endoscopic retrieval of the offending stone can be done, depending on where the stone is located.

Acute Acalculous Cholecystitis

Acute acalculous cholecystitis, which accounts for 5 to 10% of all cases of acute cholecystitis, usually occurs in critically ill patients after trauma, burns, long-term parenteral nutrition, and major nonbiliary operations (e.g., abdominal aneurysm repair, cardiopulmonary bypass). The cause of acute acalculous cholecystitis remains unclear, although gallbladder stasis with increased bacterial colonization and ischemia have been implicated.

The symptoms and signs of acute acalculous cholecystitis are similar to those of acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. The disease often has a more fulminant course than acute calculous cholecystitis and more frequently progresses to gangrene, empyema, or perforation. Except for the absence of gallstones, ultrasound and CT findings are similar to those of calculous cholecystitis, including gallbladder wall thickening and pericholecystic fluid. On cholescintigraphy, the gallbladder does not fill; however, the false-positive rate (absent gallbladder filling without acute acalculous cholecystitis) may be as high as 40%.

Emergency cholecystectomy is recommended if the diagnosis is established or even if clinical suspicion is high because the risk for gangrene, perforation, or empyema exceeds 50%. Cholecystectomy rather than cholecystostomy is usually required, but percutaneous cholecystostomy or endoscopic gallbladder stenting is recommended in patients unable to undergo surgery. The mortality rate for acute acalculous cholecystitis can be as high as 40%, mostly because of the concomitant illnesses in patients who develop this disease.

FUNCTIONAL GALLBLADDER DISORDER

Some patients present with typical symptoms of biliary colic but do not have any evidence of gallstones on ultrasound examination. If further investigations such as liver chemistries, amylase and lipase levels, CT scan, and even upper gastrointestinal endoscopy are unremarkable, the diagnosis of a functional gallbladder disorder should be considered. The pathobiology is poorly understood, but one possibility is that the obesity epidemic has increased the population-wide accumulation of fat in the gallbladder wall—cholecystosteatosis—thereby decreasing the gallbladder's ability to empty. Some patients may have intermittent gallbladder outlet obstruction due to cystic duct spasm, poor coordination between the contraction of the gallbladder and the sphincter of Oddi, or dysmotility of the gallbladder. In a cholecystokinin-stimulated ^{99m}Tc-HIDA scan, cholecystokinin is infused intravenously after the gallbladder has filled with the ^{99m}Tc-labeled radionuclide, and a gallbladder ejection fraction is calculated 20 minutes later. An ejection fraction of less than 35% at 20 minutes is considered abnormal, and most of these patients have histopathologic evidence of chronic cholecystitis, although a low gallbladder ejection fraction is not specific for a functional gallbladder disorder (Table 141-2). The efficacy of laparoscopic cholecystectomy is controversial in this setting, but the Society of American Gastrointestinal and Endoscopic Surgeons recommends it. The percentage of patients undergoing cholecystectomy for functional gallbladder disorder in the United States during the past 15 years has increased from less than 5% to more than 20% of patients having the gallbladder removed. Additionally, patients who have symptoms of typical biliary colic and a markedly high gallbladder ejection fraction (i.e., gallbladder hyperkinesia) may also benefit from cholecystectomy, even though they do not have gallstones.[A9]

TUMORS OF THE GALLBLADDER

Benign

Cholesterol polyps are not true neoplasms but rather are cholesterol-filled projections of gallbladder mucosa that protrude into the lumen. These polyps account for approximately 50% of all polypoid gallbladder lesions, are usually

TABLE 141-2 SETTINGS IN WHICH A LOW GALLBLADDER EJECTION FRACTION MAY BE IDENTIFIED

smaller than 1 cm, are typically found incidentally on imaging studies as nonmobile filling defects, are usually asymptomatic unless associated with gallstones, and do not have malignant potential.

Adenomyosis consists of a hypertrophic gallbladder muscle layer with mucosal diverticula called Rokitansky-Aschoff sinuses. This condition may affect the gallbladder locally, particularly in the fundus, where it appears as a hemispheric lesion with a central dimple; segmentally, as an annular stricture; or diffusely, when it involves the entire gallbladder wall. The cause is not entirely clear but may be secondary to a gallbladder motility disorder. Isolated adenomyosis can cause biliary-type symptoms and can progress to gallbladder cancer, so prophylactic cholecystectomy is recommended.

Gallbladder adenomas are benign epithelial tumors with malignant potential. Adenomas usually are manifested as solitary, nonmobile filling defects on ultrasound. Polyps smaller than 0.5 cm, regardless of total polyp number, can be observed with serial imaging studies, namely ultrasound, every 12 months. Larger polyps, however, may harbor a carcinoma in situ, and cholecystectomy is recommended for polyps larger than 1 cm and for any patients older than 50 years with biliary symptoms.

Malignancy

Gallbladder cancer is the most common biliary tract malignant neoplasm and fifth most common gastrointestinal cancer overall, with approximately 7000 new cases diagnosed annually in the United States (2.5 cases/100,000 population). The usual age at onset is the sixth or seventh decade, with a female-to-male ratio of 3 : 1. Gallbladder cancer is more common in Native Americans, Mexicans, Alaskans, and American Hispanics, as well as in residents of Israel, Chile, and northern Japan.

Perhaps because of chronic inflammation, gallbladder cancer is strongly associated with gallstones, which are identified in more than 90% of patients with gallbladder carcinoma. Conversely, only 1% of patients with gallstones develop gallbladder carcinoma. Choledochal cysts are associated with an increased risk for malignant neoplasms throughout the biliary tree, including the gallbladder, perhaps because of increased stasis, chronic inflammation, and infection. In patients with choledochal cysts, excision of extrahepatic cysts is recommended to avoid biliary tract cancer. By comparison, biliary sphincterotomy alone may be adequate for a type III extrahepatic cyst.

About 90% of gallbladder cancers are adenocarcinomas (90% scirrhous, 5% papillary, 5% colloid). The remaining tumors are anaplastic or squamous cell cancers. Gallbladder cancers spread by local extension and direct invasion of adjacent structures, including the common hepatic duct, liver, duodenum, and colon. Lymphatic drainage is to adjacent lymph nodes, and disseminated disease is to the liver and the peritoneal surface.

Most patients (80%) present with abdominal pain of less than 1 month in duration, which may be difficult to distinguish from symptoms of biliary colic or acute cholecystitis. Nausea and vomiting (50%) and weight loss (40%) are often present, and jaundice (30%) is a poor prognostic sign that typically signifies porta hepatis involvement with tumor. Up to 20% of gallbladder cancers are found at cholecystectomy performed for gallstones, whereas incidental cancers are found at 1% of cholecystectomies.

Diagnosis may be difficult preoperatively because laboratory test results may be normal or nonspecific even when advanced disease is manifested by hypoalbuminemia and anemia. There is no reliable tumor marker. Liver test results are abnormal when the tumor or periportal lymphadenopathy is associated with biliary obstruction. Ultrasonography has a sensitivity of 75 to 80% for detection of gallbladder cancer, with findings ranging from a complex luminal mass to gallbladder wall thickening, polypoid mass, or gallstones. Doppler ultrasound has a sensitivity and specificity of about 80% for the diagnosis of gallbladder cancer. Detection of color flow within a lesion supports the diagnosis, but its absence does not exclude malignancy.[11] CT or magnetic resonance cross-sectional imaging can assess the extent of disease, including regional and distant metastases. Endoscopic ultrasound may aid in determining the extent of local invasion and nodal involvement, but it rarely is necessary in the preoperative evaluation. ERCP is indicated only in patients who have clinical evidence of biliary obstruction and are being considered for stent placement to palliate their jaundice.

PREVENTION AND TREATMENT

Patients with gallstones larger than 3 cm have a 10-fold increased risk for development of gallbladder cancer, so prophylactic cholecystectomy should be considered even in an asymptomatic patient. A porcelain gallbladder, with diffuse calcification of the gallbladder wall, is an indication for cholecystectomy in the asymptomatic patient because of the increased risk for cancer. Cholecystectomy also is indicated for any gallbladder polyp larger than 1 cm, in patients with choledochal cysts other than type III, in anomalous pancreaticobiliary union, and in adenomyosis of the gallbladder.

The resectability rates for gallbladder cancer range from 15 to 30%. When the tumor does not extend beyond the lamina propria layer of the gallbladder wall (T1a), simple cholecystectomy alone may be curative, with a 5-year survival rate approaching 100%.[12] Tumors that involve the muscularis propria (T1b) may gain access to the lymphatic system and be associated with occult metastases. Current recommendations for pT1b cancers involve complete operative staging with laparoscopy, portal lymphadenectomy, cystic duct margin assessment, and partial central liver excision. Tumors that extend through the gallbladder wall (stage II/III) require a more extensive resection (cholecystectomy, partial central hepatectomy, lymph node dissection). Stage II tumors (no invasion beyond the gallbladder serosa) may have up to a 60 to 80% 5-year survival rate, whereas stage III tumors have a 25% 5-year survival rate. Median survival with unresectable (stage IV) disease is typically less than 6 months. Radiation therapy has not been shown to be effective, whereas chemotherapy regimens in unresectable disease (typically similar to regimens for pancreatic cancer [Chapter 180]) are associated with response rates of approximately 20%. Capecitabine (1250 mg/m^2 twice daily on days 1 to 14 of a 21-day cycle, for eight cycles) appears to improve overall survival in patients with resected cancer when used as adjuvant therapy,[A10] while second-line FOLFOX (folinic acid, fluorouracil, and oxaliplatin) chemotherapy leads to a clinically meaningful increase in 6- and 12-month overall survival rates after progression on cisplatin and gemcitabine.[A11] Molecular-targeted therapies may be helpful in a subset of patients.[13] Because of the late presentation of this disease and spread of tumor at diagnosis, the overall 5-year survival is less than 10%.

BILE DUCTS

Bile Duct Stones

PATHOBIOLOGY

Bile duct stones, or choledocholithiasis, can be classified as either primary or secondary. Primary duct stones develop de novo within the bile ducts, whereas secondary stones develop in the gallbladder and subsequently pass into the bile duct. In the Western world, more than 85% of all bile duct stones are secondary. Primary duct stones typically occur in conditions associated with bile stasis (e.g., benign biliary strictures, sclerosing cholangitis, choledochal cysts, periampullary diverticula), which promotes bacterial overgrowth with subsequent bilirubin deconjugation and the breakdown of biliary lipids, thereby resulting in the formation of brown pigment stones.

CLINICAL MANIFESTATIONS

Bile duct stones are discovered incidentally in 5 to 12% of patients during the evaluation of gallbladder stones and suspected cholecystitis. It is difficult to determine whether the existing bile duct stones are asymptomatic in patients who present with biliary pain alone because pain can originate from either the gallbladder stones or bile duct stones. More than 50% of patients with retained bile duct stones experience recurrent symptoms during a follow-up period of 6 months to 13 years, and 25% of cases develop serious complications.

Common clinical symptoms and signs of bile duct stones include epigastric or right upper quadrant pain, fever, and jaundice (referred to as the Charcot triad). Pain can be mild or severe, and severe episodes must be differentiated from other potentially life-threatening events. Occasional patients may present with painless jaundice and weight loss mimicking pancreaticobiliary malignant disease (Chapter 180).

DIAGNOSIS

Patients with cholangitis, with or without associated pancreatitis (Chapter 130), typically have elevated serum aminotransferase levels. The serum bilirubin level usually is less than 15 mg/dL with choledocholithiasis because most bile duct stones cause intermittent, incomplete biliary obstruction. In unusual cases, the serum aminotransferase levels can be profoundly elevated (up to 2000 IU/L), mimicking acute viral hepatitis.

Although ultrasound is the most common initial test for patients with suspected gallbladder stones, it has a low sensitivity rate (25 to 60%) for detection of bile duct stones, in part because the bile duct may not be dilated in acute obstruction. CT scan may demonstrate calcified bile duct stones (Fig. 141-6), but its sensitivity for this purpose is generally little better. CT is useful, however, for identifying other potential causes of biliary obstruction (e.g., mass lesion) and local complications, such as a liver abscess (Chapter 137). Magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound can detect bile duct stones with an accuracy comparable to that of ERCP (Fig. 141-7). Because of potential procedure-related risks, ERCP is now reserved for patients with confirmed or a high suspicion of biliary disease who are likely to require therapeutic intervention.

TREATMENT

Given the potential serious complications of bile duct stones (i.e., cholangitis, pancreatitis),[14] specific therapy is generally required regardless of symptoms. About 85 to 90% of bile duct stones can be removed at ERCP by standard balloon dilation and basket extraction after biliary endoscopic sphincterotomy, with a complication rate, including pancreatitis, bleeding, cholangitis, cholecystitis, and perforation, of less than 10%. Data are conflicting on whether asymptomatic patients are at increased risk for post-ERCP pancreatitis compared with patients who have symptomatic bile duct stones.[15–17] Endoscopic biliary orifice dilation without sphincterotomy may reduce some acute complications but increases the risk for pancreatitis and may lead to more subsequent procedures.[18]

The 10 to 15% of bile duct stones that cannot be removed by standard ERCP are generally larger than 1.5 cm, impacted, or located above a stricture.[19] Alternative therapies include the use of large-diameter dilation balloons (12 to 18 mm)[A12] and fragmentation by mechanical or electrohydraulic lithotripsy. Whenever stones cannot be completely removed endoscopically, biliary stents should be placed to ensure adequate biliary drainage and to prevent recurrent symptoms while awaiting further therapy. Long-term biliary stenting can also be used in patients with severe comorbid medical conditions that preclude surgery or repeated endoscopic interventions.

Ideally, patients with concomitant gallbladder and bile duct stones would be best treated with a single laparoscopic cholecystectomy and bile duct exploration, which is preferable to ERCP followed by cholecystectomy.[A13] However, only a minority of surgeons can successfully perform laparoscopic bile duct exploration, so open common bile duct exploration is generally performed if endoscopic and laparoscopic approaches are unsuccessful. A novel combined laparoendoscopic rendezvous procedure, where ERCP is facilitated by transcystic wire passage into the bile duct and duodenum at the time of cholecystectomy, is equivalent to the two-stage procedures in terms of ductal stone clearance, with less pancreatitis, lower morbidity, and shorter hospital stay despite a longer procedural time.[A14]

Complications of Bile Duct Stones

Cholangitis is a potentially life-threatening disease that results from bacterial infection of obstructed bile. Systemic toxicity occurs when intraductal pressure is sufficiently elevated to cause reflux of bacteria or endotoxin into the blood. About 80 to 90% of cases of acute cholangitis is caused by choledocholithiasis, with the remaining cases caused by a benign biliary stricture (e.g., primary sclerosing cholangitis, chronic pancreatitis, postoperative bile duct injury, or narrowing at an anastomosis) or by malignant biliary obstruction, typically after previous endoscopic instrumentation and stent placement. In certain parts of the world, parasitic biliary obstruction (e.g., *Ascaris*; Chapter 327) may be manifested with cholangitis. The most common bacteria are gram-negative bacilli and *Streptococcus* spp, but *Enterococcus* species are frequently seen in patients with occluded biliary stents. Prompt antibiotic therapy (e.g., intravenous ceftriaxone 1 to 2 g once daily; ampicillin-sulbactam 1.5 to 3 g every 6 hours; piperacillin-tazobactam 3.375 g every 6 hours; ciprofloxacin 400 mg twice daily; or levofloxacin 500 mg orally once daily) is critical and usually can permit conservative management with endoscopic biliary decompression within 24 to 48 hours.[A15] However, urgent decompression is indicated if improvement is not seen within a few hours. The advantages of ERCP are that it can delineate the cause of obstruction, obtain bile for culture, and rapidly decompress the biliary tree definitively by removing the stone or temporarily by placing a stent without removing the stone. Routine stenting is not indicated after successful stone removal unless the adequacy of biliary drainage is uncertain.

Acute gallstone pancreatitis accounts for up to 50% of cases of acute pancreatitis in Western countries (Chapter 130). Most patients quickly respond to conservative therapy, but some develop severe pancreatitis. Although early ERCP with biliary sphincterotomy and stone removal (Fig. 141-8) would appear to be an attractive therapeutic option, early ERCP does not reduce mortality or complications except in patients with biliary obstruction or clear evidence of cholangitis.[A16] After recovery from an episode of biliary pancreatitis, laparoscopic cholecystectomy with intraoperative cholangiography is recommended to prevent further episodes, preferably during the same hospital admission.[A17] If a common bile duct stone is found at intraoperative cholangiography, laparoscopic or open common bile duct exploration and stone removal can be accomplished with high success rates in experienced hands, or postoperative ERCP can remove any retained stones.[A18]

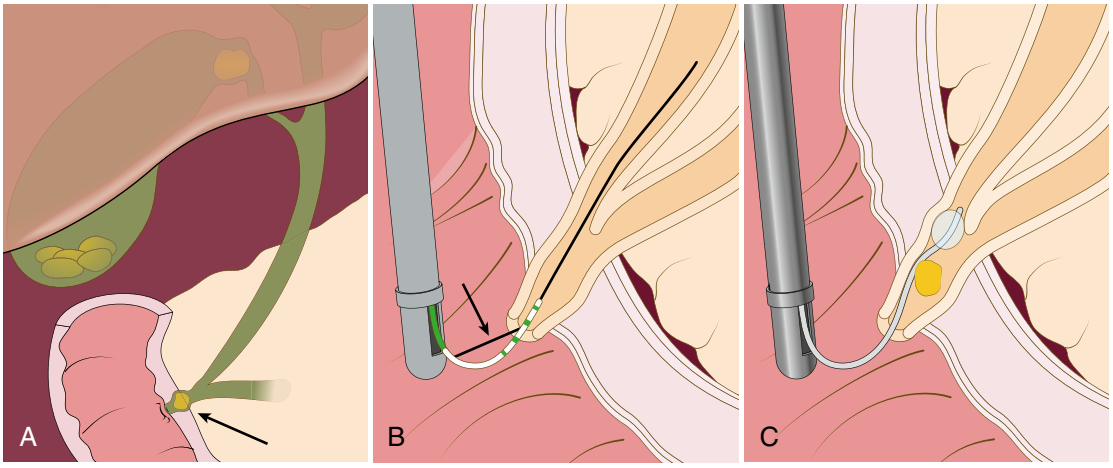

FIGURE 141-8. A, A stone that is impacted in the distal bile duct is causing biliary pancreatitis, with gallbladder stones also seen. B, Performance of biliary sphincterotomy. C, Subsequent stone removal by balloon sweep.

PREVENTION

Up to 25% of patients may have recurrent bile duct stones, with or without a gallbladder, but it remains uncertain what proportion of these recurrent stones are in fact overlooked residual stones from a prior event. A dilated extrahepatic bile duct (≥13 mm) and periampullary diverticula are risk factors for recurrent stones, perhaps by increasing biliary stasis. Identification and treatment of biliary strictures, papillary stenosis, and gallstones in patients with gallbladder in situ are essential for preventing recurrent stones. Unfortunately, no preventive therapy has been proved effective, although ursodeoxycholic acid (15 mg/kg/day) appears to reduce the risk for gallstones during weight loss.

BENIGN BILIARY STRICTURES

Postoperative extrahepatic bile duct strictures occur after 0.25 to 1% of cholecystectomies. Most of these lesions are manifested as abnormal liver test results, obstructive jaundice, and cholangitis within 2 to 3 months postoperatively, although the presentation can be delayed. The cholangiogram commonly shows a short, smooth narrowing near the cystic duct stump with proximal duct dilation (Fig. 141-9). Strictures typically must be redilated, and stents are exchanged at 3- to 4-month intervals for 8 to 12 months until the stricture is nearly as open as the downstream bile duct. About 80% of patients will have a good result. Covered self-expandable metal stents are as good as multiple plastic stents for resolving strictures, with fewer ERCP procedures needed to achieve resolution.[A19] However, some patients will ultimately require a bilioenteric bypass. Strictures more than 2 cm in length, strictures with clips placed securely across the duct, or strictures associated with resected segments of duct require surgical intervention.

Intrapancreatic common bile duct strictures, which may occur in 3 to 46% of patients with chronic pancreatitis, can lead to secondary biliary cirrhosis or recurrent cholangitis. With the complication of cholangitis or jaundice, intervention is clearly indicated, typically with ERCP and stent placement. In the absence of cholangitis or jaundice, either surgical repair or endoscopic biliary decompression with multiple plastic stents (Fig. 141-10) has traditionally been recommended when the alkaline phosphatase level is consistently more than twice the upper limit of normal during a 6-month period of observation. Biliary strictures that complicate liver transplantation (Chapter 140) are usually treated similarly with good results.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) frequently targets the liver, but a rapidly progressive cholangiopathy has also been reported.[20] The pathogenesis of this disorder remains poorly understood, and no specific treatment options are currently available.

ORIENTAL CHOLANGIOHEPATITIS

Recurrent cholangitis with hepatolithiasis has a prevalence of more than 10% in parts of East Asia, especially in Taiwan, owing to infection with *Ascaris lumbricoides* (Chapter 327) and *Clonorchis sinensis* (Chapter 326). This condition results in local strictures and dilation of the intrahepatic biliary tree. Biliary stasis and subsequent bacterial infection cause brown stones to form. Most patients have recurrent cholangitis, but cholangiocarcinoma can also ensue. Ultrasound or CT can establish the diagnosis. Treatment includes intravenous fluids and antibiotics. Endoscopic stone removal is usually the preferred treatment, but localized surgical resection targeted to the cultured organisms may be necessary.

PRIMARY SCLEROSING CHOLANGITIS

DEFINITION

Primary sclerosing cholangitis is a chronic cholestatic disease characterized by fibrosing inflammation of segments of the intrahepatic and extrahepatic bile ducts.[21] It results in progressive narrowing of the duct lumen and ultimately may be manifested with recurrent episodes of ascending cholangitis or, alternatively, may progress to secondary biliary cirrhosis and its associated complications. Cholangiocarcinoma (Chapter 181) is a dreaded complication with a reported incidence of 25 to 40% at autopsy or liver transplantation.

EPIDEMIOLOGY

The true prevalence of primary sclerosing cholangitis is unknown, but current estimates are 0.2 to 8.5 per 100,000 in the U.S. population. Its prevalence is much higher in populations in which inflammatory bowel disease (Chapter 127) is more common. Affected men outnumber women in a 2 : 1 ratio, with the mean age at diagnosis of 32 to 40 years. However, primary sclerosing cholangitis has been reported in infants, children, and the elderly.

PATHOBIOLOGY

The cause of primary sclerosing cholangitis and the mechanisms responsible for its progression are unknown. However, autoimmune and genetic causes are supported by its frequent association with inflammatory bowel disease and the increased prevalence of the HLA B8, DR3 haplotype. Evidence from both fecal- and mucosa-associated microbial studies suggests that patients with primary sclerosing cholangitis harbour an abnormal enteric microbiome. About two thirds of patients with primary sclerosing cholangitis have ulcerative colitis or Crohn colitis, and it is rarely associated with Crohn disease that is limited to the small bowel. However, only 1 to 13% of patients with colitis are diagnosed with primary sclerosing cholangitis during their lifetime. First-degree relatives of patients with primary sclerosing cholangitis have a 9- to 39-fold increased risk for development of the disease.

On pathologic examination, involved segments of bile ducts in strictured areas show diffuse thickening with a mononuclear inflammatory cell infiltrate. The most characteristic biopsy features are bile duct proliferation, periductal fibrosis, periductal inflammation, and loss of bile ducts. Obliterative cholangitis with a chronic inflammatory cell infiltrate and periductular "onion ring" fibrosis is strongly associated with primary sclerosing cholangitis but is infrequently observed in biopsy specimens. Given the patchy nature of the disease and possible lack of significant intrahepatic involvement, however, the histologic appearance of primary sclerosing cholangitis is variable and may resemble extrahepatic biliary obstruction, chronic active hepatitis, or, rarely, primary biliary cirrhosis.

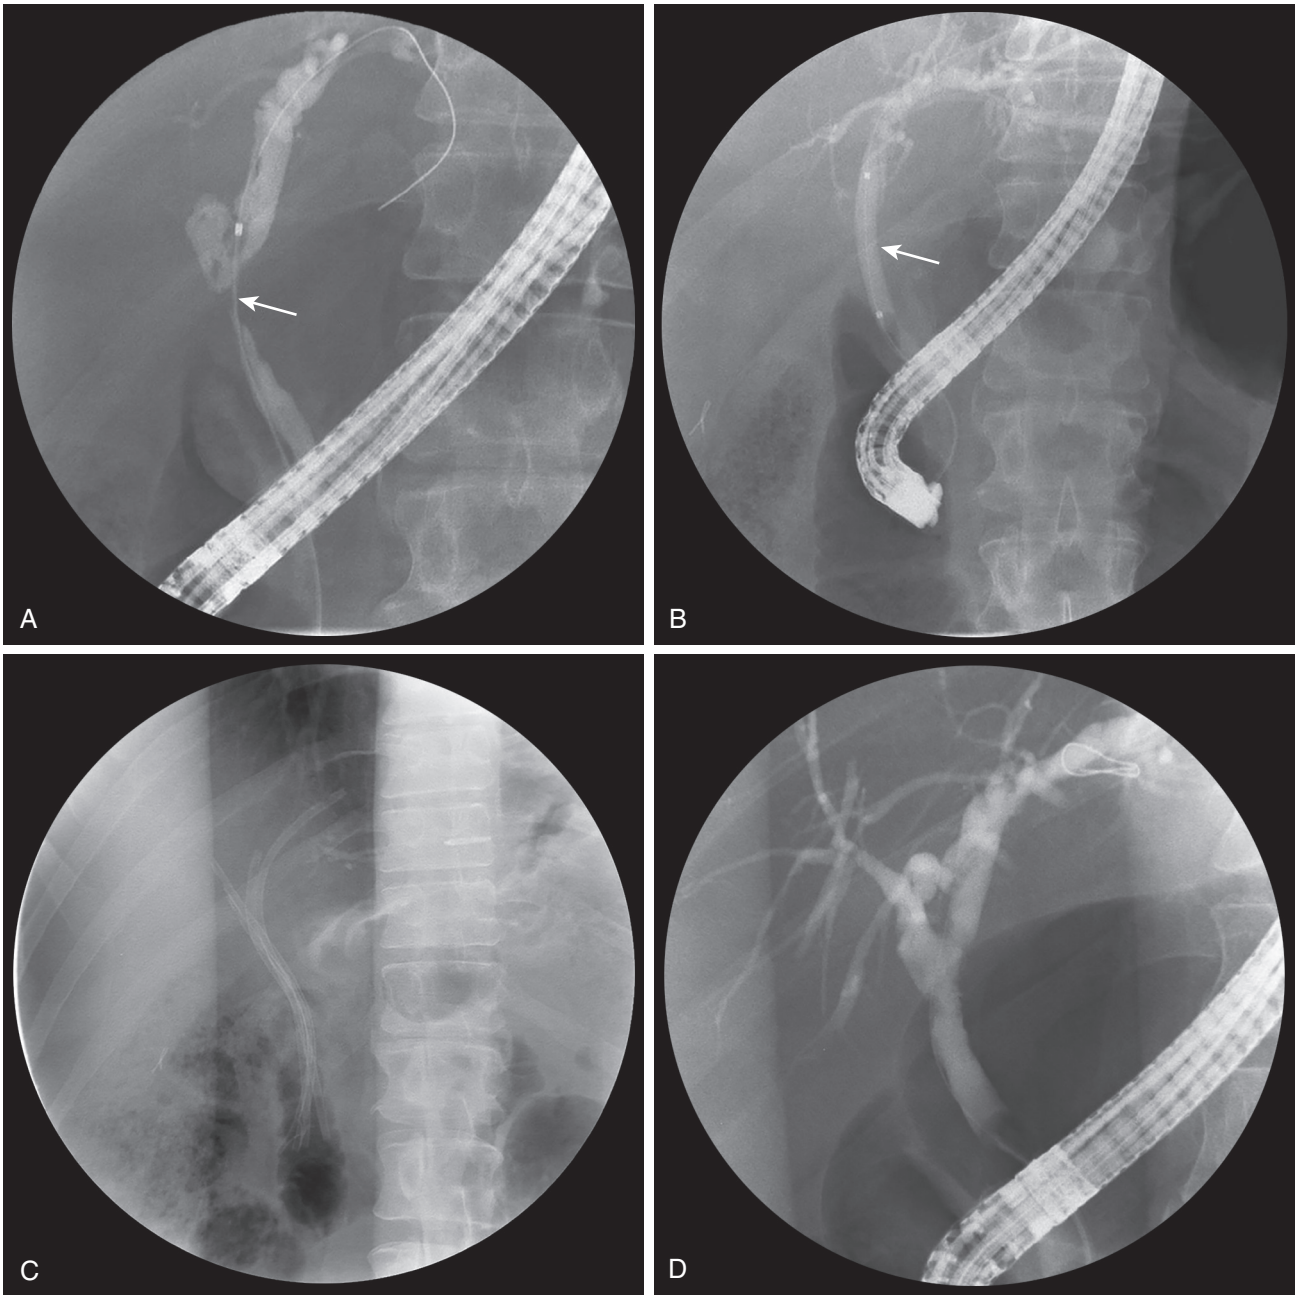

FIGURE 141-9. **Endoscopic retrograde cholangiopancreatography images obtained from a patient who presented with painless jaundice 8 months after cholecystectomy. A, Benign common hepatic duct stricture. B, Balloon dilation of the stricture. C, Multiple stents placed. D, Resolution of stricture after a 1-year stenting interval.**

CLINICAL MANIFESTATIONS

Most patients with primary sclerosing cholangitis are asymptomatic at presentation and are identified after investigation of an elevated alkaline phosphatase level (Chapter 133).[22] Overall, about 90% of patients have an elevated alkaline phosphatase level, with or without mildly elevated serum aminotransferase levels. Fatigue, anorexia, malaise, and weight loss are common but may erroneously be attributed to a patient's inflammatory bowel disease. Patients may exhibit signs or symptoms of cholestatic liver disease, including pruritus, upper abdominal pain, and fever. The serum bilirubin concentration is elevated in only about 40% of patients at presentation. Some patients have anemia, hypoalbuminemia, or hypergammaglobulinemia, and a prolonged international normalized ratio suggests biliary obstruction or synthetic dysfunction. Nearly 90% of patients will have a positive perinuclear antineutrophilic cytoplasmic antibody, but this antibody is also nonspecific and may be found in both ulcerative colitis (Chapter 127) and autoimmune hepatitis (Chapter 135). Antinuclear or anti–smooth muscle antibodies are found in 25% of patients but are not specific, and a positive antimitochondrial antibody suggests primary biliary cholangitis as the diagnosis.

DIAGNOSIS

Cholangiography is necessary to establish the diagnosis of primary sclerosing cholangitis (Fig. 141-11).[23] MRCP generally is the test of choice, but ERCP may be indicated if MRCP is inconclusive, particularly when the disease is confined to small intrahepatic ducts. The role of biopsy remains uncertain owing to the segmental nature of the disease and the overlap of the histologic features with other disease states. Diffuse multifocal strictures are usually short, with intervening normal or dilated segments that give a beaded appearance. Other frequent findings on cholangiography include pseudodiverticula, mural irregularities, and biliary stones and sludge. Secondary causes of sclerosing cholangitis include obstruction (postoperative, autoimmune cholangiopathy, choledocholithiasis, and recurrent pyogenic cholangitis), ischemic (hepatic artery instillation of the chemotherapeutic agent 5-fluorouracil, radiation, and paroxysmal nocturnal hemoglobinuria), and neoplastic (cholangiocarcinoma, hepatocellular carcinoma, lymphoma, and metastasis).

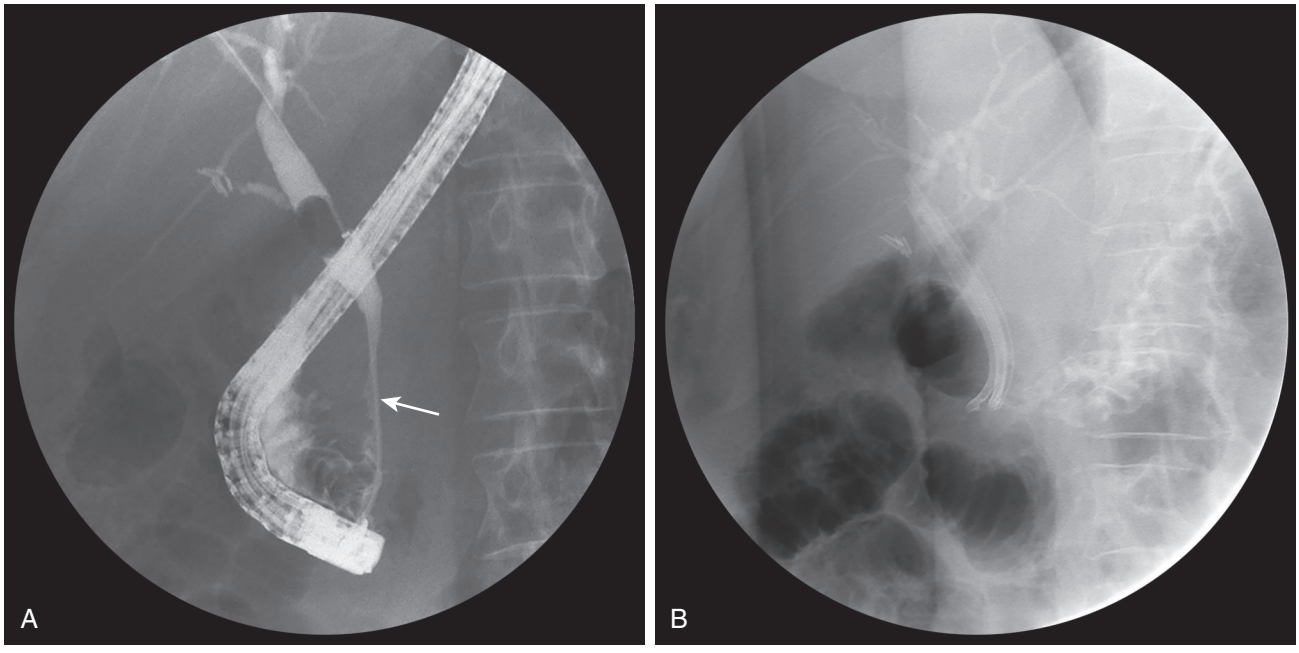

FIGURE 141-10. Endoscopic retrograde cholangiopancreatography images obtained from a patient with a history of alcohol abuse who presented with pruritus and was found to have a markedly elevated alkaline phosphatase level. A, A smooth distal bile duct stricture is seen (*arrow*). **B**, Four stents have been placed through the stricture.

TREATMENT

The chronic cholestasis of primary sclerosing cholangitis can be treated with cholestyramine (4 to 8 g/day), ursodeoxycholic acid (15 mg/kg/day), rifampicin (300 to 600 mg/day), or phenobarbital (30 to 120 mg/day) with modest success. Obeticholic acid, which is a potent farnesoid X receptor agonist approved for the treatment of primary biliary cholangitis (at 5 to 10 mg once daily), reduces the serum alkaline phosphatase level in patients with primary sclerosing cholangitis, although its effects on disease progression are not known.[A20] Another experimental farnesoid X receptor agonist, cilofexor, has shown promise in patients who have large-duct primary sclerosing cholangitis.[A21] Fat-soluble vitamin deficiencies (Chapter 199) must be corrected. The prevalence of osteoporosis (Chapter 225) in primary sclerosing cholangitis is between 4 and 10%, so bone densitometry should be performed at diagnosis and every 2 to 3 years thereafter. Supplementation with oral vitamin D and calcium seems prudent, even in the absence of symptomatic deficiency. Treatment with bisphosphonates (Chapter 225) is reserved for patients with confirmed osteoporosis. Unfortunately, no medical treatment slows the progression of disease; ursodeoxycholic acid, D-penicillamine, corticosteroids, cyclosporine, methotrexate, and colchicine have all been shown to be ineffective for improving survival or delaying the time to liver transplantation. Whether repeated endoscopic treatment to maintain bile duct patency can improve outcomes is unknown, although patients with a dominant stricture may benefit.[24] Furthermore, short-term stents are not superior to balloon dilatation and are associated with a significantly higher occurrence of treatment-related adverse events (e.g., cholangitis, pancreatitis).[25]

Liver transplantation (Chapter 140) is the only potentially curative therapy. The 1-year and 5-year survival rates typically are in the 90% and 80% range, respectively. Primary sclerosing cholangitis may recur in the transplanted organ in 15 to 20% of patients.

PROGNOSIS

The natural history of primary sclerosing cholangitis is variable and incompletely understood. Asymptomatic patients have a much better prognosis than symptomatic patients, with 10-year actuarial survival rates of 80% and 50%, respectively. In symptomatic patients, the median time of survival until death or liver transplantation is 9 years, compared with 12 to 18 years for all patients with primary sclerosing cholangitis, regardless of symptoms. An elevated serum bilirubin level and hepatomegaly appear to correlate with a poor prognosis, whereas cholangiographic appearance, the presence or absence of inflammatory bowel disease, and the patient's age do not. Cholangiocarcinoma (Chapter 181) is a dreaded complication of primary sclerosing cholangitis, and the risk appears to be greatest in patients with long-standing ulcerative colitis and cirrhosis.

FIGURE 141-11. Magnetic resonance cholangiopancreatography demonstrating the typical cholangiographic features of primary sclerosing cholangitis. Note the narrowed segment of the common bile duct (*arrow*) as well as the diffuse strictures and dilated segments of several intrahepatic bile ducts, giving the classic "beaded" appearance.

CHOLEDOCHAL CYSTS AND ANOMALOUS PANCREATICOBILIARY DUCT JUNCTION

Choledochal cysts are uncommon anomalies of the biliary tree that are manifested as cystic dilation of the intrahepatic or extrahepatic ducts (or both). The incidence is 1 in 100,000 to 150,000 births in Western populations and 1 in 1000 in Asian populations. There is a 3 : 1 to 4 : 1 female-to-male preponderance.

TABLE 141-3 CLASSIFICATION OF CHOLEDOCHAL CYSTS

TYPES	DESCRIPTION	PROPORTION OF CHOLEDOCHAL CYSTS
I	Segmental or diffuse fusiform dilation of the bile duct	50-80%
II	Choledochal diverticulum	2%
III	Dilation of the intraduodenal portion of the bile duct	1.4-5%
IVa	Multiple intrahepatic and extrahepatic cysts	15-35%
IVb	Multiple extrahepatic cysts	
V (Caroli disease)	Single or multiple dilations of the intrahepatic ducts	20%
VI	Dilatation of the cystic duct between the neck of the gallbladder and the common hepatic duct	Rare

These cysts (E-Fig. 141-1) usually involve only the extrahepatic biliary tree, but they can present as extrapancreatic bile duct diverticula, involve only the intraduodenal part of the common bile duct, or present as multiple intrahepatic and extrahepatic cysts (Table 141-3). An anomalous pancreaticobiliary duct junction (E-Fig. 141-2) is frequently associated with choledochal cysts but may be found in isolation, especially in Asian populations.

Patients with choledochoceles commonly have biliary colic, cholangitis, jaundice, or unexplained pancreatitis. Bile reflux may also result in acute pancreatitis or predispose to biliary cancers.

Cholangiography, preferably by ERCP, is the diagnostic "gold standard," although MRCP can also delineate the anatomy noninvasively. Because of the increased risk for development of biliary tract cancers, cyst resection (including cholecystectomy) is the generally recommended treatment, although it does not eliminate the risk entirely.[26]

BILIARY FISTULA

A biliary fistula represents an injury to the bile duct, most commonly seen as a complication of cholecystectomy, common bile duct exploration, or inadvertent operative injury of the bile duct or as a consequence of a local infection. Rarely, biliary fistulas result from long-standing untreated biliary tract disease. With more widespread use of laparoscopic cholecystectomy, the incidence of bile duct injury, including biliary fistula, has increased, but it remains less than 0.5% in most published series.

Postoperative bile duct leaks are usually manifested within a week after surgery, with patients presenting with abdominal pain (90%), tenderness (80%), fever (75%), nausea and vomiting (50%), and jaundice (40%). Clinically detectable ascites is rare. Biochemical testing is usually nonspecific, with variable elevations in serum liver test values and the white blood cell count.

Patients with suspected biliary fistulas often undergo abdominal ultrasonography or CT to look for evidence of a biloma as well as a hepatobiliary scan to diagnose the leak. However, ERCP is the most sensitive test to detect a biliary fistula. Treatment options for biliary leaks include percutaneously or endoscopically placed biliary drains or stents and surgical drainage and repair of the leak.

VANISHING BILE DUCT SYNDROMES

The vanishing bile duct syndrome is characterized by a paucity of intrahepatic bile ducts, an elevated alkaline phosphatase level, and cholestasis. Causes include primary biliary cholangitis, primary sclerosing cholangitis, autoimmune hepatitis (Chapter 135), graft-versus-host disease, chronic liver transplant rejection (Chapter 140), ischemia, intrahepatic chemotherapy, drug toxicity (e.g., ampicillin, amoxicillin, flucloxacillin, erythromycin, tetracycline, doxycycline, cotrimoxazole), human immunodeficiency virus (HIV) infection (Chapter 359), sarcoidosis (Chapter 83), and histiocytosis. Ursodeoxycholic acid (15 mg/kg/day) can increase bile flow, but the condition inexorably progresses to biliary cirrhosis, which ultimately requires liver transplantation.

PRIMARY BILIARY CHOLANGITIS

Primary biliary cholangitis, previously known as primary biliary cirrhosis, is an obliterative autoimmune cholangiopathy that involves the small and medium-sized bile ducts and that slowly progresses during a decade or so. As the ducts are obliterated, patients develop cholestasis, fibrosis, and, ultimately, liver failure.[27]

EPIDEMIOLOGY

About 95% of patients with primary biliary cholangitis are women, and the peak age at onset is between 20 and 60 years. The incidence of the disease may be increasing. In the United States, the estimated annual incidence is about 4.5 per 100,000 per year for women and 0.7 for men. Because of the limited life expectancy of affected patients, the age- and gender-adjusted prevalence of primary biliary cholangitis is about 65 per 100,000 in women and about 12 per 100,000 in men.

PATHOBIOLOGY

Although the mechanism of progressive destruction of the small interlobular ducts is unknown, primary biliary cholangitis is considered to be an autoimmune disorder. Genome-wide studies show an association with HLA, interleukin-12A, and interleukin-12RB2 variants, suggesting that interleukin-12 signaling might be important. The disease progresses slowly and can eventually lead to biliary cirrhosis, portal hypertension, and liver failure. The classic histologic finding is noncaseating granulomas and paucity of bile ducts in the portal tracts.

CLINICAL MANIFESTATIONS

The most common symptoms are fatigue (50%), which can be debilitating and is unrelated to the degree of underlying liver disease, and pruritus (30%), but about 50% of patients are asymptomatic at the time of diagnosis. Many patients are initially seen by dermatologists for pruritus, which may be first noticed in pregnancy but persists after delivery.

Autoimmune syndromes associated with primary biliary cholangitis include autoimmune thyroid dysfunction (Chapter 207), Sjögren syndrome (Chapter 247), Raynaud phenomenon (Chapter 246), and celiac disease (Chapter 126). Vitamin D malabsorption can also lead to metabolic bone disease (Chapters 225 and 226).[28]

DIAGNOSIS

The first clue to primary biliary cholangitis is an elevated serum alkaline phosphatase level, which should be confirmed by an elevated γ-glutamyl transpeptidase level (Chapter 133). The antimitochondrial antibody level has a sensitivity and specificity of more than 95% when the titer is higher than 1 : 40, and it may be positive even before there is any clinical or biochemical evidence of the disease. By comparison, the bilirubin level often is not elevated until later in the course of the disease, with most of the elevation typically due to an elevation in conjugated bilirubin. Total immunoglobulins are generally normal, but immunoglobulin M levels can be elevated.

An ultrasound examination of the biliary tree is critical to confirm the absence of extrahepatic disease. A liver biopsy is occasionally needed to confirm the diagnosis, particularly in antimitochondrial antibody–negative patients, and to stage the disease.

TREATMENT

Ursodeoxycholic acid therapy (12 to 15 mg/kg/day) improves serum bilirubin, alkaline phosphatase, and cholesterol levels and has a variable effect on pruritus.[29] Unfortunately, it does not relieve fatigue, reduce mortality, or delay the need for liver transplantation. In patients who do not respond to ursodeoxycholic acid, obeticholic acid in a daily dose of 10 mg can significantly reduce alanine aminotransferase, alkaline phosphatase, and γ-glutamyl transpeptidase levels, but its effect on clinical outcomes such as liver failure and the need for liver transplantation is unknown.[A22] Bezafibrate therapy also improves liver chemistry test results and pruritus[A23] but has not been shown to reduce liver-related mortality or overall mortality. Saroglitazar, a peroxisome proliferator–activated receptor agonist, may also lead to improved alkaline phosphatase levels in patients who are resistant to or intolerant of ursodeoxycholic acid.[30]

There is no definite benefit from steroids, colchicine, azathioprine, or methotrexate. Bisphosphonates (Chapter 225) are commonly prescribed for the accompanying metabolic bone disease, but their benefit is uncertain. Liver transplantation (Chapter 140) is indicated for refractory disease. The posttransplantation prognosis is excellent, with 2-year and 5-year survival rates of 80% and 70%, respectively. However, studies suggest an 8 to 40% recurrence in the transplanted liver.

PROGNOSIS

Up to two thirds of asymptomatic patients become symptomatic within 2 to 4 years. Significant bridging fibrosis or cirrhosis on biopsy carries a worse prognosis. Prognosis is also influenced by the serum bilirubin and albumin levels,

the international normalized ratio, older age, and the presence of peripheral edema. Liver failure develops in about 25% of patients within 10 years after diagnosis, and median survival after diagnosis is 12 to 15 years.

BILE DUCT TUMORS

BENIGN

Benign bile duct tumors are exceedingly rare compared with malignant tumors and are much less common than benign gallbladder tumors. They can be divided into three histologic types (papillomas, adenomas, cystadenomas), may be solitary or multiple, and often are found incidentally during the evaluation of bile duct dilation or intraductal filling defects. Patients may be asymptomatic or have symptoms of biliary obstruction. Treatment typically consists of surgical bile duct resection with hepaticojejunostomy reconstruction. Even benign tumors tend to recur after excision, and some undergo malignant change.

CHOLANGIOCARCINOMA

Cholangiocarcinoma is discussed in Chapter 181.

AMPULLARY TUMORS

Benign ampullary lesions seen on endoscopic or radiologic studies include heterotopic gastric mucosa, a lipoma, or an impacted common bile duct stone. Primary tumors of the ampulla of Vater can be premalignant or malignant, but the overwhelming majority (>95%) are either adenomas or adenocarcinomas. The prevalence of ampullary adenomas has been estimated to be 0.04 to 0.12% in autopsy series, but the prevalence is higher in patients with hereditary polyposis syndromes (Chapter 179), in which ampullary adenomas occur in up to 80% of individuals and progress to malignancy in 4%.

Malignant ampullary lesions are most commonly adenocarcinomas, although metastatic breast cancer, renal cell cancers, and melanomas also have been identified. Carcinoid tumors (Chapter 213) and other neuroendocrine tumors are rare. Ampullary adenomas probably follow an adenoma-to-carcinoma sequence similar to colorectal adenocarcinoma (Chapter 179), with a 25 to 85% risk for transformation to carcinoma.

Patients with ampullary lesions may present with biliary colic, obstructive jaundice, pancreatitis, or nonspecific upper abdominal pain, with or without fluctuating serum liver test results, malaise, and anorexia. However, ampullary lesions are often found incidentally on cross-sectional imaging or during upper endoscopy performed for a different indication.

For ampullary adenomas, options include observation with surveillance biopsies and attempts to resect the lesion completely through endoscopy or surgery. Surveillance of an ampullary adenoma in the setting of familial adenomatous polyposis is reasonable if the lesion is small (<1 cm) and asymptomatic, but resection is preferred if advanced histology (e.g., villous features, dysplasia) is identified. Surgical resection has been the standard for ampullary tumors. Treatment modalities include pancreatoduodenectomy, which has a high rate of morbid and even fatal complications, and transduodenal excision, which is associated with high recurrence rates. The 5-year survival rates after pancreaticoduodenectomy range from 64 to 80% for patients with node-negative disease and from 17 to 50% for node-positive disease. Limited data exist regarding adjuvant therapy, the benefits of which are uncertain. A common practice is to treat these patients in a manner similar to patients with resected pancreatic adenocarcinomas (Chapter 180). Patients who present with unresectable disease tend to receive combination gemcitabine (1000 mg/m^2) plus cisplatin (25 mg/m^2) chemotherapy, each administered on days 1 and 8, every 3 weeks for eight cycles. Palliative biliary stenting can be performed in individuals who have a short life expectancy.

In patients with small, localized, and clearly benign ampullary adenomas, endoscopic resection represents an alternative to surgical therapy in appropriately selected patients (E-Fig. 141-3). Whether endoscopic resection is effective for larger or higher-risk adenomas is uncertain. Furthermore, recurrence rates after endoscopic papillectomy approach 20%, thereby emphasizing the need for careful follow-up endoscopic surveillance.

SPHINCTER OF ODDI DYSFUNCTION

Sphincter of Oddi dysfunction is a benign, noncalculous obstruction to the flow of bile or pancreatic juice through the pancreaticobiliary junction. It may be manifested clinically by pain, pancreatitis (Chapter 130), abnormal liver test results, or abnormal pancreatic enzymes. Post-cholecystectomy pain resembling the patient's preoperative biliary colic occurs in at least 10 to 20% of patients.

Evaluation of patients with suspected sphincter of Oddi dysfunction includes standard serum liver chemistries, serum amylase and lipase levels, and an abdominal ultrasound examination or CT scan. The specimens for serum enzyme studies should be drawn during bouts of pain, if possible. Mild elevations (less than two times the upper limits of normal) are frequent in sphincter of Oddi dysfunction, whereas greater abnormalities are more suggestive of stones, tumors, and parenchymal liver disease. The findings on CT and abdominal ultrasound studies are usually normal, but abnormal liver or pancreatic enzymes or a dilated bile duct or pancreatic duct may occasionally be found. ERCP and sphincter of Oddi manometry may be considered in patients who have objective evidence of pancreatic or biliary disease (abnormal liver or pancreatic enzymes or a dilated bile or pancreatic duct) or clinically significant or disabling symptoms and in whom definitive sphincter ablation is planned if abnormal sphincter function is found. In patients without objective evidence of pancreatic or biliary disease, ERCP and manometry are no longer recommended.[A24]

Medical therapy with nonspecific antispasmodics (e.g., dicyclomine 10 to 20 mg every 6 hours; hyoscyamine 0.375 mg every 12 hours) or smooth muscle relaxants (e.g., nifedipine 60 mg daily) for a 1-month trial should be considered in patients with pancreaticobiliary-type pain (with or without abnormal liver enzyme, amylase, or lipase levels) or a dilated bile or pancreatic duct. If patients do not respond satisfactorily, ERCP and endoscopic sphincterotomy can improve pain in 55 to 95% of patients with abnormal findings on laboratory testing or abdominal imaging. Alternatively, only about 25% of patients without objective evidence of pancreatic or biliary disease improve after sphincterotomy.

142 HEMATOPOIESIS AND HEMATOPOIETIC GROWTH FACTORS

KENNETH KAUSHANSKY

Hematopoiesis is the process by which bone marrow stem cells develop into all of the cell types present in the blood (erythrocytes, neutrophils, eosinophils, basophils, monocytes, platelets, T lymphocytes, B lymphocytes, and natural killer cells) (Fig. 142-1). The regulation of the numbers of each cell type is carefully controlled by paracrine and endocrine hematopoietic growth factors, which exert antiapoptotic, proliferative, and differentiative effects on hematopoietic stem, progenitor, and maturing blood cells. Many of these glycoproteins are now produced by recombinant DNA technology and have been among the most successful therapeutics in modern medicine.

HEMATOPOIETIC STEM AND PROGENITOR CELLS

Hematopoietic stem cells comprise 1 in 10^5 to 10^6 marrow cells and are not morphologically distinguishable from other progenitors or small lymphocytes but can be purified to homogeneity using physical characteristics and combinations of monoclonal antibodies (including $CD34^+$) to cell surface proteins. The two critical characteristics of a hematopoietic stem cell are its ability to differentiate into all blood cell types and to self-renew. The decision to self-renew or differentiate is a stochastic process, at the stem cell stage and at the subsequent multipotent or unipotent stages of differentiation, that can be influenced by a number of cell extrinsic (growth factors and stromal proteins) and cell intrinsic (transcription factors) molecules. Hematopoietic stem cells reside in specialized microenvironments (niches) within the bone marrow. The complex and diverse stromal cell populations that comprise the critical perivascular stem cell niche include endothelial cells, CXCL12 abundant reticular [CAR] cells, nestin+ mesenchymal stem cells, and megakaryocytes and provide signals that support stem cell maintenance, self-renewal, and long-term multilineage repopulation ability.[1]

Clonal hematopoiesis with somatic mutations, which can be detected by DNA sequencing, is more common with advancing age (currently referred to as clonal hematopoiesis of undetermined potential [CHIP]),[2] and is associated with higher risks of hematologic cancer and all-cause mortality.[3] Some genes that are mutated in patients with myeloid cancers are frequently mutated in apparently healthy persons; these mutations may represent characteristic early events in the development of hematologic cancers[4] and are associated with increased risk of atherosclerotic cardiovascular disease.[5] Interestingly, the concordance of clonal hematopoiesis among twins is limited, thereby suggesting in utero or subsequent environmental influences.[6] Evidence based on recapitulating the genetic changes in patients with CHIP in engineered mice strongly suggests that dysregulated inflammation in the affected monocytes/macrophages is responsible for the excess cardiovascular and cerebrovascular disease seen in such patients.[7,8]

HEMATOPOIETIC CELL EXPANSION: HEMATOPOIETIC GROWTH FACTORS

A large number of transcription factors regulate stem cell number and differentiation state. Several molecular switches have been identified that determine hematopoietic cell fate.

Equally important to hematopoiesis is a group of hematopoietic growth factors that share structural homology and bind to nonredundant type I transmembrane proteins belonging to the cytokine receptor family. Many of these proteins are the physiologic regulators of a specific lineage of blood cells (e.g., erythropoietin, granulocyte colony-stimulating factor, thrombopoietin); others appear to represent redundant hematopoietic growth-promoting activities of molecules essential for other biologic functions (e.g., interleukin-3 [IL-3], interleukin-11 [IL-11], granulocyte-macrophage colony-stimulating factor).

Erythropoietin is produced predominantly by the kidneys and to a lesser extent in the liver and acts on marrow erythroid progenitors to enhance their survival, proliferation, and differentiation. Levels of erythropoietin are inversely related to hemoglobin concentrations in the blood, sensed as renal oxygen tension. In the presence of tissue (renal) hypoxia, the transcription factor hypoxia-induced factor (HIF) 1α is stabilized against proteasome-mediated

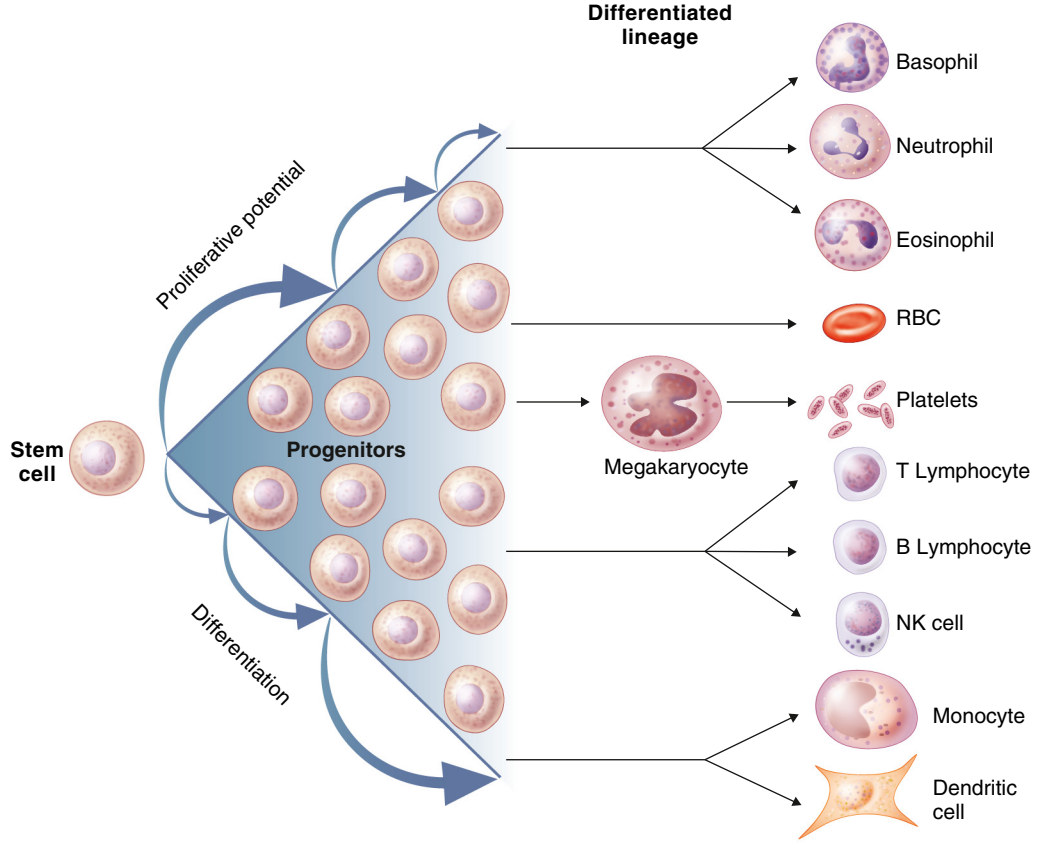

FIGURE 142-1. Hierarchical model of lymphohematopoiesis. NK = natural killer; RBC = red blood cell.

ABSTRACT

Hematopoiesis is the process by which marrow hematopoietic stem cells expand and differentiate into all the formed elements of the blood. The process is under strict control to assure adequate cell numbers to carry oxygen and carbon dioxide to and from the tissues, to fight infection, and to carry out hemostasis. A wide variety of glycoprotein hormones have now been identified that regulate hematopoiesis, many of which have been developed as therapeutics for patients with inadequate numbers of erythrocytes, neutrophils, lymphocytes, and/or platelets.

destruction and drives erythropoietin transcription by binding to a critical hypoxia responsive element located in the 3′ untranslated region of the gene. Genetic elimination of erythropoietin or its receptor results in embryonic lethality, establishing that although other cytokines can influence erythropoiesis, red blood cell production is absolutely dependent on the hormone.

Granulocyte colony-stimulating factor stimulates the production of neutrophils from their marrow progenitors (Fig. 142-2). Levels of the hormone are also inversely related to neutrophil numbers but are regulated primarily by inflammatory stimuli, including tumor necrosis factor-α (TNF-α) and IL-1α acting on endothelial cells, fibroblasts, and macrophages. Similar to the action of erythropoietin on erythroid progenitors, granulocyte colony-stimulating factor acts to enhance the survival, proliferation, and differentiation of neutrophil progenitors.[9] In addition, the cytokine acts to functionally activate the mature cells it helps to produce. Genetic elimination of granulocyte colony-stimulating factor or its receptor in mice reduces neutrophil levels to 25% of normal, the only hormone known to exert this great an impact on granulopoiesis.

Thrombopoietin, the primary regulator of platelet production, is produced in the liver and by marrow stromal cells. Plasma levels of the hormone are normally inversely related to platelet mass and are regulated by the level of senescent platelet uptake, mediated by the hepatocyte Ashwell-Morrell receptor; inflammation, mediated by IL-6; removal of thrombopoietin by circulating platelets; and by transcriptional feedback inhibition of the thrombopoietin gene in marrow stromal cells by platelet granule proteins. Similar to erythropoietin and granulocyte colony-stimulating factor, thrombopoietin stimulates the survival, proliferation, and differentiation of its corresponding lineage, megakaryocytes and their precursors, and primes mature platelets to respond to platelet activation agonists.[10] But unlike the other two cytokines, thrombopoietin also has important, nonredundant effects on the hematopoietic stem cell, which has important implications for leukemogenesis. Genetic elimination of thrombopoietin or its receptor in mice or congenital nonsense or missense mutations in the gene for the thrombopoietin receptor in humans results in platelet levels approximately 10% of normal and a reduction in stem cells, eventuating in aplastic anemia in children by 1 to 2 years of age.

Chemokines and other cytokines also regulate hematopoiesis. The chemokine ligands CXCR2 and CXCL4 affect the survival and self-renewal of hematopoietic stem cells,[11] as does interferon signaling, the effects of which vary with the type of interferon but can play an important role during inflammation.[12] Additional cytokine-receptor systems are essential for one or more aspects of hematopoiesis and mature blood cell function and include IL-7, critical for all types of lymphocyte production; IL-5, the primary regulator of eosinophil production; IL-4, responsible for immunoglobulin class switching in B lymphocytes; IL-15, essential for normal natural killer cell differentiation; and IL-2, a lymphocyte activation cytokine.

Although the effects of these hematopoietic cytokines are clear, a number of lines of evidence suggest that they may exert additional effects outside of blood cell production. For example, both erythropoietin and the leukocyte colony-stimulating factors (GM-CSF and G-CSF) have been found to protect neurons against damage in experimental models of traumatic and ischemic brain injury.[13,14] Although holding much promise, initial clinical trials of erythropoietic stimulating agents in such settings have not yet proven clear efficacy.[15]

The molecular mechanisms by which the hematopoietic growth factors affect blood cell survival, proliferation, and differentiation are becoming increasingly well understood. Binding of cognate ligand to each of the hematopoietic cytokine receptors results in activation of one or more tyrosine kinases, either tethered cytoplasmic kinases of the Janus (JAK) family for the hematopoietic cytokine receptor family or the intrinsic kinase of the cytokines that use the receptor tyrosine kinase class of receptors (stem cell factor, Flt3 ligand, and macrophage colony-stimulating factor). After activation, these kinases phosphorylate tyrosine residues within the cytoplasmic domains of each receptor, providing docking sites for cytoplasmic signaling intermediates possessing Src homology (SH)2 domains. Among the best characterized SH2 domain-containing proteins that bind to hematopoietic receptors are nascent transcription factors, such as the signal transducers and activators of transcription (STAT) proteins; adapter proteins, including Grb2, Gab1, tensin2, and SHC; phosphatases, for example, SHP1 and SHP2; and the regulatory subunit (p85) of phosphoinositol-3-kinase (PI3K). When bound to one or more of the newly induced phosphotyrosine residues of the cytokine receptor or receptor tyrosine kinase, these secondary molecules are phosphorylated, either by JAK or other kinases, making them competent to bind additional molecules (e.g., the adapters that ultimately activate Ras, and p85 PI3K that binds its kinase [p110] subunit) or are activated as transcription factors (e.g., STATs). The downstream effector molecules then activated include a number of kinases, transporter molecules, and transcription factors, ultimately leading to hematopoietic cell survival, proliferation, and differentiation.

CLINICAL USES OF HEMATOPOIETIC CELLS AND GROWTH FACTORS

The clinical development of erythropoietin and related compounds (erythropoietic stimulating agents), granulocyte colony-stimulating factor, and thrombopoietin receptor agonists represent some of the very best examples of harnessing recombinant DNA technology for therapeutic benefit. Patients with renal failure, widespread inflammation, or bone marrow replacement and those undergoing chemotherapy for cancer all experience variable degrees of anemia that is often very debilitating. Administration of erythropoietic stimulating agents (ESAs) almost invariably results in a rapid reticulocyte response and correction of the anemia. Most patients undergo an enhanced sense of well-being as the blood hemoglobin concentration rises to 10 g/dL. Clinical trials have demonstrated the efficacy of these agents in patients with renal failure and with cancer, although recent analyses call into question the safety of these agents in some settings.[A1] For example, patients receiving higher levels of the drug for anemia secondary to kidney failure progressed to requiring dialysis more frequently and experienced increased cardiovascular events, such as myocardial infarction and stroke, than patients on low levels of the hormone sufficient to maintain their blood Hgb at 10 g/dL or lower. The only patients who regularly demonstrate a poor response are individuals with severe inflammation. Overall, erythropoietic stimulating agents are safe and effective drugs for patients with anemia caused by a wide range of conditions, but their use and dose must be carefully considered.

Many patients undergoing cytotoxic therapy for cancer experience severe neutropenia and are thus at substantial risk for life-threatening infection. Clinical trials of recombinant granulocyte colony-stimulating factor in patients undergoing aggressive chemotherapy for leukemia and solid tumors resulted in the Food and Drug Administration (FDA) approval of the drug for use in patients undergoing chemotherapy of intensity sufficient to produce severe neutropenia (Chapter 153). The use of the drug and its numerous biosimilars

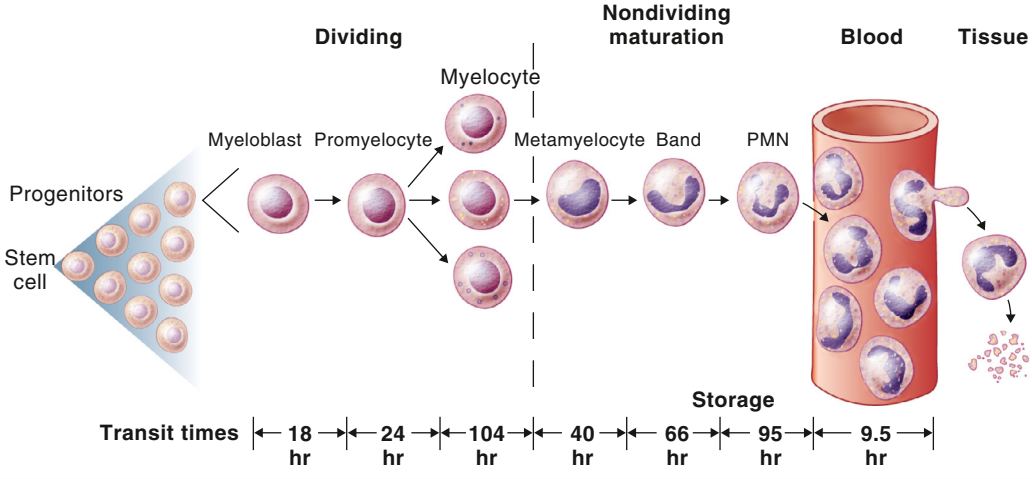

FIGURE 142-2. Neutrophil production system. PMN = polymorphonuclear leukocyte.

is associated with the more rapid return of neutrophils to safe levels if administered soon after the inciting chemotherapy is completed, but not at the nadir of neutrophil production, and results in lower risk of severe infections. However, the use of granulocyte colony-stimulating factor has not enhanced survival in patients with any tumor type. And similar to the use of erythropoietin in patients with cancer, the administration of granulocyte colony-stimulating factor to some patients receiving cytotoxic chemotherapy for cancer (e.g., breast cancer) has been associated with a statistically significant increase in cancer recurrence, although this finding is controversial.

Thrombopoietin was cloned and characterized in 1994 and was quickly advanced to clinical trials following the model of granulocyte colony-stimulating factor use in patients undergoing cancer chemotherapy. Initial results with the intact hormone and a truncated version that included only the receptor-binding domain were mixed, and use of the truncated form of the drug, administration to healthy volunteer donors to improve platelet apheresis yields, resulted in a significant number of subjects developing antidrug antibodies that cross-reacted with their native thrombopoietin, resulting in severe thrombocytopenia. This experience caused manufacturers of thrombopoietin to cease clinical trials. Instead, several small molecules that bind to and stimulate the thrombopoietin receptor and stimulate thrombopoiesis have been developed for clinical use.[A2,A3] Two such drugs approved by the FDA for use in patients with severe immune thrombocytopenia include a peptibody that contains four copies of a thrombopoietin receptor–binding peptide grafted onto an immunoglobulin scaffold and a small organic molecule that is orally bioavailable and binds to a spatially distinct site on the thrombopoietin receptor. The use of each drug results in a high rate of platelet responses into the normal range in patients with severe immune thrombocytopenia (Chapter 158) who were refractory to conventional therapies. It was initially thought that although thrombopoietin receptor agonists would stimulate platelet production in excess of immune destruction, they would not alter the pathophysiology of immune thrombocytopenia purpura (ITP), and hence be required for very long periods of time. However, a growing number of patients who have extremely refractory ITP have been reported no longer to require a thrombopoietin receptor agonist after a variable number of months of therapy, thereby suggesting that these drugs might be able to alter the immune response in such patients. In addition to the treatment of patients with ITP, thrombopoietin receptor agonists have been approved for use in patients with thrombocytopenia secondary to interferon treatment of hepatitis C viral infection and for patients with aplastic anemia. Additional clinical indications are being tested.

143 THE PERIPHERAL BLOOD SMEAR

BARBARA J. BAIN

With the development of sophisticated automated instruments to count and characterize blood cells, Romanowsky (Wright-Giemsa or May-Grünwald-Giemsa)–stained peripheral blood smears are now performed on only a minority of blood specimens received in a hematology laboratory. Nevertheless, the blood smear remains important for a number of reasons: it can (1) verify the result of an automated instrument, (2) provide an immediate specific diagnosis, or (3) indicate a narrow range of diagnostic possibilities, permitting focused rather than indiscriminate investigation.[1-3] A blood film can provide a rapid diagnosis in cases in which speed is crucial, such as in acute promyelocytic leukemia, thrombotic thrombocytopenic purpura, Burkitt lymphoma, and certain infections.[4] It also can aid in the rapid diagnosis of malaria (Chapter 316)[5] and babesiosis (Chapter 324).[6] Sometimes a smear reveals an error in an automated blood count[7] or provides unexpected information that is of value in patient management.[8]

Usually, blood smears are initially interpreted by a laboratory scientist. In some countries, it is customary for clinicians to examine the blood smears of their own patients because the clinician has the final responsibility for integrating all information and making a diagnosis. However, the interpretation of a blood smear can be difficult, and a trained laboratory hematologist or hematopathologist often has a major role in interpreting smears that may have been initially examined by a laboratory scientist.[9] Digital microscopy permits a preliminary assessment and is a practical option for expert evaluation and triage of peripheral blood smears in locations where experienced staff are not available on site.[10]

It is crucial that, when requesting a blood count, the clinician provides all the essential information needed to interpret the count and any associated smear. Regardless of whether the clinician examines the blood film, he or she must be able to interpret the written report issued by the laboratory. To do so, the clinician must be familiar with the terms generally used by laboratory staff and the possible significance of the abnormalities described. The most important of these terms are illustrated in Figs. 143-1 through 143-20.

REASONS FOR PERFORMING A BLOOD SMEAR

A blood smear may be requested by a clinician or initiated by a laboratory scientist or a laboratory hematologist. Clinical findings that should lead a clinician to request a blood smear are summarized in Table 143-1.

Laboratory scientists and physicians may initiate a blood smear that has not been requested by the clinician if the clinical details indicate the possibility of a significant hematologic abnormality. However, they are also likely to evaluate a blood smear in response to abnormalities revealed by an automated instrument. These abnormalities may be quantitative or qualitative. Quantitative abnormalities that require evaluation include anemia, polycythemia, macrocytosis, microcytosis, neutrophilia, lymphocytosis, eosinophilia, thrombocytopenia, and thrombocytosis.

Modern automated instruments are able to "flag" the presence of qualitative abnormalities that require a blood film to be examined for confirmation of the abnormality or for further elucidation. "Flags" are generated in response to the electrical impedance or the light scattering characteristics of individual cells. Some instruments are dependent on cytochemical reactions of cells or on the cells' ability to polarize light. Most instruments can indicate the

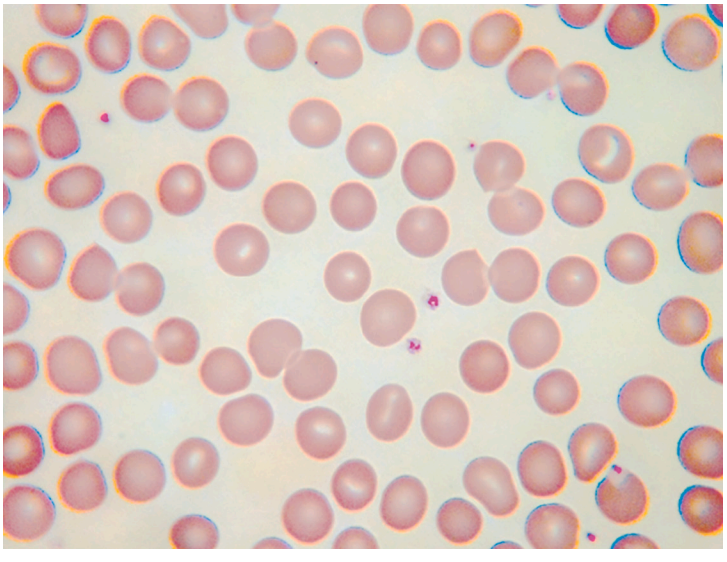

FIGURE 143-1. Normal peripheral blood smear. These normal red cells are described as *normocytic* (i.e., of normal size) and *normochromic* (i.e., their staining characteristics are normal). Normal erythrocytes are biconcave discs, causing them to have an area of central pallor that does not exceed one third the diameter of the cell. There are also scattered normal platelets (×1000).

However, the interpretation of a blood smear can be difficult, and a trained laboratory hematologist or hematopathologist often has a major role in interpreting smears that may have been initially examined by a laboratory scientist.[9] Digital microscopy permits a preliminary assessment and is a practical option for expert evaluation and triage of peripheral blood smears in locations where experienced staff are not available on site.[10]

It is crucial that, when requesting a blood count, the clinician provides all the essential information needed to interpret the count and any associated smear. Regardless of whether the clinician examines the blood film, he or she must be able to interpret the written report issued by the laboratory. To do so, the clinician must be familiar with the terms generally used by laboratory staff and the possible significance of the abnormalities described. The most important of these terms are illustrated in Figs. 143-1 through 143-20.

REASONS FOR PERFORMING A BLOOD SMEAR

A blood smear may be requested by a clinician or initiated by a laboratory scientist or a laboratory hematologist. Clinical findings that should lead a clinician to request a blood smear are summarized in Table 143-1.

Laboratory scientists and physicians may initiate a blood smear that has not been requested by the clinician if the clinical details indicate the possibility of a significant hematologic abnormality. However, they are also likely to evaluate a blood smear in response to abnormalities revealed by an automated instrument. These abnormalities may be quantitative or qualitative. Quantitative abnormalities that require evaluation include anemia, polycythemia, macrocytosis, microcytosis, neutrophilia, lymphocytosis, eosinophilia, thrombocytopenia, and thrombocytosis.

Modern automated instruments are able to "flag" the presence of qualitative abnormalities that require a blood film to be examined for confirmation of the abnormality or for further elucidation. "Flags" are generated in response to the electrical impedance or the light scattering characteristics of individual cells. Some instruments are dependent on cytochemical reactions of cells or on the cells' ability to polarize light. Most instruments can indicate the

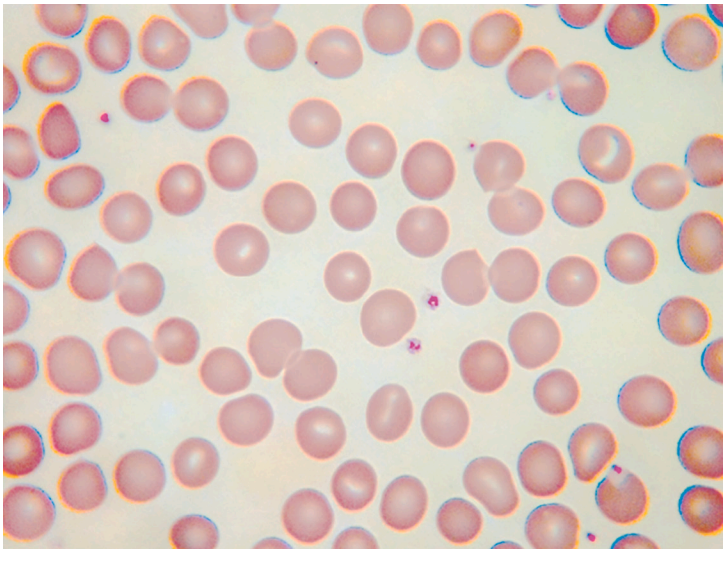

FIGURE 143-1. Normal peripheral blood smear. These normal red cells are described as *normocytic* (i.e., of normal size) and *normochromic* (i.e., their staining characteristics are normal). Normal erythrocytes are biconcave discs, causing them to have an area of central pallor that does not exceed one third the diameter of the cell. There are also scattered normal platelets (×1000).

ABSTRACT

Despite major advances in other diagnostic methods, the blood smear remains very useful in hematologic diagnosis. Sometimes it is critical, either because it yields a diagnosis very quickly or because it provides information that is not available in any other way. Blood smear examination permits other tests to be targeted to confirming a diagnosis or exploring a differential diagnosis.

KEYWORDS

blood smear

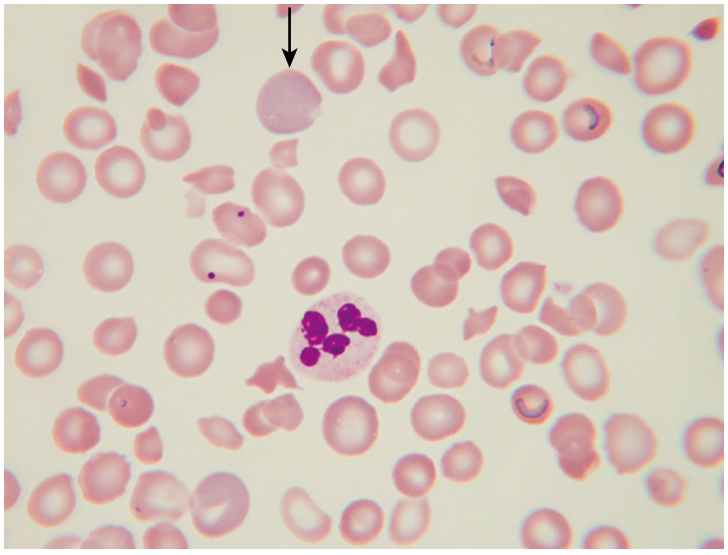

FIGURE 143-2. Smear showing multiple abnormalities. There is *anisocytosis*, defined as an increased variation in cell size; *poikilocytosis*, defined as an increased variation in cell shape; and *polychromasia*, defined as the presence of erythrocytes with a blue tinge to their cytoplasm—indicating a young cell recently released from the bone marrow in which the polychromasia is due to the presence of RNA. *Polychromatic cells* are erythrocytes with a blue tinge; because polychromatic cells are larger than normal mature erythrocytes, they are known as *polychromatic macrocytes* (*arrow*). The film also shows two cells containing bluish purple *Howell-Jolly bodies;* these inclusions are nuclear remnants (×1000).

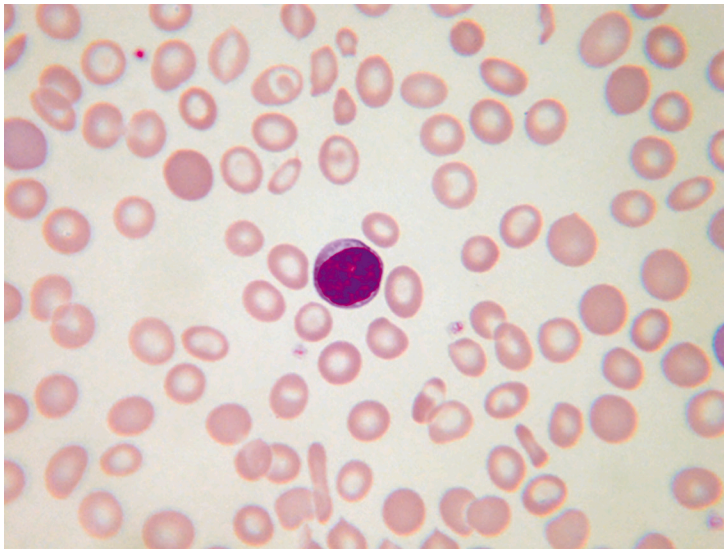

FIGURE 143-3. Microcytic red cells from a case of thalassemia minor (β-thalassemia heterozygosity). In a blood smear, a *microcyte* can be defined as a cell with a diameter less than that of the nucleus of a normal small lymphocyte (generally 7 to 8 μm). There are also some cells showing *hypochromia*, an area of central pallor that is larger than one third of the diameter of the red cell. In addition, there are two *target cells*, with a hemoglobinized area in the center of the area of pallor (×1000).

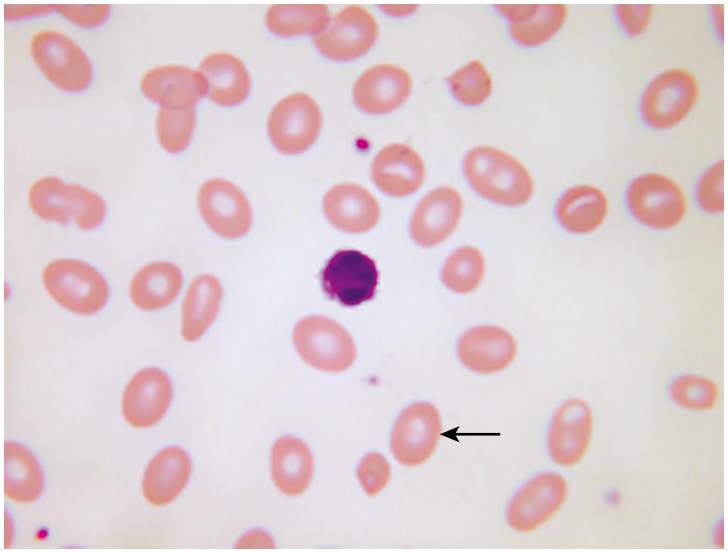

FIGURE 143-4. Macrocytic anemia. A *macrocyte* is recognized on a blood film as a cell with a diameter that is considerably greater than that of the nucleus of a small lymphocyte. In addition, this smear shows *oval macrocytes* (also known as *macro-ovalocytes*), defined as cells that are larger than normal and oval in shape (*arrow*). They are of considerable diagnostic importance, being characteristic of megaloblastic anemia and Southeast Asian ovalocytosis; they can also be seen in dyserythropoiesis (×1000).

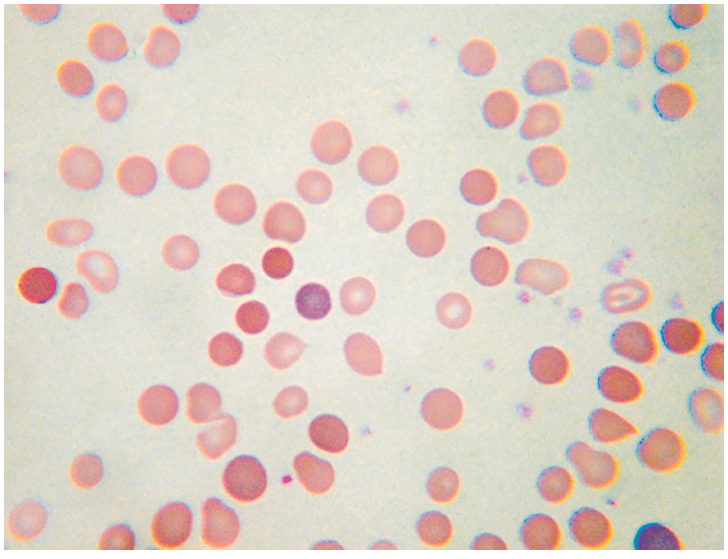

FIGURE 143-5. Hereditary spherocytosis. A *spherocyte* is a red cell that lacks central pallor because of its spherical shape. In hereditary spherocytosis, there are usually cells in which the central pallor is reduced rather than absent, and they are intermediate in shape between a spherocyte and a *discocyte*, which is an erythrocyte with the normal shape of a biconcave disc (×1000).

possibility of the presence of blast cells, reactive or other atypical lymphocytes, granulocyte precursors, or nucleated red blood cells. Some instruments can enumerate nucleated red blood cells. Instruments using a cytochemical reaction for peroxidase to help identify neutrophils, eosinophils, and monocytes may flag the appearance of large, unstained (i.e., peroxidase-negative) cells; such cells may indicate a harmless inherited peroxidase deficiency, but sometimes such cells are lymphoma cells, reactive lymphocytes, or leukemic blast cells. Instruments often flag the possibility of an erroneous platelet count, such as when there is an overlap in size between platelets and red cells or when light-scattering characteristics suggest the presence of platelet aggregates (a potential cause of pseudothrombocytopenia). A reported increase in basophil count should generally also be regarded as a flag because it often represents a pseudobasophilia, resulting from the presence of leukemia or lymphoma cells. Some instruments alert the instrument operator to the possible presence of malaria parasites.

International consensus guidelines indicate which automated instrument results require blood smear review. Whether a review is needed is determined in part by whether that specimen is the first one obtained from that patient and whether there has been a significant change from a previously validated result (referred to as a *delta check*). Laboratory computers can be programmed to indicate when a result meets the criteria for smear review.

Automated red cell measurements can, to some extent, replace examination of the blood film.[11] An increased red cell distribution width indicates the presence of anisocytosis. A decreased mean cell volume is usually a reliable indicator of microcytosis. A reduction in the mean cell hemoglobin concentration indicates hypochromia (for most instruments, however, this measurement is less sensitive than the human eye in the detection of hypochromia). An increased mean cell volume usually indicates macrocytosis, but examination of a smear is necessary both to confirm that the result is not an artifact and to elucidate the cause. Some instruments can measure the hemoglobin concentration in individual cells and thus flag the presence of hyperdense cells; however, a blood film is still necessary to distinguish spherocytes from irregularly contracted

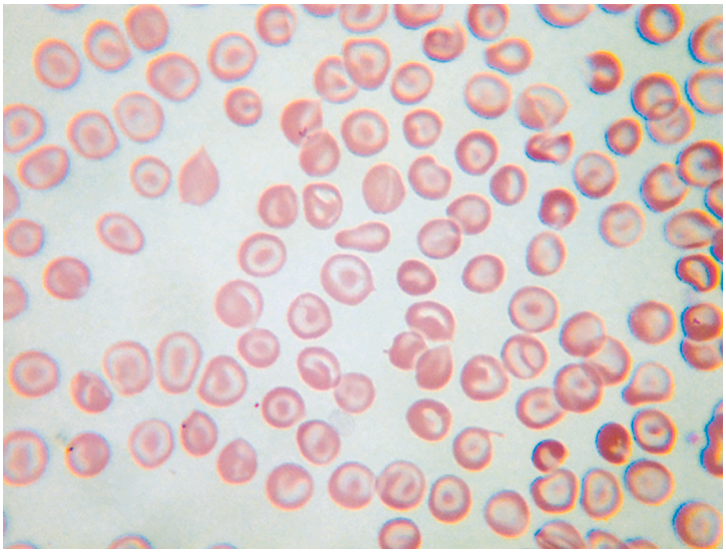

FIGURE 143-6. Target cells. A *target cell* is an erythrocyte with a hemoglobinized area in the middle of the normal area of central pallor (×1000).

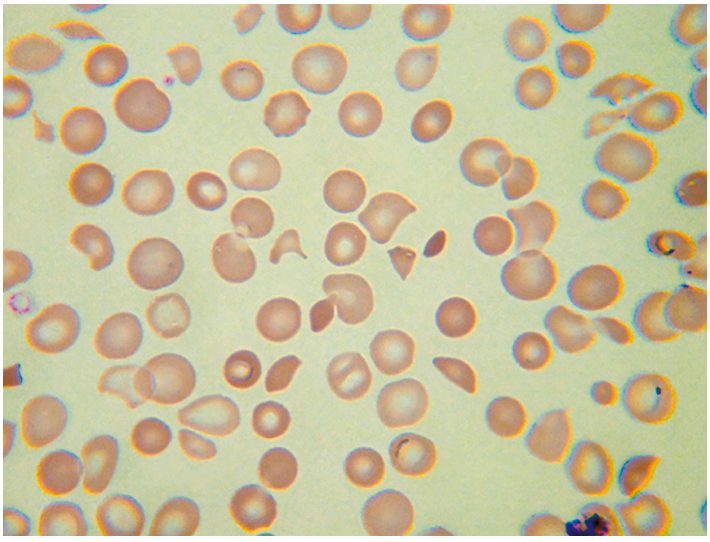

FIGURE 143-8. Red cell fragmentation. *Red cell fragments* or *schistocytes* are defined as fragments of erythrocytes. In addition to small angular fragments, there may be *microspherocytes*, cells of reduced size and spherical in form (also known as *spheroschistocytes*), and *keratocytes*, cells with two or four hornlike projections. Keratocytes can result from removal of a Heinz body, as well as from red cell fragmentation. Some schistocytes are referred to as *helmet cells* because of their typical shape. Schistocytes are seen in microangiopathic hemolytic anemias and in mechanical hemolysis (×1000).

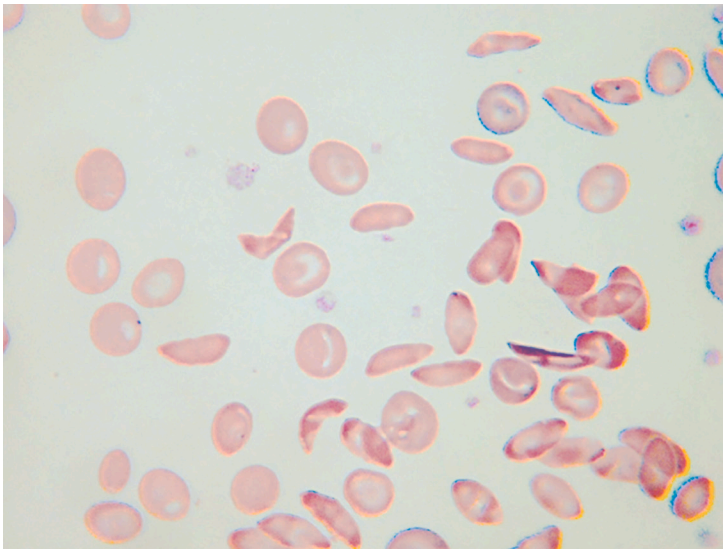

FIGURE 143-7. Sickle cells. A *sickle cell* is a cell with a sickle or crescent shape resulting from the polymerization of hemoglobin S. These cells are seen in sickle cell anemia (homozygosity for hemoglobin S) as well as in compound heterozygous states such as sickle cell/hemoglobin C disease and sickle cell/β-thalassemia, which also lead to sickle cell disease. This smear also shows target cells and boat-shaped cells with a lesser degree of polymerization of hemoglobin S than in a classic sickle cell (×1000).

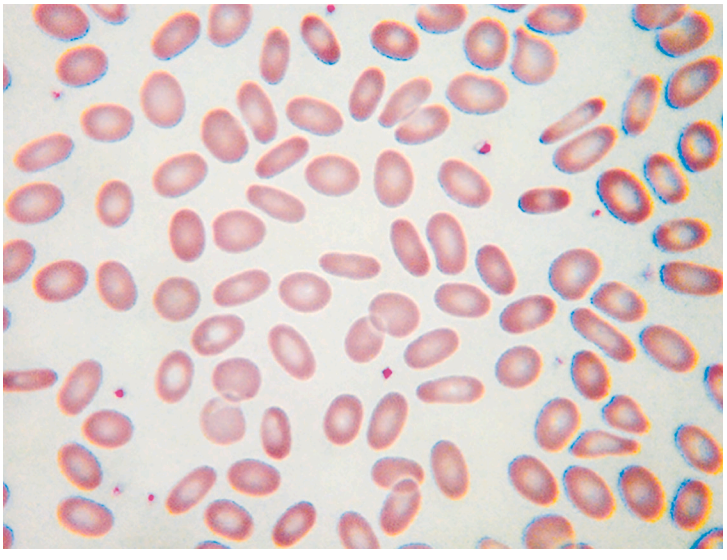

FIGURE 143-9. Hereditary elliptocytosis. An *elliptocyte* is an elliptical red cell. When seen in the numbers present in this smear, they are indicative of hereditary elliptocytosis; smaller numbers are seen in other conditions such as iron deficiency anemia, in which they are sometimes referred to as *pencil cells* (×1000).

cells, sickle cells, and other cells that have an increased hemoglobin concentration. Most instruments produce a histogram of the size distribution of red cells, and some do the same for the distribution of hemoglobin concentration; either of these graphic representations may show dimorphic red cells (i.e., two populations of cells).

THE BLOOD SMEAR IN THE DIFFERENTIAL DIAGNOSIS OF ANEMIA

MICROCYTIC ANEMIAS

In microcytic anemias (Chapter 145), the automated count is of considerable importance and may permit a distinction between iron deficiency and thalassemia heterozygosity. In iron deficiency, there is initially a normocytic normochromic anemia; only when the deficiency becomes more severe is there microcytosis. Conversely, in β-thalassemia heterozygosity, there is usually a normal or near-normal hemoglobin concentration, but the red blood cell count is increased, and there is marked microcytosis (low mean cell volume) together with a parallel reduction in mean cell hemoglobin. The blood film provides supplementary information that can favor one diagnosis or the other. Iron deficiency is more likely to be associated with hypochromia and elliptocytes ("pencil cells"), whereas in β-thalassemia heterozygosity, there is microcytosis, hypochromia is less marked, and there are more likely to be target cells and basophilic stippling. Individuals with α-thalassemia involving the deletion of two α genes (−α/−α) or (− −/α α) have red cell indices similar to those of β-thalassemia heterozygosity; in this case, the blood film usually does not provide any additional diagnostically useful information, although individuals with nondeletional α-thalassemia due to hemoglobin Constant Spring have prominent basophilic stippling. When there is deletion of a single α gene, the blood count is either less abnormal or normal, and the blood smear does not provide any extra diagnostically useful information. The blood smear is, however, a useful supplement to the blood count in suggesting a diagnosis of hemoglobin H disease (Chapter 148). The blood count shows anemia, marked microcytosis (low mean cell

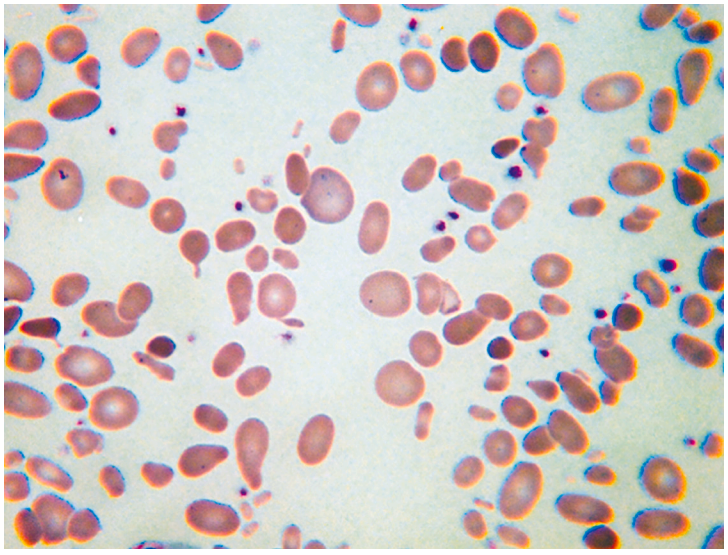

FIGURE 143-10. Hereditary pyropoikilocytosis. This smear shows striking poikilocytosis, including elliptocytes, microspherocytes and other fragments, as well as teardrop cells. Hereditary pyropoikilocytosis is a congenital condition, similar to hereditary elliptocytosis, which usually results from the inheritance of two different mutated genes, one from each parent, and is characterized by a severe hemolytic anemia (×1000).

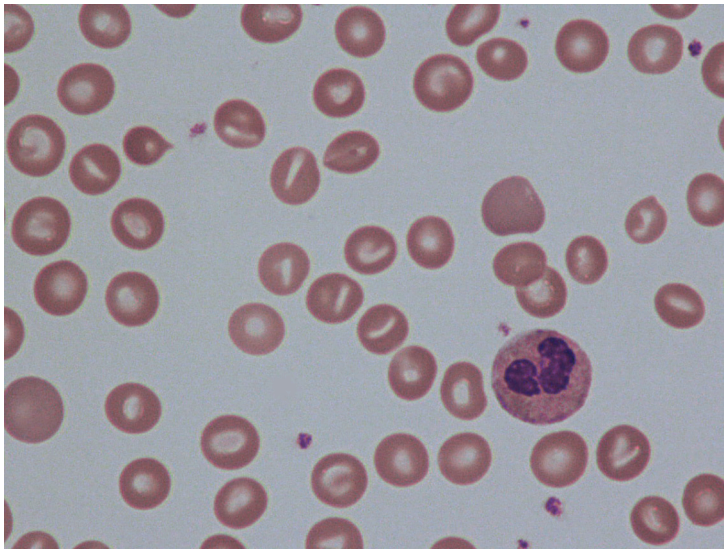

FIGURE 143-12. Stomatocytosis. A *stomatocyte* is a cell that appears to have a central mouth-shaped or slitlike stoma. Among the less common causes are hereditary stomatocytosis and phytosterolemia (also known as sitosterolemia). Alcohol and hydroxycarbamide (hydroxyurea) therapy are more common causes (×1000).

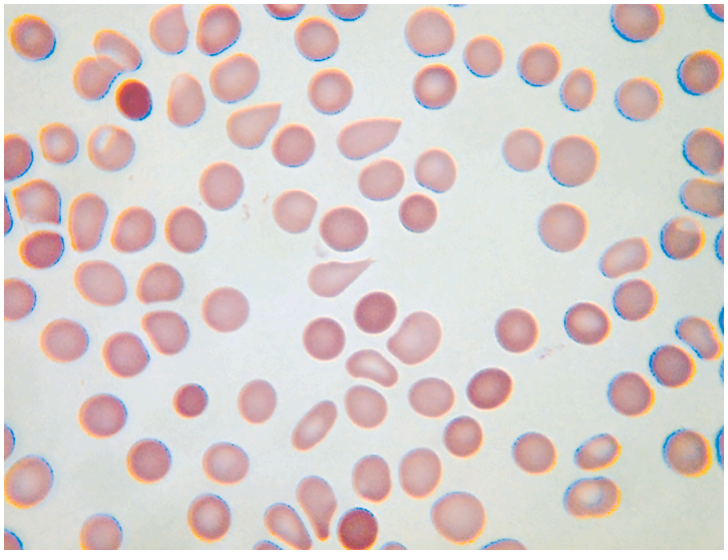

FIGURE 143-11. Teardrop poikilocytes. *Teardrop poikilocytes*, or *dacrocytes*, are teardrop-shaped red cells; they are characteristic of primary myelofibrosis but are also seen in myelofibrosis following other myeloproliferative neoplasms or secondary to bone marrow infiltration and in megaloblastic anemia (×1000).

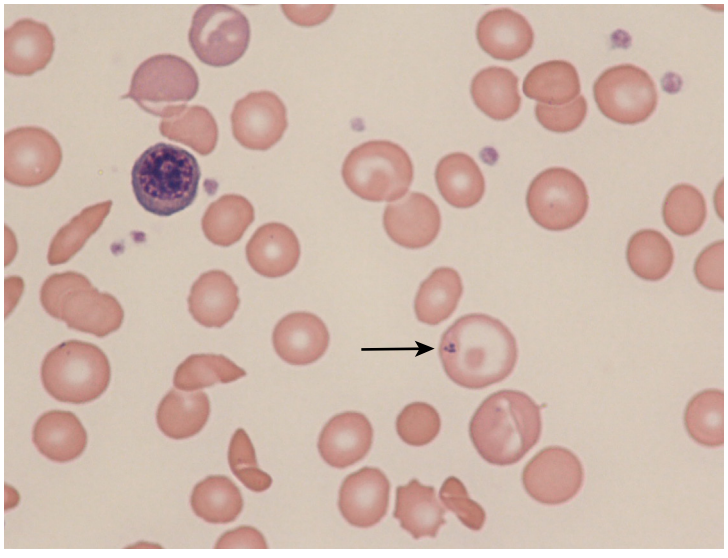

FIGURE 143-13. A cluster of Pappenheimer bodies within a target cell in sickle cell anemia. A *Pappenheimer body* is an iron-containing red cell inclusion. It is smaller and more angular than a Howell-Jolly body and stains navy blue rather than purple. Pappenheimer bodies are seen following splenectomy, in other hyposplenic states, and in sideroblastic anemias. The smear also shows boat-shaped cells, a nucleated red blood cell, polychromatic macrocytes, and a polychromatic stomatocyte (×1000). A Perls stain confirms the iron content in a Pappenheimer body.

volume and mean cell hemoglobin), and usually a reduction in the mean cell hemoglobin concentration. The smear usually shows marked poikilocytosis in addition to microcytosis, and there may be polychromasia, correlating with an elevated reticulocyte count. Iron deficiency anemia should also be distinguished from anemia of chronic disease. The blood counts may be quite similar in the two conditions, but microcytosis is less common in anemia of chronic disease, and the smear often shows features of inflammation, such as increased rouleaux formation, background staining (as a result of increased plasma proteins), and sometimes neutrophilia. Other rare microcytic anemias that must be distinguished from iron deficiency include congenital sideroblastic anemia (Chapter 145) and lead poisoning. In congenital sideroblastic anemia, the film is dimorphic, with one population of hypochromic microcytes and another of normochromic normocytic cells. In lead poisoning, the presence of basophilic stippling and polychromasia in a patient with microcytosis can suggest the diagnosis. Sometimes a blood film provides the first clue that apparent microcytosis is actually the result of red cell fragmentation.

MACROCYTIC ANEMIAS

A blood film can be important in distinguishing true macrocytosis from factitious macrocytosis as a result of the presence of red cell agglutinates (see Fig. 143-16). Diagnostic features that can suggest the cause of macrocytosis are shown in Table 143-2.

A smear is particularly important in evaluating the possibility of a megaloblastic anemia (Chapter 150) (Figs. 143-4 and 143-21). Sometimes assays of vitamin B_{12} and folate are normal despite a deficiency, and only the blood film features suggest the true diagnosis and indicate the need for further investigation.

NORMOCYTIC NORMOCHROMIC ANEMIA

A blood smear is only occasionally useful in determining the cause of a normocytic normochromic anemia. Signs of inflammation may be present in

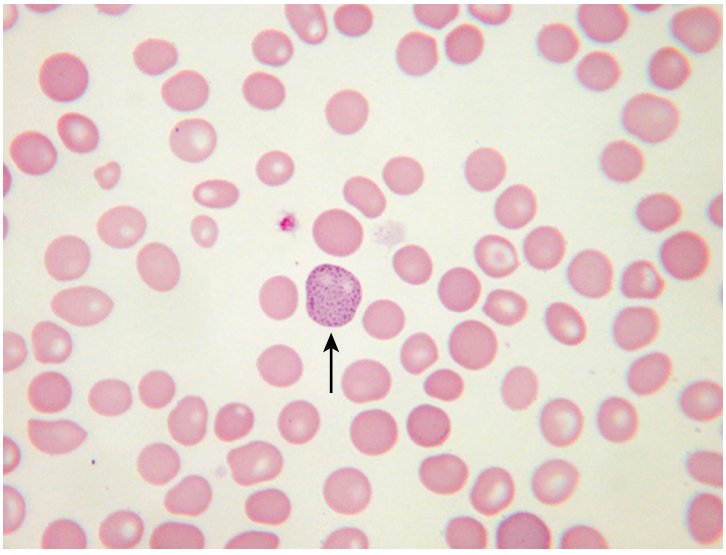

FIGURE 143-14. Basophilic stippling. *Basophilic stippling*, also known as punctate basophilia, means that there are fine (as in this case) or coarse purplish blue dots dispersed through the red cell (*arrow*). They are a very nonspecific feature occurring in thalassemia trait, lead poisoning, pyrimidine 5′-nucleotidase deficiency, and dyserythropoiesis in general (×1000).

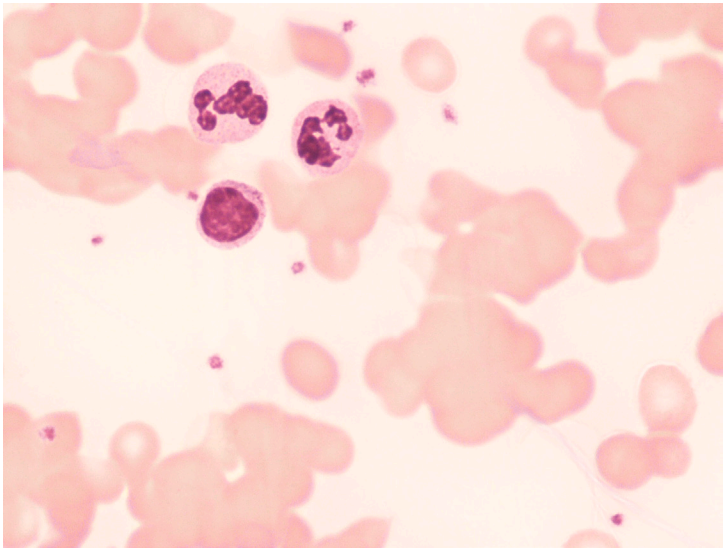

FIGURE 143-16. Red cell agglutination. *Red cell agglutinates* are irregular aggregates of red cells, often seen in *Mycoplasma pneumoniae* infection; other infections, such as infectious mononucleosis; and in chronic cold hemagglutinin disease (×1000).

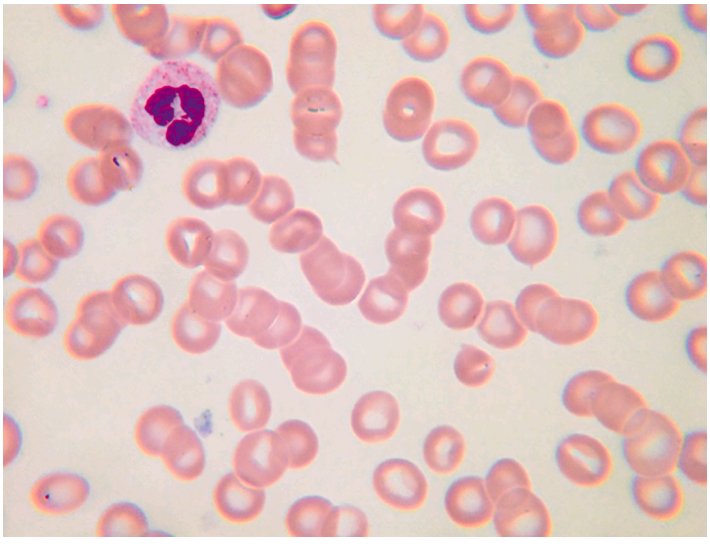

FIGURE 143-15. Rouleaux formation. *Rouleaux* are stacks of red cells, often compared to stacks of coins. Rouleaux formation results from an increase of high-molecular-weight globulins in the plasma, either as a reactive change or as a result of secretion of a paraprotein in a plasma cell neoplasm (×1000).

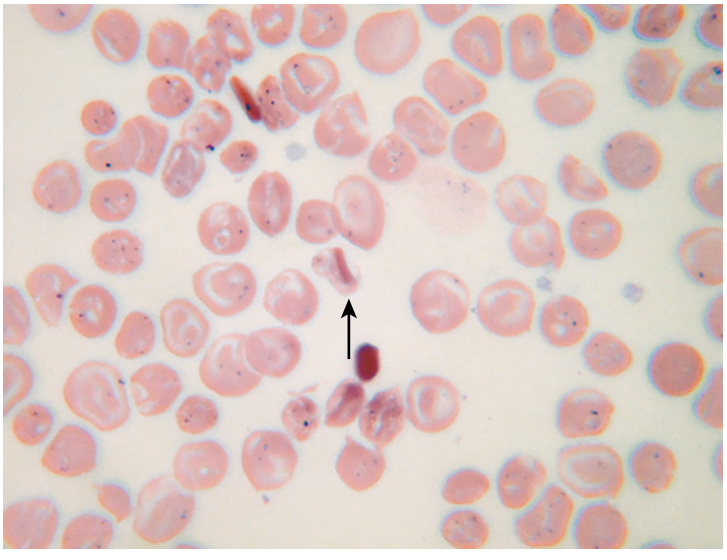

FIGURE 143-17. Homozygous hemoglobin C or hemoglobin C disease. Three *hemoglobin C crystals* are present, one indicated by an *arrow*. Hemoglobin C crystals are usually six-sided, with a long axis having parallel edges. In addition to hemoglobin C disease, these crystals can also be seen in sickle cell/hemoglobin C compound heterozygosity and in hemoglobin C/β^0 thalassemia (×1000).

anemia of chronic disease. Rouleaux formation and increased background staining can also indicate multiple myeloma. Polychromasia suggests the possibility of young red cells as a result of recent blood loss or hemolysis. Small numbers of acanthocytes may indicate hypothyroidism or anorexia nervosa. Dysplastic features, such as hypogranular or pseudo-Pelger neutrophils, suggest a myelodysplastic syndrome.

HEMOLYTIC ANEMIAS

The possibility of hemolysis is suggested by the presence of polychromasia and macrocytosis. Specific causes of hemolysis are suggested by the presence of various poikilocytes, as shown in Table 143-3.

The distinction between spherocytes and irregularly contracted cells is important; both are dense cells with absent central pallor, but the differential diagnosis is quite different. Recognition of the features of oxidant damage is important in diagnosing glucose-6-phosphate dehydrogenase (G6PD) deficiency because sometimes an assay for G6PD performed during an acute hemolytic episode is normal (Chapter 147). In addition to irregularly contracted cells, there may be ghost cells, hemi-ghost cells ("blister cells"), and even Heinz bodies protruding from the red cells and confirmed on a Heinz body preparation. The observation of these features is an indication to repeat the assay when the acute hemolytic episode is over.

ASSESSMENT OF THROMBOCYTOPENIA, THROMBOCYTOSIS, AND PLATELET MORPHOLOGY

A blood smear is essential to validate the count whenever an automated count shows thrombocytopenia (e.g., a count $<60 \times 10^9$/L) (Chapter 158). This should be done quickly before patient management is altered, such as by postponing surgery or initiating further diagnostic workup. A platelet transfusion should never be given for an unexpected thrombocytopenia without microscopic confirmation of the count. A factitiously low platelet count is often the result of in vitro platelet aggregation (Chapter 157) and is occasionally the result of platelet satellitism (platelets surrounding neutrophils, generally seen in samples anticoagulated with EDTA), and possibly also with platelet phagocytosis. To detect aggregates reliably, the edges and the tail of the smear

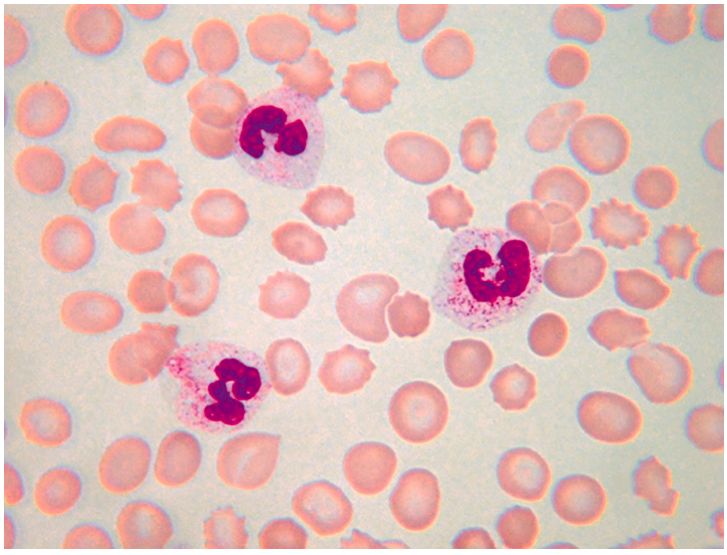

FIGURE 143-18. Toxic granulation. *Toxic granulation* refers to heavy staining of azurophilic granules of neutrophils. When accompanied by neutrophil vacuolation, it is often indicative of infection, but toxic granulation can also result from inflammation, tissue damage, administration of granulocyte colony-stimulating factor, and normal pregnancy. Rarely it results from chronic neutrophilic leukemia or a leukemoid reaction to multiple myeloma (×1000).

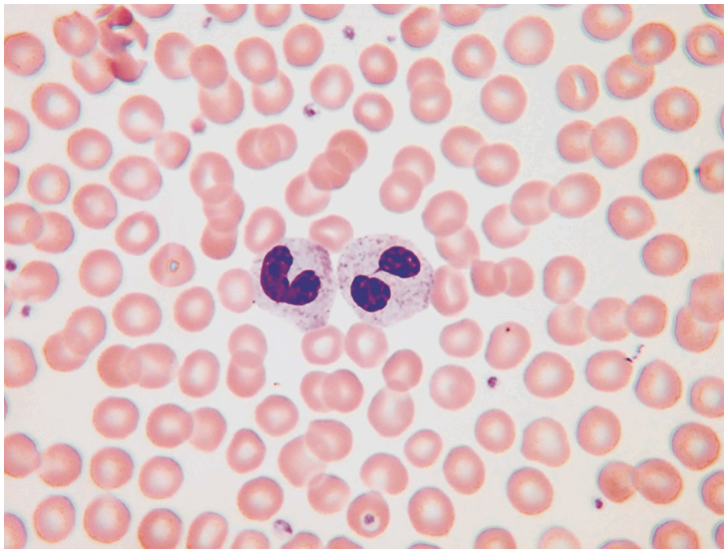

FIGURE 143-20. Pelger-Huët anomaly. A *Pelger-Huët anomaly* is a cytologic abnormality of neutrophils in which there is hypolobulation of nuclei and increased chromatin clumping. Nuclei may have a shape resembling a peanut or a pince-nez, as in the example shown. The Pelger-Huët anomaly is inherited, but similar pseudo-Pelger neutrophils are seen in myelodysplastic syndromes, in which the neutrophils may also be hypogranular (×1000). They can also be seen as an acquired reversible phenomenon in response to specific drugs, including tacrolimus and mycophenolate mofetil.

FIGURE 143-19. Döhle body. A *Döhle body* (*arrow*) is a pale blue-gray amorphous inclusion near the cell membrane of a neutrophil. Döhle bodies can result from infection and inflammation. Similar but different inclusions (larger and more angular) are seen in the May-Hegglin anomaly (MYH9-related disorder) (×1000).

TABLE 143-1 CLINICAL FEATURES SUGGESTING THE NEED FOR A BLOOD SMEAR

CLINICAL FEATURE	REASON TO PERFORM A BLOOD SMEAR
Lymphadenopathy or splenomegaly	May be indicative of infectious mononucleosis or another reactive condition or of leukemia or lymphoma
Clinically evident anemia	Helps in the differential diagnosis
Bruising or bleeding tendency, including unexplained retinal hemorrhages	May confirm thrombocytopenia or show morphologically abnormal platelets (which may have defective function); sometimes shows acute leukemia or other condition causing bone marrow failure
Acute kidney injury	Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura should be confirmed or excluded
Jaundice and hypertension in a pregnant woman	May show schistocytes, supporting a diagnosis of HELLP syndrome
Bone pain	May indicate multiple myeloma, bone marrow infiltration, or sickle cell disease
Unexplained chest or abdominal pain or acute splenic enlargement in a child	Possible sickle cell disease
Unexplained hyperbilirubinemia	Assessment of possible hemolysis

HELLP = hemolysis, elevated liver enzymes, low platelets.

should be examined. The presence of fibrin strands also suggests the activation of coagulation and an erroneous platelet count.

If a low platelet count is confirmed, the film may give clues to the cause (Chapter 158).[12] Giant platelets (Figs. 143-22 and 143-23) occur in a number of inherited thrombocytopenias, including Bernard-Soulier syndrome and MYH9-related disorders (the May-Hegglin anomaly and related conditions).[13] Small platelets are less common but are a feature of Wiskott-Aldrich syndrome. Agranular platelets occur in gray platelet syndrome, and platelets with a reduced number of larger-than-normal granules are seen in Jacobsen/Paris-Trousseau syndrome. The presence of May-Hegglin inclusions (Döhle-like bodies; see Fig. 143-19) in neutrophils indicates that the cause of the thrombocytopenia is a mutation in *MYH9*. In acquired thrombocytopenias, increased platelet turnover is often accompanied by the presence of large platelets, whereas bone marrow failure is associated with platelets of normal size. It is important to look for red cell fragments to confirm or exclude a diagnosis of thrombotic thrombocytopenic purpura and atypical hemolytic-uremic syndrome in any patient with the apparent recent onset of thrombocytopenia; because platelet transfusions are usually contraindicated in these conditions, the smear should be examined before platelet transfusion is contemplated. Occasionally the smear reveals clinically unsuspected malaria. The smear of any patient with the apparent recent onset of severe thrombocytopenia should be examined carefully for evidence of acute promyelocytic leukemia; the leukemic cells may be infrequent in the circulating blood. Hemorrhagic manifestations and a low platelet count can also be indicative of meningococcal septicemia; in some patients, organisms are seen in the blood smear and the diagnosis is confirmed; in other patients, only marked toxic changes in neutrophils are detected.

Thrombocytosis should also be confirmed on a smear. Factitiously elevated counts may be the result of the presence of red cell fragments (in

TABLE 143-2 USEFUL FEATURES FOR DETERMINING THE CAUSE OF MACROCYTIC ANEMIA

CAUSE	SMEAR FEATURES
Megaloblastic anemia (vitamin B_{12} or folic acid deficiency)	Oval macrocytes, teardrop poikilocytes, hypersegmented neutrophils; when severe, marked anisocytosis and poikilocytosis, which may include red cell fragments
Ethanol excess	Target cells and stomatocytes; anisocytosis and poikilocytosis less than in megaloblastic anemia
Liver disease	Target cells, stomatocytes
Myelodysplastic syndromes, including sideroblastic anemias	Other dysplastic features such as hypogranular and hypolobulated neutrophils; if erythropoiesis is sideroblastic, a population of hypochromic microcytic cells and Pappenheimer bodies
Chronic hemolytic anemia	Polychromasia; characteristic poikilocytes sometimes present (e.g., irregularly contracted cells if there is an unstable hemoglobin)

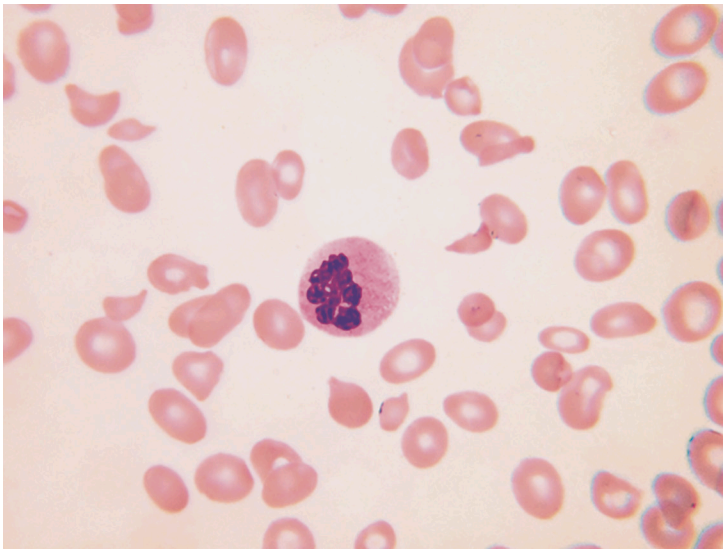

FIGURE 143-21. Hypersegmented neutrophils. A *hypersegmented neutrophil* is one in which the nucleus has more than five lobes, as in this example from an individual with megaloblastic anemia. Neutrophil hypersegmentation is also said to be present if there are increased numbers of neutrophils with five lobes or if the median lobe count is increased. Hypersegmented neutrophils should be distinguished from macropolycytes, in which an increased lobe count results from a doubled content of DNA (×1000).

microangiopathic or mechanical hemolytic anemia, burns, or accidental in vitro heating of the blood sample), white cell fragments (in acute leukemia and, less often, in lymphoma), cryoglobulin precipitates, or microorganisms (particularly *Candida* species). If the count is confirmed, the blood smear may be useful to indicate a likely cause (e.g., features of hyposplenism or the presence of basophilia in a myeloproliferative disorder).

It is sometimes necessary to examine a smear to confirm that an apparently normal platelet count is valid. This should always be done in patients with acute leukemia and an elevated white cell count; the presence of white cell fragments of a similar size to platelets can suggest that the platelet count is at a safe level when it is in fact dangerously low. Counting the ratio of platelets to other particles of similar size permits the count to be corrected. Any unexpectedly normal count should be confirmed; for example, the sudden rise of the automated platelet count in a patient being treated for a hematologic neoplasm may be the result of fungi that have colonized an indwelling intravenous line and are being shed into the blood stream.

LEUKOCYTOSIS AND LEUKOPENIA

The finding of leukocytosis is not necessarily an indication for a blood smear (Chapter 153). For example, this finding would be expected in a patient with infection or following surgery or trauma, in which case smear confirmation is not required. However, unexpected leukocytosis requires examination of a smear.

TABLE 143-3 BLOOD SMEAR FEATURES SUGGESTING A SPECIFIC CAUSE OF INHERITED OR ACQUIRED HEMOLYTIC ANEMIA

BLOOD SMEAR FEATURES	CONDITIONS SUGGESTED
Spherocytes	Hereditary spherocytosis, autoimmune hemolytic anemia, alloimmune hemolytic anemia (e.g., hemolytic disease of the newborn, delayed hemolytic transfusion reaction), drug-induced immune hemolytic anemia, *Clostridium perfringens* sepsis
Elliptocytes	Hereditary elliptocytosis
Oval macrocytes plus stomatocytes	Southeast Asian ovalocytosis
Irregularly contracted cells	Glucose-6-phosphate dehydrogenase deficiency, oxidant damage from chemicals or drugs in individuals with normal red cell enzymes (e.g., dapsone administration), liver failure due to Wilson disease (release of copper from liver), unstable hemoglobin, hemoglobin C homozygosity
Sickle cells and boat-shaped cells	Sickle cell disease (e.g., sickle cell anemia or compound heterozygous states such as S/C, S/D-Punjab, S/O-Arab, S/β-thalassemia)
Target cells	Hemoglobin C homozygosity, other hemoglobinopathies, hereditary xerocytosis
Stomatocytes	Hereditary stomatocytosis, phytosterolemia
Acanthocytes	Liver failure (spur cell hemolytic anemia)
Basophilic stippling	Lead poisoning, pyrimidine 5'-nucleotidase deficiency
Red cell fragments (schistocytes)	Microangiopathic hemolytic anemia (including hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, HELLP syndrome, and sometimes hemolysis associated with disseminated intravascular coagulation), mechanical hemolytic anemia (e.g., defective cardiac prosthetic valve, march hemoglobinuria)
Erythrophagocytosis	Paroxysmal cold hemoglobinuria
Red cell agglutinates	Acute or chronic cold antibody-induced hemolysis

HELLP = hemolysis, elevated liver enzymes, low platelets.

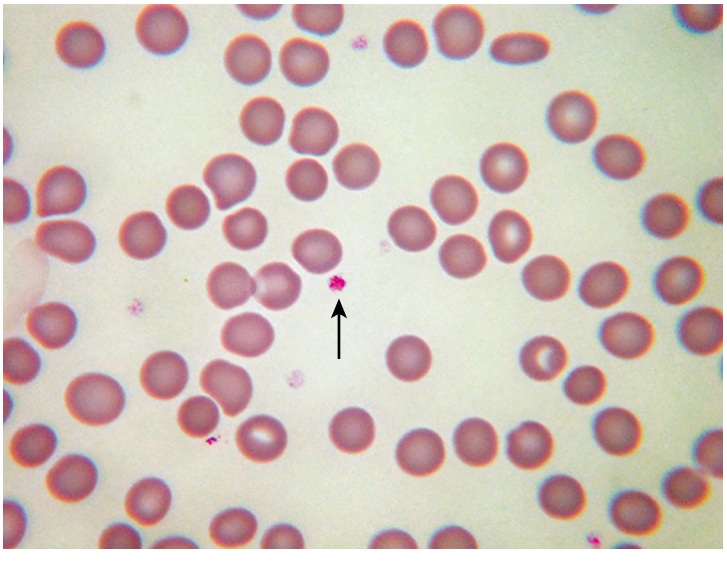

FIGURE 143-22. Normal-sized platelet *(arrow)*. Platelets have central granules, although this is not apparent in this photomicrograph (×1000).

Artifactual white count elevation is unusual but can occur as a result of cryoglobulinemia, hyperlipidemia, or the presence of *Candida* species. Distinguishing reactive changes from leukemia on the basis of morphology is usually straightforward for neutrophil leukocytosis but more difficult for lymphocytosis. In

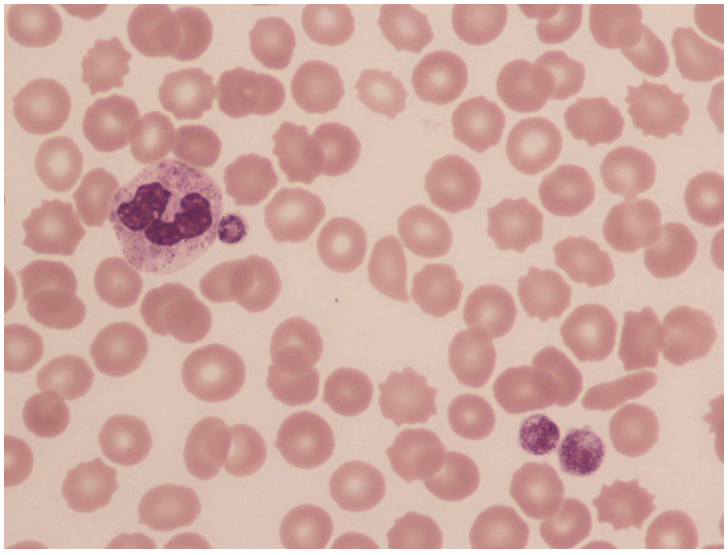

FIGURE 143-23. Giant platelets. Giant platelets are as large as or larger than normal red cells. Giant platelets can indicate increased platelet turnover or an inherited or acquired defect in thrombopoiesis (×1000).

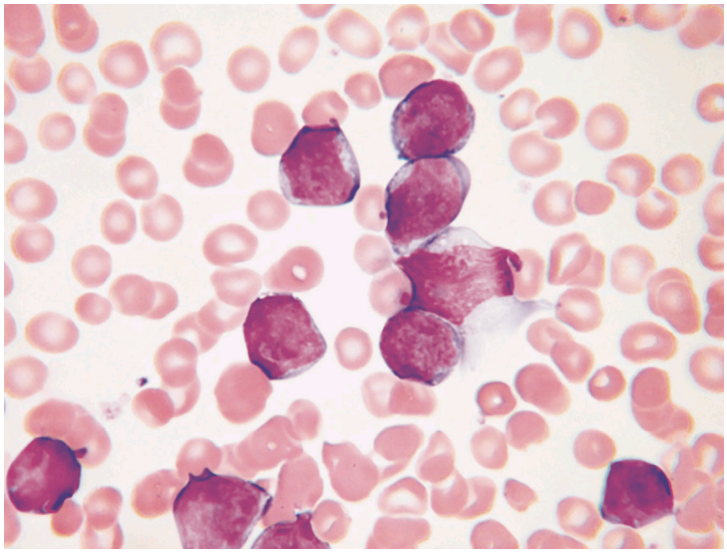

FIGURE 143-24. Acute lymphoblastic leukemia. Numerous agranular blast cells with a high nuclear-to-cytoplasmic ratio are present. Platelets are decreased in number (×1000).

reactive leukocytosis, there is usually toxic granulation, and Döhle bodies may be present (see Figs. 143-18 and 143-19). Vacuolation is particularly characteristic of bacterial infection, and there may be some degranulation of neutrophils. The hematologist should be aware of the changes induced by granulocyte colony-stimulating factor so that they are not confused with a response to infection. Granulocyte colony-stimulating factor can cause toxic granulation, Döhle bodies, vacuolation, and the presence of macropolycytes (giant neutrophils) and circulating neutrophil precursors. The changes typical of leukemia are discussed later.

Leukopenia (Chapter 153) usually requires a film for confirmation and elucidation. The exception is when it is expected in a given clinical context, such as when a patient has had recent chemotherapy. Rarely, an apparent leukopenia is artifactual, owing to the aggregation of neutrophils mediated by an autoantibody or resulting from infection-induced changes in adhesion molecules of the leukocyte surface membrane.

With some automated instruments, it is necessary to confirm that reported neutropenia is real. If the automated count is based on peroxidase cytochemistry, the presence of an inherited deficiency will lead to an apparent neutropenia associated with an increase of large, unstained (i.e., peroxidase-negative) cells. The scatter plot is characteristic, but because the same features could be due to acute leukemia with neutropenia and circulating blast cells, a smear is needed for confirmation.

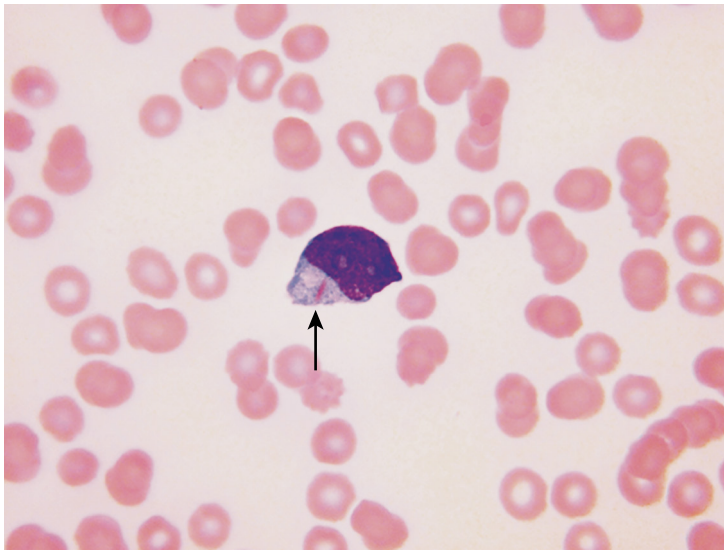

FIGURE 143-25. Auer rod. An Auer rod (*arrow*) is a rod-shaped inclusion in the cytoplasm of cells of myeloid lineage formed by the crystallization of azurophilic granule constituents. Auer rods are seen only in acute myeloid leukemia and high-grade myelodysplastic syndromes. They are usually seen in blast cells but are occasionally found in maturing cells (×1000).

LEUKEMIAS AND LYMPHOMAS

The blood smear is critical in the diagnosis of leukemias and lymphomas. The lymphoblasts of acute lymphoblastic leukemia are usually medium-sized agranular cells with relatively scanty cytoplasm (Fig. 143-24), whereas in acute myeloid leukemia, blast cells are generally larger, with more plentiful cytoplasm that may contain granules or Auer rods (Fig. 143-25). Myeloid blast cells vary in appearance according to whether they are myeloblasts or monoblasts. Myeloblasts are usually medium sized and may have plentiful granules, scanty granules, or no visible granules; they may contain Auer rods or, rarely, giant granules. Monoblasts are much larger cells with plentiful cytoplasm containing few granules and, very rarely, Auer rods. Megakaryoblasts are present in some patients and are sometimes cytologically distinctive because of their tendency to form cytoplasmic blebs or develop platelet-type granules.

Chronic myeloid leukemia has a very characteristic blood smear (Fig. 143-26) in which the most numerous cells are myelocytes and mature neutrophils. Eosinophils and basophils are also present. Dysplastic features are generally absent. In atypical Philadelphia chromosome–negative chronic myeloid leukemia, monocytosis is more frequent and dysplastic features are present. Chronic myelomonocytic leukemia is characterized by increased monocytes, some of them immature, with inconspicuous dysplastic features and infrequent granulocyte precursors. Chronic neutrophilic leukemia and a neutrophilic leukemoid reaction to a plasma cell neoplasm have similar hematologic features and need to be distinguished by supplementary tests, including analysis for a *CSF3R* mutation.[14]

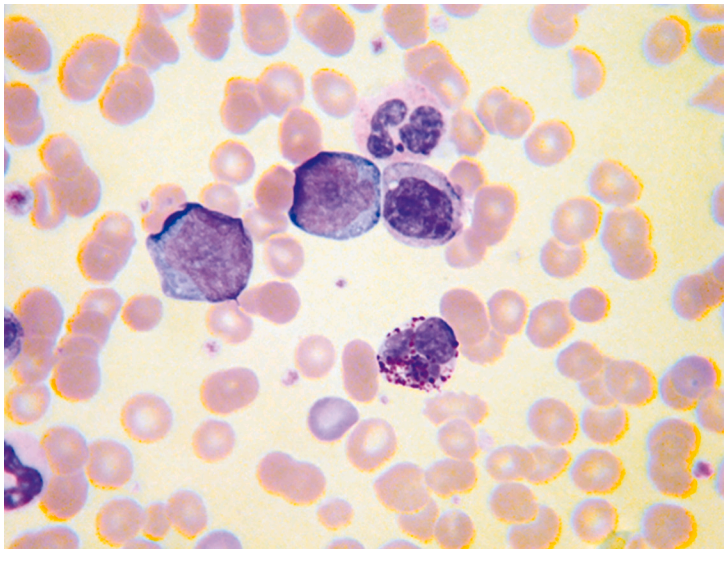

FIGURE 143-26. Chronic myeloid leukemia. In this view there are myeloblasts, a myelocyte, a basophil, and a segmented neutrophil (×1000).

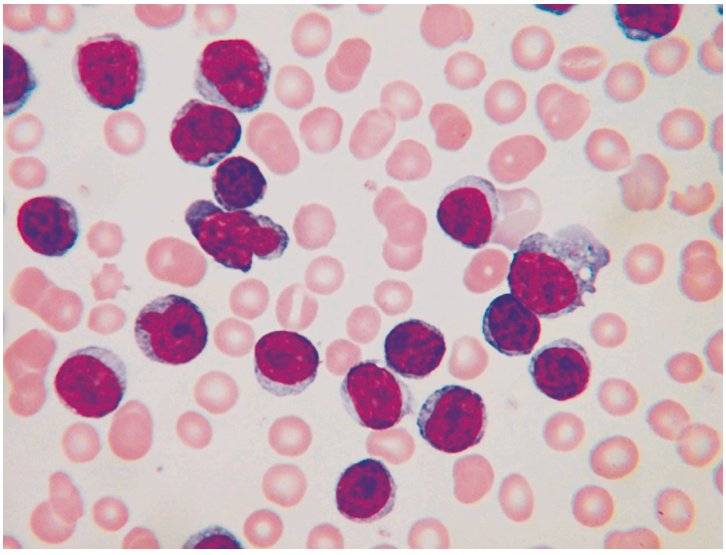

FIGURE 143-27. Chronic lymphocytic leukemia. There are large numbers of rather monotonous, mature small lymphocytes with chromatin clumping. Smear cells (or smudge cells), reflecting the mechanical fragility of the cells, are characteristic but are not seen in this photomicrograph (×1000).

TABLE 143-4 INCIDENTAL BUT CLINICALLY RELEVANT BLOOD SMEAR OBSERVATIONS

OBSERVATION	POSSIBLE SIGNIFICANCE
Acanthocytes	Abetalipoproteinemia, neuroacanthocytosis (includes choreoacanthocytosis, McLeod phenotype, Huntington-like disease 2, and pantothenate-kinase–associated neurodegeneration)
Howell-Jolly bodies, target cells, and acanthocytes	Hyposplenism (congenital, previous splenectomy, celiac disease, amyloidosis)
Cryoglobulin precipitates	Hepatitis C, multiple myeloma, Waldenström macroglobulinemia
Vacuolated lymphocytes	Inherited metabolic disorders
Parasites (e.g., malaria parasites, *Babesia*, microfilaria, trypanosomes, *Leishmania*)	Parasitic infection
Fungi (*Candida* spp, *Histoplasma capsulatum, Talaromyces marneffei, Cryptococcus neoformans, Malassezia furfur*)	Disseminated fungal infection or, in the case of *Candida*, colonization of an indwelling intravenous line
Bacteria (e.g., pneumococcus, meningococcus, *Capnocytophaga canimorsus, Borrelia, Ehrlichia, Anaplasma, Yersinia pestis*)	Bacterial infection
Leukoerythroblastic blood film	Bone marrow infiltration (e.g., metastatic malignancy)

Chronic lymphocytic leukemia also has a very characteristic blood film, with an increase of small, mature lymphocytes of rather uniform appearance. The chromatin is often irregularly clumped, creating a mosaic effect (Fig. 143-27). Smear cells (or smudge cells) are almost always increased in number but are not pathognomonic.

Lymphoma in the leukemic phase often has cytologic features that aid in the diagnosis. Follicular lymphoma (cleft nuclei), Burkitt lymphoma (hyperbasophilic vacuolated cytoplasm), and splenic marginal zone lymphoma (villous lymphocytes) can all be distinctive.

THE INCIDENTAL DETECTION OF CLINICALLY SIGNIFICANT ABNORMALITIES

Sometimes the examination of a blood film reveals unexpected but clinically significant information. Examples are given in Table 143-4. Detection of microorganisms is particularly likely in patients with acquired immunodeficiency syndrome (AIDS), hyposplenic patients, and patients with overwhelming sepsis, but sometimes they are detected in immunologically normal patients with only trivial symptoms. It should be noted that microorganisms in blood smears sometimes represent contaminants, particularly if specimens have been obtained by skin prick or from the umbilical cord and if there has been a delay in making the film.

CONCLUSION

Despite major advances in other diagnostic methods, the blood smear remains very useful in hematologic diagnosis. Sometimes it is critical either because it yields a diagnosis very quickly or because it provides information that is not available in any other way.

144 APPROACH TO THE ANEMIAS

ROBERT T. MEANS, JR.

Anemia is defined as a significant reduction in the volume of erythrocytes, or red blood cells, in the body. The red blood cell is an anucleate biconcave disc, approximately 8 μm in diameter, composed of various enzymes and chemicals surrounded by a lipid bilayer. The major component of the red blood cell is hemoglobin. A normal red blood cell contains 30 to 40 pg of hemoglobin. Hemoglobin is a highly specialized molecule, optimally enabled to deliver oxygen from the lungs through the circulation to the peripheral tissues and to remove carbon dioxide from the peripheral tissues and return it to the lungs for expiration. The red blood cell is generated in the bone marrow from erythroid precursors (Chapter 142) and survives approximately 120 days in the circulation before its clearance by the reticuloendothelial system.

The direct measurement of the red cell mass is a complex process; therefore, surrogate measures are used to define anemia in the clinical setting. The most common measures are the blood hemoglobin concentration and the hematocrit. The red blood cell count per microliter is also reported in routine hematologic analysis but is rarely used to define anemia. The hematocrit derives its name from the graduated tube in which blood was centrifuged for analysis. The percentage of the blood column represented by red cells compressed by centrifugation (also called packed cell volume) is the quantity physically represented by the hematocrit. Hematocrit values determined by centrifugation-based techniques are used mainly in limited-resource environments where electronic cell counting is not available. In laboratories where complete blood counts are performed using electronic cell counting methods, the hematocrit is a calculated value reflecting the product of the red blood cell count and the mean corpuscular volume of the red cells, both of which are measured directly. Because the hemoglobin concentration is directly measured rather than calculated, many physicians prefer to use the measurement of hemoglobin in the definition of anemia.

PATHOBIOLOGY

Anemia and Oxygen Delivery

The function of hemoglobin is to deliver oxygen to tissues. Oxygen delivery is a function of blood flow, blood hemoglobin content as reflected by hemoglobin concentration, and the gradient between arterial and venous oxygen content (Fick equation). The effect of anemia on blood hemoglobin content is readily apparent, and it also has a role in the other elements of the Fick equation.

In severe anemia associated with blood volume loss or in severe anemia with preserved blood volume, heart rate typically increases, and blood flow is

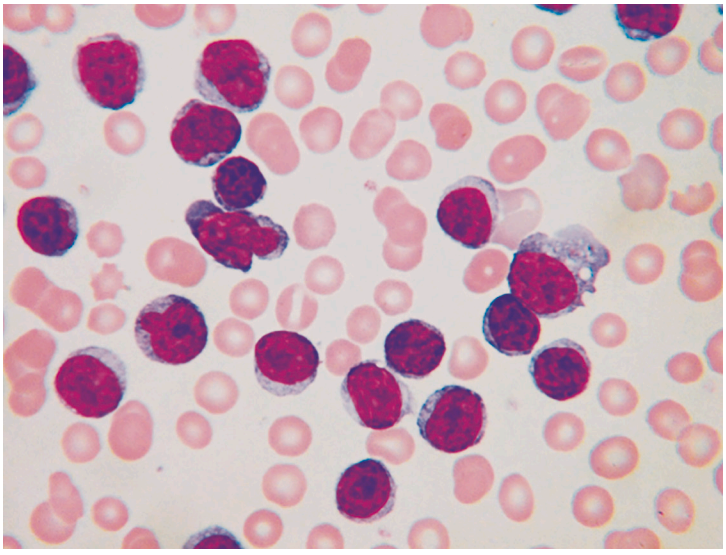

FIGURE 143-27. Chronic lymphocytic leukemia. There are large numbers of rather monotonous, mature small lymphocytes with chromatin clumping. Smear cells (or smudge cells), reflecting the mechanical fragility of the cells, are characteristic but are not seen in this photomicrograph (×1000).

TABLE 143-4 INCIDENTAL BUT CLINICALLY RELEVANT BLOOD SMEAR OBSERVATIONS

OBSERVATION	POSSIBLE SIGNIFICANCE
Acanthocytes	Abetalipoproteinemia, neuroacanthocytosis (includes choreoacanthocytosis, McLeod phenotype, Huntington-like disease 2, and pantothenate-kinase–associated neurodegeneration)
Howell-Jolly bodies, target cells, and acanthocytes	Hyposplenism (congenital, previous splenectomy, celiac disease, amyloidosis)
Cryoglobulin precipitates	Hepatitis C, multiple myeloma, Waldenström macroglobulinemia
Vacuolated lymphocytes	Inherited metabolic disorders
Parasites (e.g., malaria parasites, *Babesia*, microfilaria, trypanosomes, *Leishmania*)	Parasitic infection
Fungi (*Candida* spp, *Histoplasma capsulatum, Talaromyces marneffei, Cryptococcus neoformans, Malassezia furfur*)	Disseminated fungal infection or, in the case of *Candida*, colonization of an indwelling intravenous line
Bacteria (e.g., pneumococcus, meningococcus, *Capnocytophaga canimorsus, Borrelia, Ehrlichia, Anaplasma, Yersinia pestis*)	Bacterial infection
Leukoerythroblastic blood film	Bone marrow infiltration (e.g., metastatic malignancy)

Chronic lymphocytic leukemia also has a very characteristic blood film, with an increase of small, mature lymphocytes of rather uniform appearance. The chromatin is often irregularly clumped, creating a mosaic effect (Fig. 143-27). Smear cells (or smudge cells) are almost always increased in number but are not pathognomonic.

Lymphoma in the leukemic phase often has cytologic features that aid in the diagnosis. Follicular lymphoma (cleft nuclei), Burkitt lymphoma (hyperbasophilic vacuolated cytoplasm), and splenic marginal zone lymphoma (villous lymphocytes) can all be distinctive.

THE INCIDENTAL DETECTION OF CLINICALLY SIGNIFICANT ABNORMALITIES

Sometimes the examination of a blood film reveals unexpected but clinically significant information. Examples are given in Table 143-4. Detection of microorganisms is particularly likely in patients with acquired immunodeficiency syndrome (AIDS), hyposplenic patients, and patients with overwhelming sepsis, but sometimes they are detected in immunologically normal patients with only trivial symptoms. It should be noted that microorganisms in blood smears sometimes represent contaminants, particularly if specimens have been obtained by skin prick or from the umbilical cord and if there has been a delay in making the film.

CONCLUSION

Despite major advances in other diagnostic methods, the blood smear remains very useful in hematologic diagnosis. Sometimes it is critical either because it yields a diagnosis very quickly or because it provides information that is not available in any other way.

144 APPROACH TO THE ANEMIAS

ROBERT T. MEANS, JR.

Anemia is defined as a significant reduction in the volume of erythrocytes, or red blood cells, in the body. The red blood cell is an anucleate biconcave disc, approximately 8 μm in diameter, composed of various enzymes and chemicals surrounded by a lipid bilayer. The major component of the red blood cell is hemoglobin. A normal red blood cell contains 30 to 40 pg of hemoglobin. Hemoglobin is a highly specialized molecule, optimally enabled to deliver oxygen from the lungs through the circulation to the peripheral tissues and to remove carbon dioxide from the peripheral tissues and return it to the lungs for expiration. The red blood cell is generated in the bone marrow from erythroid precursors (Chapter 142) and survives approximately 120 days in the circulation before its clearance by the reticuloendothelial system.

The direct measurement of the red cell mass is a complex process; therefore, surrogate measures are used to define anemia in the clinical setting. The most common measures are the blood hemoglobin concentration and the hematocrit. The red blood cell count per microliter is also reported in routine hematologic analysis but is rarely used to define anemia. The hematocrit derives its name from the graduated tube in which blood was centrifuged for analysis. The percentage of the blood column represented by red cells compressed by centrifugation (also called packed cell volume) is the quantity physically represented by the hematocrit. Hematocrit values determined by centrifugation-based techniques are used mainly in limited-resource environments where electronic cell counting is not available. In laboratories where complete blood counts are performed using electronic cell counting methods, the hematocrit is a calculated value reflecting the product of the red blood cell count and the mean corpuscular volume of the red cells, both of which are measured directly. Because the hemoglobin concentration is directly measured rather than calculated, many physicians prefer to use the measurement of hemoglobin in the definition of anemia.

PATHOBIOLOGY

Anemia and Oxygen Delivery

The function of hemoglobin is to deliver oxygen to tissues. Oxygen delivery is a function of blood flow, blood hemoglobin content as reflected by hemoglobin concentration, and the gradient between arterial and venous oxygen content (Fick equation). The effect of anemia on blood hemoglobin content is readily apparent, and it also has a role in the other elements of the Fick equation.

In severe anemia associated with blood volume loss or in severe anemia with preserved blood volume, heart rate typically increases, and blood flow is

ABSTRACT

Anemia is a significant issue in clinical medicine, whether as a disease in itself or as a sign of disease. For anemia more than for many syndromes in medicine, appropriate treatment is based on diagnosis. Diagnosis in turn requires appropriate use of laboratory testing informed by the history, physical examination, and prevalence of diseases in the population relevant to the patient. After an outline of the basic physiology regulating red cell production, an approach to anemia is outlined, based on classification by the reticulocyte response to anemia and further refined by division into normocytic, microcytic, and macrocytic anemia syndromes. In addition, specific anemia syndromes are discussed including methemoglobinemia, anemia of chronic kidney disease, anemia of liver disease, anemia of endocrine deficiencies, physiologic anemia of pregnancy, and unexplained anemia of aging.

classification of anemia

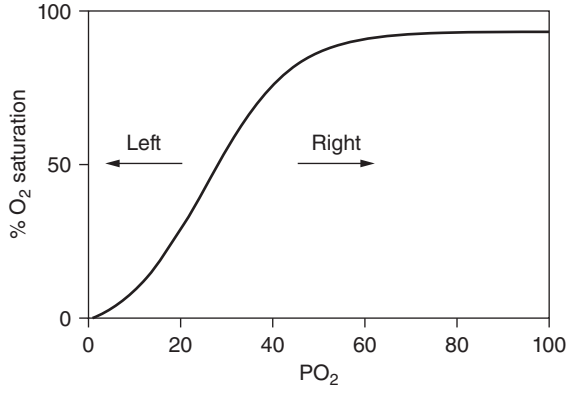

FIGURE 144-1. Oxyhemoglobin dissociation curve. Directions of right and left shift indicated. The curve plots the percentages of hemoglobin in its saturated (oxygen-laden) form on the vertical axis as a function of ambient oxygen tension on the horizontal axis. A rightward shift of the curve indicates a decreased affinity of hemoglobin for oxygen, making it easier for hemoglobin to release its oxygen to supply hypoxic tissue through which the blood passes.

shunted from the periphery to critical organs such as the brain, liver, kidneys, and coronary circulation to preserve oxygen delivery.

The arterial/venous oxygen gradient is also affected by anemia. When the oxyhemoglobin dissociation curve is shifted to the right, the oxygen affinity of hemoglobin is decreased—it requires a higher partial pressure of oxygen to attain a given level of hemoglobin saturation, and oxygen is more readily released to the tissues (Fig. 144-1). In anemia, the principal cause of a right shift is increased intracellular 2,3 diphosphoglycerate (DPG, also called 2,3 bisphosphoglycerate), a product of red cell metabolism. A right shift can also be induced by hyperthermia, hypercapnia, or acidosis. The opposite conditions can produce a left shift, resulting in oxygen being held more tightly by hemoglobin (high affinity).

Methemoglobin

Hemoglobin is composed of two α-globin chains and two β-globin chains, each of which has a covalently bound iron-containing porphyrin ring. Movement of the iron atom in relation to the plane of the porphyrin ring results in changes in the oxygen affinity of hemoglobin. Iron in normal hemoglobin is in the reduced ferrous state (Fe^{2+}). When hemoglobin iron becomes oxidized to the ferric state (Fe^{3+}), it is no longer able to bind oxygen and is called methemoglobin. Under normal circumstances, red cells contain a cytochrome b_5-based enzymatic system that rapidly reduces methemoglobin iron back to the ferrous state.

Methemoglobinemia occurs when this system fails. It may be a congenital condition, or it may be the result of exposure to toxic agents, perhaps in association with a subclinical cytochrome b_5 deficiency (Table 144-1). There are also mutations in globin genes that result in variant hemoglobins (M-hemoglobin) in which iron stabilizes in the ferric state.

Patients with methemoglobin concentrations greater than 10% show cyanosis (bluish discoloration of the skin) with normal oxygen saturation on arterial blood gas. Pulse oximetry may be inaccurate in methemoglobinemia. Arterial blood in methemoglobinemia is a chocolate brown color that does not become red with oxygen exposure. However, addition of potassium cyanate (KCN) to the blood sample will cause the blood to become red with methemoglobinemia but not with M-hemoglobins. Most blood gas machines, particularly in hospitals, can quantify methemoglobin.

Congenital methemoglobinemia patients typically do well even with methemoglobin concentrations of 30 to 40% because of adaptation and primarily have the cosmetic or social problem of cyanosis. Ascorbic acid (vitamin C) may be helpful, or methylene blue can be used. In contrast, acute methemoglobinemia from toxic exposure can be life threatening. Lethargy or headache can occur at methemoglobin levels around 20%. Above 40%, confusion, altered consciousness, and dyspnea can be noted. At concentrations above 50 to 60%, coma and death may occur. The treatment for acute methemoglobinemia is methylene blue 1 to 2 mg/kg, although higher doses up to 6 to 7 mg/kg can be required. M-hemoglobins do not require treatment.

Regulation of Red Cell Production

The primary regulator of red cell production is the effectiveness of oxygen delivery. This critical need may explain why hemoglobin concentration or hematocrit are controlled in a relatively narrow normal range as compared to the white blood count or platelet count, where the upper limit of normal may be two or three times the lower limit of normal. The mediator that translates peripheral oxygen need to red cell production is the hormone erythropoietin. After birth, the predominant physiologic site of erythropoietin production is the kidney, although the liver retains some limited capacity for erythropoietin production. Neoplasms arising from liver, kidney, or other tissues may secrete erythropoietin in an unregulated manner. Anemia results in decreased oxygen tension in the renal cortex, thereby inducing the transcription factor HIF (hypoxia-inducible factor), which in turn upregulates erythropoietin production. Erythropoietin binds to specific receptors on erythroid progenitors in the marrow leading to increased red cell production. When correction of anemia normalizes the oxygen tension in the renal cortex, erythropoietin production falls back to basal levels. Ambient hypoxia, or underoxygenation of the blood by a right-to-left cardiopulmonary shunt, also leads to the production of erythropoietin. This hypoxia causes the erythrocytosis seen in dwellers at high altitudes and in individuals with uncorrected cyanotic heart disease.

Although an adequate supply of other factors such as iron, vitamin B_{12}, or folate is required for red cell production, polycythemia does not occur in the absence of an increased erythropoietin stimulus. Red cell production has feedback regulation of iron availability through the erythroferrone/hepcidin/ferroportin axis (Chapter 145).

CLINICAL MANIFESTATIONS

Symptoms

In general, the symptoms of anemia are nonspecific and highly dependent on the patient's general physical condition or other comorbid illnesses. Anemia of rapid onset, as may be seen with massive acute hemolysis or with acute blood loss, is more likely to be symptomatic than anemia from red cell underproduction or from slow gastrointestinal blood loss. In both of these cases, the total blood volume is preserved, and there is time for the cardiovascular system to accommodate to the changes in hematocrit. Preservation of blood volume and cardiovascular accommodation are likely the reasons that patients with slow-onset anemias such as B_{12} deficiency are traditionally reported to become symptomatic at much lower hemoglobin concentrations or hematocrits than patients with iron deficiency anemia from blood loss. A person with coronary artery disease or chronic obstructive lung disease is more likely to become symptomatic than an anemic individual without those disorders who has the same hemoglobin concentration.

Common symptoms in anemia include fatigue but typically not dyspnea. Palpitations or a sense of the heart racing or pounding may occur, representing a more rapid heart rate and increased ejection fraction in order to maintain oxygen delivery. Symptomatology in anemia syndromes that develop as a

consequence of some other disease (such as the anemia of inflammation in association with rheumatoid arthritis) will most likely be dominated by the symptoms of the associated disease. Pica, the desire to eat nonnutritive substances such as ice, is very specific to iron deficiency. Restless leg syndrome may also be a manifestation of iron deficiency.

Physical Findings

Pallor may occur in patients with anemia but may be difficult to appreciate in patients seen for the first time due to the widespread differences in skin pigmentation among healthy individuals, but its presence in mucous membranes obviates that variable. Pallor can also occur in other conditions associated with shunting of blood away from the periphery to the critical organs. In the assessment of anemia, pallor of the conjunctival mucosa or of the creases in the palm are more specific than pallor in other sites. Pallor of the conjunctival mucosa generally indicates a hemoglobin concentration less than 9 g/dL, and failure of the palmar creases to become more prominent when the extended fingers are pushed down, thereby extending the palm, generally indicates a hemoglobin no higher than 7 to 8 g/dL. Tachycardia and a systolic ejection murmur may develop as a result of anemia and cardiovascular accommodation to it. Peripheral edema, which may be occasionally seen with moderately severe anemia, may reflect a combination of high-output heart failure and loss of oncotic pressure associated with fewer blood cells. On rare occasions, retinal hemorrhages may be seen on fundoscopic examination in severe anemia. All of these vascular and cardiac manifestations of anemia will resolve with correction of anemia.

DIAGNOSIS

Medical History

The initiating step of any evaluation for anemia is demonstration by hemoglobin concentration or hematocrit that the patient is anemic (see Tables 144-2 and 144-3). A number of elements in the history and physical examination can guide the subsequent laboratory evaluation (Tables 144-4 and 144-5). Duration of anemia assists in distinguishing congenital from chronic or acute causes. Because iron deficiency is the most common etiology of anemia in clinical medicine, dietary history (vegetarian or vegan) and a history of blood loss should always be pursued. In women, this questioning should also include asking about the number of previous pregnancies and whether iron supplementation was used during pregnancy. Every child delivered at term represents an investment of 800 mg of maternal iron (Chapter 145). Persistent jaundice suggests active hemolysis, and episodic jaundice is frequently observed in individuals with congenital hemolytic anemias, whether they result from metabolic defects such as glucose-6-phosphate dehydrogenase (G6PD) deficiency or from red cell membrane defects such as hereditary spherocytosis. A history of cholelithiasis in early adulthood is suggestive of congenital hemolytic disorders. A history of chronic inflammatory disorders raises the possibility of the anemia of inflammation (Chapter 145). A history of petechiae or easy bruising or a history of recurrent infection raises the possibility of a hematopoietic disorder not limited to the erythroid lineage. A family history of a specific diagnosis, such as sickle cell anemia or thalassemia, is obviously helpful. Similarly, a history of family members with episodes of jaundice following minor illnesses suggests a congenital hemolytic anemia. In contrast, a history of a similar disorder in the mother, aunts, and sisters of a female patient with suspected iron deficiency is not particularly helpful in the diagnosis of anemia.

Physical Examination

Certain physical findings may help guide the evaluation of anemia by providing clues to specific syndromes, underlying disorders, or bleeding (Table 144-5). Evidence of bleeding mandates evaluation for iron deficiency. Petechiae, purpura, or thrush suggests abnormalities of the platelets or white cells and raises the possibility of a generalized marrow disorder not limited to the erythroid lineage. Frontal bossing (prominence of the forehead due to expansion of red marrow in the skull) is seen in congenital hemolytic anemias but can be a normal variant; in general, adults with hemolytic anemia and this physical finding have had their diagnosis defined earlier in life. The neurologic findings of B_{12} deficiency generally require a more thorough examination than is part of the routine physical examination (Chapter 150).

Complete Blood Counts

The usual complete blood count provided by automated cell counters includes a variety of directly measured and calculated parameters, which at a minimum include the white blood cell count, the red blood cell count, the hemoglobin concentration and hematocrit, the platelet count, and the red cell indices described later. Many automated counters also provide a differential white blood count and a semiquantitative description of red cell abnormalities. Decreased counts of white blood cells and platelets are discussed in Chapters 153 and 158, respectively. Typical values are shown in Table 144-2. Clinicians should become familiar with the normal values specific to the laboratories they use.

The hemoglobin, hematocrit, and red cell counts are all concentrations, which means that a change in the plasma volume can elevate them or decrease them relative to the actual total body red cell mass. An example of an anemia associated with a normal or slightly increased red cell mass occurs in the second trimester of normal pregnancy. In contrast, an elevated hemoglobin concentration or hematocrit with a normal or decreased total body red cell mass can be seen in dehydration or the capillary leak syndrome

Red cells can also be described by parameters called red cell indices, which are routinely calculated by most electronic cell counters. These include the mean corpuscular volume (MCV), the mean corpuscular hemoglobin (MCH),

TABLE 144-2 NORMAL RED BLOOD CELL MEASUREMENTS

MEASUREMENT	NORMAL RANGE
Hemoglobin concentration	12-16 g/dL Female 13.5-17.5 g/dL Male
Hematocrit	36-48% Female 40-52% Male
Red blood cell (RBC) count	$4.0\text{-}5.4 \times 10^6$/μL Female $4.5\text{-}6.0 \times 10^6$/μL Male
Mean corpuscular volume (MCV)	81-99 fL
Mean corpuscular hemoglobin (MCH)	30-34 pg

and the mean corpuscular hemoglobin concentration (MCHC) (Table 144-3). Another parameter automatically calculated by most electronic cell counters is the red cell distribution width (RDW), which represents either the coefficient of variation of the distribution curve of red cell sizes (RDW-CV) or the standard deviation of the red cell distribution width curve (RDW-SD) and is a marker of red cell anisocytosis (variation in size).

Red blood cell parameter determinations (Table 144-2) will vary between laboratories depending upon the equipment used and on the population serving as the basis for the normal range. For example, the normal red cell values among patients living at high altitude are higher than those in normal subjects at sea level due to lower ambient oxygen tension driving higher erythropoietin production. Normal values are different between newborns, children, and adults and between men and women after puberty. The difference in normal hemoglobin concentration, hematocrit, and red cell count between adult men and women is attributed to the action of testosterone in sensitizing erythroid progenitors to erythropoietin.

Reticulocyte Count

Red cells newly released from the bone marrow that have shed their nuclei but still contain some nuclear material in the cytoplasm are called reticulocytes. Reticulocytes were traditionally measured through supravital staining on fresh smears, but now are most frequently measured by flow cytometry technology incorporated into electronic blood counters. On the routine Wright-Giemsa–stained peripheral blood smear, reticulocytes are slightly larger than red cells, have little or no central pallor, and have a more grayish (polychromatic) tinge to the cytoplasm. The reticulocyte activity in a particular specimen can be expressed in a variety of ways (Table 144-3). All are based on the principle that the reticulocyte response of the marrow to anemia varies with the degree of anemia. The uncorrected reticulocyte count, sometimes called the reticulocyte percentage, represents the percentage of red blood cells that are reticulocytes. However, an uncorrected reticulocyte count of 2% would be entirely normal in a person with a hematocrit of 42% or hemoglobin concentration of 14 g/dL but would be grossly inadequate in a person with a hematocrit of 20% or hemoglobin concentration of 7 g/dL. The other reticulocyte parameters represent an effort to adjust this uncorrected value for the degree of anemia. The simplest and most common adjustment is to express the reticulocyte count as the absolute reticulocyte count, which is the reticulocyte percentage multiplied by the red blood cell count. The most complex is the reticulocyte production index (RPI), which corrects the reticulocyte count for the degree of anemia and then adjusts by a factor that compensates for the release of less mature reticulocytes into the circulation under circumstances of more severe anemia.

Reticulocyte counts are helpful in the initial approach to anemia in distinguishing anemias due to underproduction of red cells from those associated with adequate or increased production but shortened survival in the circulation. During treatment of anemia, increases in the reticulocyte count can predict response to therapy prior to increments in the hemoglobin concentration or hematocrit. Alternately, failure of the reticulocyte count to increase at the expected time can predict failure of current therapy and dictate a change of approach.

Blood Smear Examination

Even in the era of more sophisticated electronic hematologic analysis, including ability of device software to provide descriptions of red cells, value remains in the examination of peripheral blood smear (Chapter 143) by a physician familiar with the clinical situation of the patient. In congenital hemolytic anemias, the morphologic changes characteristic of red cell membrane abnormalities may be seen (spherocytes, elliptocytes, etc.). The "bite" and "blister" red cells found in hereditary defects of red cell oxidative metabolism are unlikely to be appreciated except by direct examination by a clinician. Sideroblastic anemia is characterized as a microcytic anemia (see later) but is frequently associated with a normal MCV because the sideroblastic clone is not large enough to alter the average red cell size. The finding of a dimorphic red cell population is a significant clue to this disorder but may also be seen in partially treated iron deficiency. Macroovalocytes and hypersegmented neutrophils are highly suggestive of B_{12} deficiency.

Bone Marrow Examination

Bone marrow aspiration and biopsy are required for the diagnosis of many primary marrow disorders giving rise to anemia. In general, it is most likely to be indicated in underproduction anemias rather than in those associated with an appropriate or increased reticulocyte response. However, paroxysmal nocturnal hemoglobinuria (PNH), which can include elements of both hemolysis and marrow failure, is an exception. Disorders that require bone marrow examination for diagnosis at the present time are aplastic anemia and pure red cell aplasia, myelodysplastic syndromes, and anemias associated with marrow replacement (lymphoma, leukemia, myelofibrosis, myeloma, or metastatic cancer). Marrow examination is rarely required for assessment of iron status, given the availability of other diagnostic tools (Chapter 145). Bone marrow examination for the diagnosis of anemia should include both aspiration and biopsy and routinely include Prussian blue staining for evaluation of iron stores and possible detection of ringed sideroblasts. Flow cytometry to phenotype myeloid or lymphoid/plasma cell populations should also be performed, as should standard cytogenetics, when suspecting a clonal disorder. If there is suspicion on clinical grounds of a specific disease associated with a molecular abnormality, polymerase chain reaction (PCR) or fluorescence in situ hybridization (FISH) testing for that abnormality should be performed. Molecular studies for parvovirus in cases of possible pure red cell aplasia can be performed on peripheral blood. A more recent discovery is that clonal abnormalities of hematopoiesis can be identified on peripheral blood molecular testing, particularly in the elderly (Chapter 142).[1] It is possible that such testing may obviate the need for bone marrow examination in certain selected populations.[2]

Iron assessment for iron deficiency anemia/anemia of inflammation
Serum iron concentration
Serum total iron binding capacity and serum percent transferrin saturation
Serum ferritin concentration

*This approach would also apply in an ambulatory setting with in-office laboratory capacity.

Initial Laboratory Approach to Anemia

The traditional approach to the evaluation of anemia has been to obtain a complete blood count with indices and reticulocyte count, categorize the anemia on that basis, and then proceed with specific testing indicated by reticulocyte count and MCV, informed by the findings on history and physical examination and review of the blood smear. This is an appropriate and intellectually valid approach at any time, but particularly in the inpatient or hospital-based clinic settings. In the ambulatory practice environment for many internists, third-party payers may mandate that laboratory studies be sent to outside reference laboratories. The consequence of such policies is that blood count and reticulocyte count results may not be available on the day of the visit, and personal review of the blood smear may be challenging. In such a practice environment, it is reasonable to include an assessment of iron status in the initial laboratory evaluation of anemia. Iron deficiency anemia and the anemia of inflammation (also called anemia of chronic disease)[3] can both be diagnosed by these tests and are the two most common etiologies of anemia (Chapter 145). Although iron deficiency anemia is more likely to be microcytic and anemia of inflammation is more likely to be normocytic, both of these syndromes can be either microcytic or normocytic; therefore, it is likely that iron testing will be needed in nearly all circumstances not associated with an elevated reticulocyte response. This approach is outlined in Table 144-6.

ANEMIAS ASSOCIATED WITH INCREASED RETICULOCYTE PRODUCTION

Anemia associated with increased reticulocyte production after adjustment for anemia suggests the presence of either blood loss or hemolysis (Fig. 144-2). In certain situations, bleeding or hemolysis may not be associated with an appropriate reticulocyte response; these situations typically indicate some concurrent restriction on red cell production such as iron or folate deficiency.

ANEMIA DUE TO BLOOD LOSS

The symptoms of acute blood loss are dependent on the rapidity and volume of blood loss and secondarily on the site of blood loss. They are heavily influenced by effects of hypovolemia. Hypovolemia and loss of the oxygen-carrying capacity of red cells may impair oxygen delivery to tissues.

In the initial setting of acute blood loss, plasma and red cells are depleted in their same relative ratio. The result of this is that the hemoglobin concentration and hematocrit do not change acutely. As the intravascular volume is expanded, either rapidly with exogenous intravenous colloid or crystalloid in the setting of trauma, or more slowly by endogenous redistribution of plasma from the extravascular space, the hematocrit and hemoglobin concentration will begin to move downward over hours to days to reveal the true extent of loss of circulating red cell mass. In this setting, therefore, the degree of blood loss is initially underestimated by the blood counts. Further complicating the situation in the case of acute trauma is cytokine activation and the "coagulopathy of trauma." For this reason, trauma transfusion protocols have been developed in which packed red blood cells, fresh frozen plasma, and platelet concentrate are administered in specific ratios in order to return as quickly as possible to the physiologic state.[4]

Clinical findings vary with the volume and site of blood loss. Bleeding into the gastrointestinal tract can lead to hematemesis, melena, and/or hematochezia, depending on the location and rate of bleeding. The serum blood urea nitrogen (BUN) concentration will rise out of proportion to the creatinine level even with relatively modest gastrointestinal bleeding due to the breakdown and absorption of hemoglobin protein. When a patient has a large hematoma, whether intracavitary or between tissue planes, hyperbilirubinemia and occasionally clinically apparent jaundice, as well as some rise in BUN, may occur as the extravascular hemoglobin breaks down. Bleeding may be associated with reactive thrombocytosis and occasionally leukocytosis.

The management of massive blood loss is by transfusion (Chapter 162) and correction of the cause of bleeding. In smaller-volume acute blood loss, where the hemoglobin concentration comes to equilibrium at a point that does not impair oxygen delivery in that specific patient, patients may be allowed to recover on their own, mobilizing their own iron stores. When there is concern about adequate iron stores, iron replacement can be given.

Chronic blood loss is rarely at a level that produces acute volume shifts and the dramatic symptomatology of acute blood loss. The reticulocyte count remains appropriately elevated until iron becomes depleted by its utilization for increased erythropoiesis, at which time the reticulocyte response decreases and the hemoglobin concentration and hematocrit begin to drift downward. The decline in MCV begins shortly after the hemoglobin concentration and hematocrit fall below the normal range.

ANEMIA DUE TO HEMOLYSIS

Hemolysis (Chapters 146 to 149) indicates a reduction in the survival of red cells in the circulation from increased red cell destruction. Some reduction in red cell survival is an element in many hematologic syndromes, including the anemia observed with chronic kidney disease, the anemia seen with inflammation, and the anemia seen with liver disease (distinct from spur cell anemia). Microangiopathic hemolytic morphology is occasionally seen in disseminated intravascular coagulation.

Certain laboratory studies raise suspicion of a hemolytic anemia and some confirm it (Table 144-7). These are not specific to any etiology of hemolytic anemia. The distinction between extravascular hemolysis (which includes hemolysis in the spleen) and intravascular hemolysis is helpful in understanding these disorders at the pathophysiologic level. However, it is not absolute in terms of diagnostic testing. While the haptoglobin tends to become lower in intravascular hemolysis, it is generally decreased in extravascular hemolysis also. Hemoglobinemia and hemoglobinuria are specific for intravascular hemolysis.

The causes of hemolysis (Table 144-8) can be grouped using a classification that separates etiologies that are (1) entirely external to the red cell (e.g., immunologic, mechanical, or toxic processes); (2) defects that are intrinsic to the red cell membrane (e.g., hereditary spherocytosis or spur cell anemia), and (3) processes primarily related to red cell metabolism or to abnormalities of hemoglobin. The enzymatic defects producing hemolysis are typically related to oxidative metabolism and particularly to oxidative stress, such as that induced by medications.

The approach to the diagnosis of the various classes of hemolytic anemia syndromes (Fig. 144-2) begins with the examination of the peripheral smear. Identification of the characteristic microangiopathic changes of thrombotic thrombocytopenic purpura immediately provides direction to life-saving therapy. Similarly, congenital defects in the intrinsic proteins of the red cell membrane produce specific morphologic features, which can lead rapidly to a confirmable diagnosis. If the morphology on the peripheral blood smear is normal or shows only a small number of spherocytes, then evaluation for an immunologic etiology of hemolysis should be pursued. In general, autoimmune hemolytic anemia is associated with an abnormal direct antiglobulin (Coombs) test. In individuals with a previous transfusion history or a history of pregnancy in which fetal-maternal transfusion may have occurred, the possibility of other immune hemolytic mechanisms arises, and an antibody screen (also called the indirect antiglobulin test) should be ordered. If negative, metabolic or toxic causes of hemolysis should be considered.

Sustained hemolysis of any etiology creates an increased demand for folic acid, and it is reasonable to supplement individuals with chronic hemolysis with folate (1 mg/day). In countries that do not routinely fortify food with folic acid, a higher level of supplementation may be needed. During pregnancy, when folate demands are increased, a higher level of supplementation than the recommended 0.8 mg/day is reasonable for individuals with chronic hemolysis. Hemolysis that is primarily extravascular is generally not associated with increased iron demands, because the hemoglobin iron from the hemolyzed red cells is recycled in the reticuloendothelial system. In intravascular hemolysis, the haptoglobin/hemopexin system for recycling heme iron is readily overwhelmed and iron supplementation may be necessary.

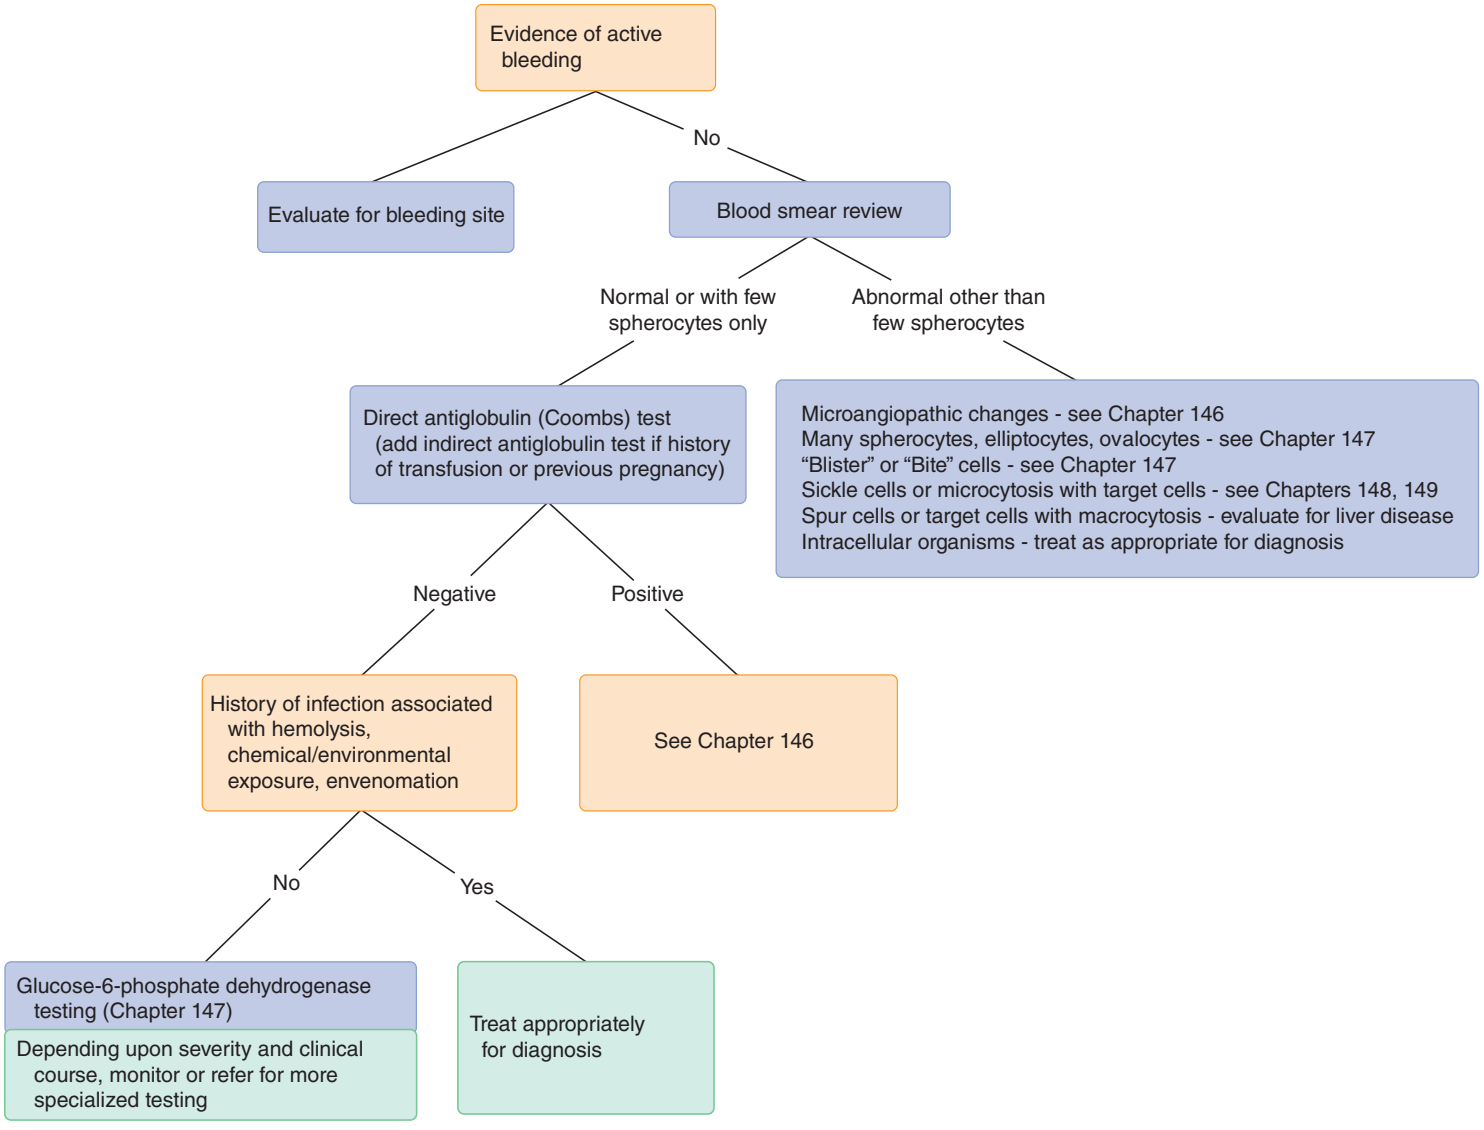

FIGURE 144-2. **Approach to the workup of hemolysis, beginning with examination of the peripheral blood smear.** (See Chapter 143.)

TABLE 144-7 GENERAL LABORATORY FINDINGS IN HEMOLYTIC ANEMIA

FINDINGS SUGGESTIVE OF HEMOLYSIS
Peripheral blood smear
Polychromasia
Abnormal red cell morphology
Elevated reticulocyte count (adjusted for anemia)
Elevated serum bilirubin (indirect/unconjugated)
Elevated serum lactate dehydrogenase
Slightly elevated serum aspartate aminotransferase
FINDINGS CONFIRMATORY OF HEMOLYSIS
Decreased serum haptoglobin (lower in intravascular hemolysis)
Increased plasma hemoglobin
Increased urobilinogen
Hemoglobinuria (intravascular hemolysis)
Hemosiderinuria (intravascular hemolysis; chronic or recurrent)

ANEMIAS ASSOCIATED WITH INADEQUATE RETICULOCYTE RESPONSE (UNDERPRODUCTION ANEMIAS)

The vast majority of anemias seen in adults are associated with decreased red cell production. A useful approach to the evaluation of these anemias is to classify them by MCV as microcytic, normocytic, or macrocytic (Table 144-9 and Fig. 144-3). A limitation to this approach is that the MCV used in defining this model was based on examination of the blood smear and not necessarily on the measured MCV value provided by the electronic cell counter. The dimorphic population of microcytic and normocytic red cells seen in sideroblastic anemia has already been mentioned. In the presence of concurrent inflammation or of elevated serum immunoglobulin (whether polyclonal or monoclonal), stacking of red cells ("rouleaux formation") as they pass through the aperture of the counter may artifactually elevate the measured MCV.

MICROCYTIC ANEMIAS

Microcytic anemias (Chapter 145) share the common pathogenesis of defective cellular hemoglobin synthesis. These defects may be at the globin level, as in the hemoglobinopathies and thalassemia, or may affect synthesis of the heme moiety. Lead poisoning suppresses ferrochelatase, interfering with synthesis of the heme porphyrin ring. Anemia of inflammation (anemia of chronic disease) is typically normocytic but may be associated with a slight reduction in MCV. In general, an MCV less than 75 fL would not be seen in the anemia of inflammation. The lowest MCVs will be seen in the hemoglobinopathies and thalassemias. A normal RDW in microcytic anemia is more likely to represent a hemoglobinopathy or thalassemia rather than iron deficiency.

MACROCYTIC ANEMIAS

Macrocytic anemias (Chapters 150, 151, and 167) represent a variety of diagnoses and pathophysiologic mechanisms. Inflammation or hypergammaglobulinemia can produce a laboratory artifact resulting in an elevated reported MCV. The elevated MCV in reticulocytosis is not an artifact because reticulocytes are larger than mature red cells. Liver disease or alcohol use are frequently associated with a mildly macrocytic anemia due to changes in red cell membrane lipids. Although the anemia of hypothyroidism is most commonly associated with a normal MCV, macrocytosis is

Aplastic anemia (some cases)
Megaloblastic anemia
Cobalamin (B_{12}) deficiency
Folate deficiency
Hydroxyurea therapy

*Homozygous sickle cell anemia (SS), sickle cell trait (AS), and hemoglobin C trait are normocytic. Compound heterozygote sickle cell syndromes like sickle-thalassemia are microcytic.

sometimes reported, and it is frequently classified as a macrocytic anemia. The syndromes outlined earlier are usually associated with an MCV less than 105 to 115 fL.

Other macrocytic anemias result from impaired DNA synthesis. These disorders include the classic megaloblastic anemias from cobalamin (B_{12}) and folate deficiency as well as primary marrow failure disorders such as the myelodysplastic syndromes and Diamond Blackfan anemia. These causes of anemia are frequently associated with abnormalities of other cell lineages. The myelosuppressive agent hydroxyurea also produces striking macrocytosis as part of its expected effect. In primary marrow failure disorders, the MCV is typically less than 110 fL. Megaloblastic anemia may be associated with extremely elevated MCV: as the MCV rises above 115 fL, the likelihood of cobalamin or folate deficiency increases. Hydroxyurea can produce elevated MCV in a similar range. Copper deficiency may be confused with cobalamin deficiency because it also is associated with neurologic findings, but the MCV is typically less than 110 fL.

NORMOCYTIC ANEMIAS

Normocytic anemias also represent a mixed group of disorders. In some cases, they are caused by a primary marrow failure state, as in pure red cell aplasia or aplastic anemia. In most other circumstances, they represent anemia associated with another systemic disorder.[5]

Iron deficiency anemia in its early stages, like the anemia of acute blood loss, is associated with a normal MCV. After iron stores are depleted, a process of iron-depleted erythropoiesis begins. As the red cells produced under these conditions become a larger proportion of the total red cell population, the MCV begins to decline. The anemia of inflammation[6] (Chapter 145) is likely the most common normocytic anemia syndrome after acute blood loss or early iron deficiency.

Myelodysplastic syndromes and other primary bone marrow failure disorders can be normocytic in many cases. Pure red cell aplasia presents as an isolated normochromic normocytic anemia with striking reticulocytopenia. In patients with isolated anemia and a reticulocyte count of 0.1% or less or an absolute reticulocyte count less than 10,000/μL, a bone marrow examination should be performed to evaluate for this diagnosis.

SPECIFIC ANEMIA SYNDROMES

ANEMIA OF CHRONIC KIDNEY DISEASE

Anemia is almost invariable in significant renal insufficiency, beginning when the estimated glomerular filtration rate (eGFR) falls below 45 mL/min/1.73 m^2 body surface area. Anemia is a less frequent complication of polycystic kidney disease because of secretion of erythropoietin by the cysts.

The major pathogenetic factor in the anemia of chronic kidney disease is erythropoietin deficiency. The use of recombinant erythropoietin (erythropoiesis-stimulating agents) has substantially mitigated this problem, although even in the erythropoietin era 48% of predialysis patients and 28% of hemodialysis patients have hematocrit values <30%. Other mechanisms contributing to the anemia of kidney disease are suppression of the erythroid progenitor response to anemia and shortened red cell survival. Shortened red cell survival has a number of proposed mechanisms, including decreased ability to regulate cellular oxidative stress, effects of toxic metabolites accumulated in uremia, and membrane lipid peroxidation.

Red cells are normocytic and normochromic. Echinocytes ("burr cells") are sometimes present. The reticulocyte count is decreased for the degree of anemia. Erythropoietin concentrations are generally not helpful in making a diagnosis because the usual feedback relationship between hemoglobin concentration/hematocrit and erythropoietin secretion is lost. eGFR <45 mL/min/

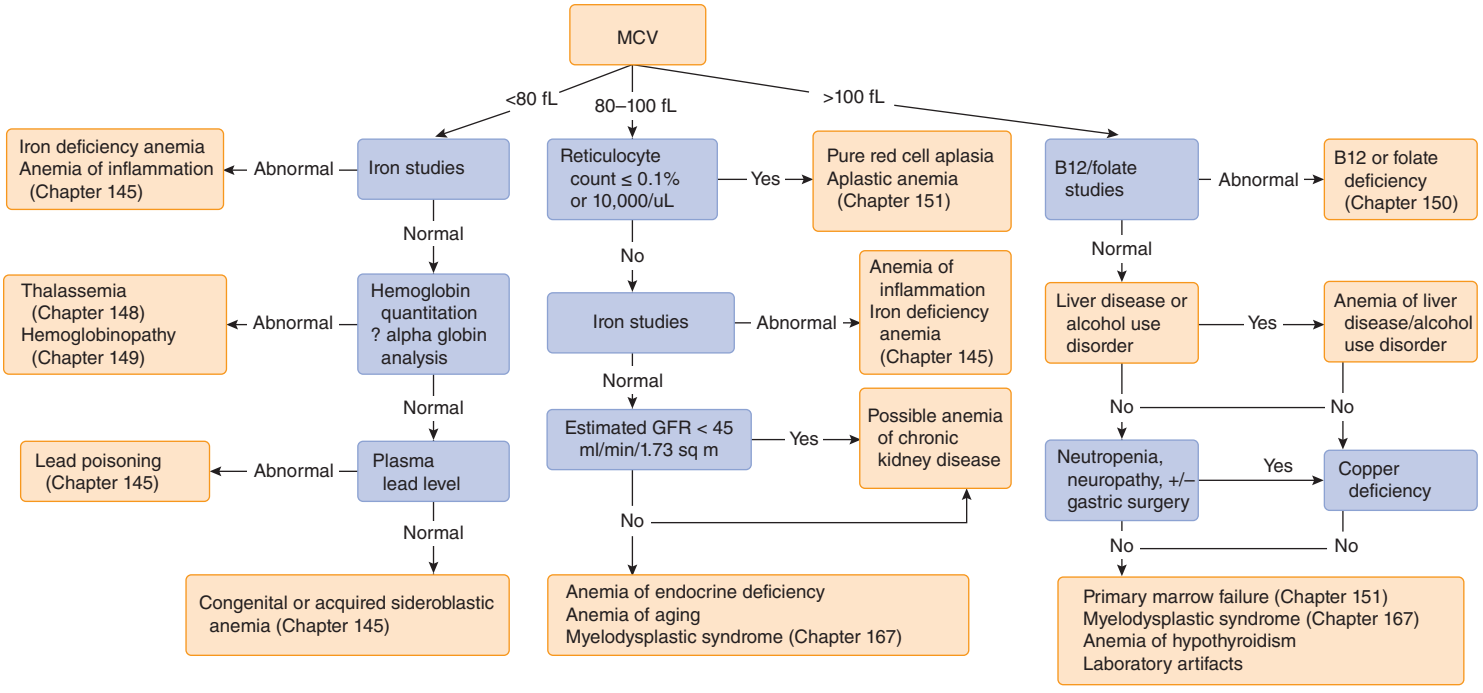

FIGURE 144-3. **Approach to anemia based on the mean corpuscular volume (MCV).** GFR = glomerular filtration rate.

1.73 m^2 surface area is the principal "permissive" condition for anemia of chronic kidney disease.

TREATMENT

The anemia of chronic kidney disease (Chapter 116 and 117) is treated with recombinant erythropoietin or an erythropoietin analog aiming for a hemoglobin level of 9 to 11 g/dL.[A1,A2] Daprodustat, which is an oral inhibitor of hypoxia-inducible factor prolyl hydroxylase and which stimulates erythropoiesis and regulates iron metabolism, is approved by the U.S. Food and Drug Administration (FDA) for patients who are on dialysis.[A3] To avoid the adverse complications of overcorrection or even just correction to normal with erythropoiesis-stimulating agents (such as seizures, accelerated hypertension, or thrombosis), treatment is not started until the hemoglobin concentration is less than 9 g/dL, and is suspended when the hemoglobin target of 9 to 11 g/dL is reached.[7] Iron supplementation should be considered when the transferrin saturation is less than 30% or serum ferritin concentration is less than 500 ng/mL. Hepcidin effects impair iron absorption in renal failure,[8] and intravenous iron is more effective for supplementation than is oral iron.[9] Resistance to erythropoietin therapy most commonly reflects iron deficiency or concurrent inflammation; folate deficiency may also contribute to erythropoietin resistance.

ANEMIA OF LIVER DISEASE

The majority of patients with chronic liver disease are mildly anemic.[10] Total blood volume in cirrhosis and other chronic liver diseases is typically increased 10 to 15%, but may be expanded as much as 30%. Dilution of the red cell mass by expanded plasma volume is a major element in the anemia of liver disease.

The hemoglobin concentration is typically 10 to 12 g/dL in cirrhosis. Red cells are generally macrocytic with an average MCV of 107 fL. Chronic alcohol abuse or even binges of alcohol consumption without established liver disease also cause mild macrocytosis, although the MCV remains generally less than 105 fL. Although alcohol abusers are at increased risk for dietary folate deficiency, folate deficiency typically is not the cause of these changes. Target cells may be present. Target cells in liver disease have an increased diameter that distinguishes them from the microcytic target cells of hemoglobinopathies or thalassemia. The reticulocyte count is generally near the appropriate level for the degree of anemia. Marked reticulocytosis may be seen with spur cell anemia or when recovering from heavy acute alcohol ingestion.

The major pathogenetic factor in the anemia of liver disease is shortened red cell survival. Many mechanisms contribute, with abnormalities in the lipid composition of the red cell membrane likely the most important. Splenic sequestration or abnormalities of oxidative metabolism may also contribute. Other factors that may contribute include suppression of erythroid progenitors by alcohol, dietary folate deficiency, or gastrointestinal blood loss and possible iron deficiency. Spur cell anemia, a morphologically distinctive consequence of abnormal red cell lipid composition in liver disease, may be associated with striking reticulocytosis. Greater than 5% spur cells in the red cell population is associated with decreased survival in liver disease.

Specific treatment of uncomplicated anemia of liver disease is not required, beyond encouraging good nutrition and alcohol abstinence. Patients should be evaluated for concurrent blood loss and iron or folate deficiency.

ANEMIA OF ENDOCRINE DEFICIENCY

Anemia in endocrine deficiencies such as hypothyroidism and adrenal or androgen insufficiency is "adaptive" in a sense, since it reflects an adjustment to downregulated basal metabolism. The degree of anemia is typically mild to moderate and of itself rarely causes symptomatology. These diagnoses should be considered after more significant etiologies of anemia such as iron deficiency or renal insufficiency have been ruled out. Less than one-third of cases of anemia in hypothyroidism are macrocytic; otherwise, anemia in endocrine deficiency is normocytic. Anemia in adrenal insufficiency may be masked by volume contraction. Anemia may be the only finding in androgen deficiency. Treatment of the underlying deficiency corrects the anemia of endocrine deficiency.

PHYSIOLOGIC ANEMIA OF PREGNANCY

A decrease in the hemoglobin concentration is a normal feature of pregnancy. Beginning around the seventh week of pregnancy, the red cell mass begins to expand up to 15 to 25% above prepregnancy baseline. At roughly the same time, the plasma volume begins to expand disproportionately, ultimately reaching 40 to 50% above baseline during weeks 16 to 24.[11] This dilutional anemia with increased red cell mass is referred to as "physiologic anemia of pregnancy." Normocytic anemia with a hemoglobin concentration greater than 11 g/dL in the late first trimester or 10 g/dL in the second and third trimesters of an uncomplicated pregnancy can be attributed to the physiologic anemia of pregnancy without further testing. Lower hemoglobin concentrations or microcytic or macrocytic anemia require evaluation. The mostly likely contributors to anemia in pregnancy are iron deficiency or folate deficiency, demand for both of which is increased during pregnancy. In the absence of a preexisting deficiency or an increased demand induced by hemolysis, the 0.8-mg daily folate dose recommended for neural tube defect prophylaxis is sufficient to avoid folate deficiency during pregnancy in countries where food fortification with folate is standard. Higher doses may be required in other circumstances.[A4] Although routine iron supplementation during pregnancy is generally not recommended in guidelines, it is quite common in the United States; such patients have a lower likelihood of developing iron deficiency in pregnancy or postpartum.

ANEMIA OF AGING

The frequency of anemia in both men and women increases after the age of 50. By age 65, roughly 10% of men and women are anemic. The prevalence of anemia is three- to four-fold increased in African Americans over 65 compared to persons of White European ancestry but only slightly elevated in Latino populations. However, gender-specific mean hemoglobin/hematocrit values for older patients are nearly identical to the overall population mean values.[12] Anemia contributes to frailty and morbidity in aging.

The increased frequency of anemia with aging in part reflects age-related declines in renal function, gastric acidity (required for iron or B_{12} absorption), and testosterone in men, as well as an increased frequency of other pathology.[13] When large populations of anemic elderly patients are evaluated, approximately one third have iron, B_{12}, and/or folate deficiency (with iron deficiency predominant); one third have anemia of inflammation and/or anemia of chronic kidney disease (with anemia of inflammation three times more frequent); and one third have other etiologies, with the largest component being normocytic anemia described as "unexplained anemia of aging." Studies of this entity suggest that it is a cytokine/hepcidin-driven analog of the anemia of inflammation/anemia of chronic disease. Specific treatment is not required. In elderly individuals with persistent unexplained anemia and abnormalities in other lineages or mild macrocytosis, bone marrow examination or molecular analysis to detect clonal disorders such as the myelodysplastic syndromes should be considered.

145 MICROCYTIC AND HYPOCHROMIC ANEMIAS

THOMAS G. DELOUGHERY

IRON DEFICIENCY

DEFINITION

Iron deficiency occurs when the body iron stores are insufficient to support iron metabolism. Iron deficiency can occur without anemia; in this setting, the lack of iron in tissues leads to fatigue, alopecia, and other symptoms. Further depletion of iron stores, however, will lead to a progressive microcytic anemia. In functional iron deficiency, iron stores are adequate, but the affected individual is unable to mobilize them to support erythropoiesis.

EPIDEMIOLOGY

In the United States, the prevalence of iron deficiency is about 1 to 2% in men but is much higher in women. Women are at greater risk for developing iron deficiency due to obligate iron losses through menstruation, with an average loss of 35 mL of blood and 16 mg of iron per menstrual period. Iron requirements in women average 1 to 3 mg per day, with higher needs for women with heavier menses. Dietary iron intake is often inadequate to maintain iron balance.[1] For example, bone marrow stores may be absent in 25% of healthy college-age women and reduced in another 33%. The average pregnancy requires 900 mg of iron stores, with requirements rising to 6 mg/day at the end of the third trimester. Furthermore, approximately 15% of women lose over 500 mL of blood at delivery, thereby adding further stress on iron stores.[2]

After menstrual blood loss, gastrointestinal bleeding is the second leading cause of iron deficiency. Some bleeding is acute, but gastrointestinal lesions also can cause gradual blood loss over long periods of time (Chapter 121). Gastrointestinal cancer, especially colon cancer but also gastric cancer, is found in up to 10% of older patients with iron deficiency anemia. Ulcers and gastritis are common nonmalignant causes of blood loss.

Iron deficiency is also seen more commonly in the elderly likely due to dietary factors in combination with chronic health conditions. The incidence of iron deficiency also is much higher in developing countries due to the lack of bioavailable dietary sources of iron.

PATHOBIOLOGY

Iron is found in a variety of foods. Meat is the richest source of heme iron, in which iron is in the ferrous form (Fe^{2+}). Iron from nonheme sources is largely in the ferric form (Fe^{3+}), which is reduced by stomach acid to the ferrous form (Fig. 145-1). In the jejunum, two receptors on the mucosal cells absorb iron. One receptor, which is specific for heme-bound iron, absorbs 30 to 40% of ingested heme iron. The other receptor, divalent metal transporter (DMT1), takes up inorganic (nonheme) iron but is much less efficient, thereby explaining the superior absorption of heme iron compared with inorganic iron. Iron is exported from the enterocyte via the transmembrane protein ferroportin (SCL40A1). Iron is subsequently delivered to plasma transferrin, which can carry up to two iron molecules and is the main transport molecule for iron. Transferrin delivers iron to the marrow, where it binds to the transferrin receptor on the red cell membrane.[3] This complex of transferrin-receptor is internalized into the cell by endocytosis. The lower pH of the endosome results in release of iron from the complex. The iron-less complex recycles to the cell surface, transferrin is released, and the cycle restarts. In a growing red cell, about 80,000 transferrin molecules bind on and off every second. Excess iron is taken to the liver, where it is stored. Ferritin, which is the storage protein for iron, consists of 24 ferritin subunits that create a shell that can store up to 4500 iron molecules. In dying red cells, iron contained in hemoglobin is reprocessed by binding to ferritin in macrophages, and it is then transferred to transferrin for recycling, either into newly developing red cells or to storage in the liver. This iron cycle is extremely efficient and loses less than 5% of iron contained in the total red cell mass.

The key protein of iron metabolism, hepcidin, controls iron absorption and the release of iron from its stores.[4] Hepcidin binds to ferroprotein, thereby leading to its degradation. When hepcidin degrades ferroprotein, iron cannot be released from the enterocyte or hepatocytes, thereby leading to both a lack of iron absorption and a halt in iron release to developing red cells. Hepcidin synthesis is upregulated not only by iron but also by inflammation. Hypoxia reduces levels of hepcidin, whereas erythropoiesis and iron deficiency increase levels of hepcidin. Rare mutations in proteins of iron absorption can lead to severe iron deficiency, but these conditions most commonly present in childhood.

The two major causes of iron deficiency are blood loss and reduced absorption of iron. Blood loss, most commonly from gynecologic or gastrointestinal sources, is the predominant cause for iron deficiency. The other mechanisms for iron deficiency are issues with the absorption of iron and the influence of iron-poor diets (Table 145-2). For example, the increasing avoidance of dietary meat is leading to an increase in iron deficiency because nonheme iron can be inadequate to maintain iron stores, especially in women. Lactovegetarians are at even higher risk.[5]

Gastrointestinal Causes

Any source of gastrointestinal bleeding (Chapter 121) can cause iron deficiency, but some gastrointestinal diseases have additional adverse effects on iron balance. For example, *Helicobacter pylori* infections can result in iron deficiency because of bleeding from ulcers (Chapter 125), but infection also results in achlorhydria, which impairs the ability to convert iron from its ferric to its ferrous form and thereby decreases the absorption of iron. *Heliobacter pylori* infections may also lead to autoimmune gastritis, which leads to iron deficiency in its early stages and to B_{12} deficiency in its later stages.

Obese patients are often iron deficient, with about 8% of obese patients having elevated hepcidin levels as a marker of reduced iron absorption. After bariatric surgery, the prevalence of iron deficiency can be as high as 50%,

ANEMIA OF AGING

The frequency of anemia in both men and women increases after the age of 50. By age 65, roughly 10% of men and women are anemic. The prevalence of anemia is three- to four-fold increased in African Americans over 65 compared to persons of White European ancestry but only slightly elevated in Latino populations. However, gender-specific mean hemoglobin/hematocrit values for older patients are nearly identical to the overall population mean values.[12] Anemia contributes to frailty and morbidity in aging.

The increased frequency of anemia with aging in part reflects age-related declines in renal function, gastric acidity (required for iron or B_{12} absorption), and testosterone in men, as well as an increased frequency of other pathology.[13] When large populations of anemic elderly patients are evaluated, approximately one third have iron, B_{12}, and/or folate deficiency (with iron deficiency predominant); one third have anemia of inflammation and/or anemia of chronic kidney disease (with anemia of inflammation three times more frequent); and one third have other etiologies, with the largest component being normocytic anemia described as "unexplained anemia of aging." Studies of this entity suggest that it is a cytokine/hepcidin-driven analog of the anemia of inflammation/anemia of chronic disease. Specific treatment is not required. In elderly individuals with persistent unexplained anemia and abnormalities in other lineages or mild macrocytosis, bone marrow examination or molecular analysis to detect clonal disorders such as the myelodysplastic syndromes should be considered.

145 MICROCYTIC AND HYPOCHROMIC ANEMIAS

THOMAS G. DELOUGHERY

IRON DEFICIENCY

DEFINITION

Iron deficiency occurs when the body iron stores are insufficient to support iron metabolism. Iron deficiency can occur without anemia; in this setting, the lack of iron in tissues leads to fatigue, alopecia, and other symptoms. Further depletion of iron stores, however, will lead to a progressive microcytic anemia. In functional iron deficiency, iron stores are adequate, but the affected individual is unable to mobilize them to support erythropoiesis.

EPIDEMIOLOGY

In the United States, the prevalence of iron deficiency is about 1 to 2% in men but is much higher in women. Women are at greater risk for developing iron deficiency due to obligate iron losses through menstruation, with an average loss of 35 mL of blood and 16 mg of iron per menstrual period. Iron requirements in women average 1 to 3 mg per day, with higher needs for women with heavier menses. Dietary iron intake is often inadequate to maintain iron balance.[1] For example, bone marrow stores may be absent in 25% of healthy college-age women and reduced in another 33%. The average pregnancy requires 900 mg of iron stores, with requirements rising to 6 mg/day at the end of the third trimester. Furthermore, approximately 15% of women lose over 500 mL of blood at delivery, thereby adding further stress on iron stores.[2]

After menstrual blood loss, gastrointestinal bleeding is the second leading cause of iron deficiency. Some bleeding is acute, but gastrointestinal lesions also can cause gradual blood loss over long periods of time (Chapter 121). Gastrointestinal cancer, especially colon cancer but also gastric cancer, is found in up to 10% of older patients with iron deficiency anemia. Ulcers and gastritis are common nonmalignant causes of blood loss.

Iron deficiency is also seen more commonly in the elderly likely due to dietary factors in combination with chronic health conditions. The incidence of iron deficiency also is much higher in developing countries due to the lack of bioavailable dietary sources of iron.

PATHOBIOLOGY

Iron is found in a variety of foods. Meat is the richest source of heme iron, in which iron is in the ferrous form (Fe^{2+}). Iron from nonheme sources is largely in the ferric form (Fe^{3+}), which is reduced by stomach acid to the ferrous form (Fig. 145-1). In the jejunum, two receptors on the mucosal cells absorb iron. One receptor, which is specific for heme-bound iron, absorbs 30 to 40% of ingested heme iron. The other receptor, divalent metal transporter (DMT1), takes up inorganic (nonheme) iron but is much less efficient, thereby explaining the superior absorption of heme iron compared with inorganic iron. Iron is exported from the enterocyte via the transmembrane protein ferroportin (SCL40A1). Iron is subsequently delivered to plasma transferrin, which can carry up to two iron molecules and is the main transport molecule for iron. Transferrin delivers iron to the marrow, where it binds to the transferrin receptor on the red cell membrane.[3] This complex of transferrin-receptor is internalized into the cell by endocytosis. The lower pH of the endosome results in release of iron from the complex. The iron-less complex recycles to the cell surface, transferrin is released, and the cycle restarts. In a growing red cell, about 80,000 transferrin molecules bind on and off every second. Excess iron is taken to the liver, where it is stored. Ferritin, which is the storage protein for iron, consists of 24 ferritin subunits that create a shell that can store up to 4500 iron molecules. In dying red cells, iron contained in hemoglobin is reprocessed by binding to ferritin in macrophages, and it is then transferred to transferrin for recycling, either into newly developing red cells or to storage in the liver. This iron cycle is extremely efficient and loses less than 5% of iron contained in the total red cell mass.

The key protein of iron metabolism, hepcidin, controls iron absorption and the release of iron from its stores.[4] Hepcidin binds to ferroprotein, thereby leading to its degradation. When hepcidin degrades ferroprotein, iron cannot be released from the enterocyte or hepatocytes, thereby leading to both a lack of iron absorption and a halt in iron release to developing red cells. Hepcidin synthesis is upregulated not only by iron but also by inflammation. Hypoxia reduces levels of hepcidin, whereas erythropoiesis and iron deficiency increase levels of hepcidin. Rare mutations in proteins of iron absorption can lead to severe iron deficiency, but these conditions most commonly present in childhood.

The two major causes of iron deficiency are blood loss and reduced absorption of iron. Blood loss, most commonly from gynecologic or gastrointestinal sources, is the predominant cause for iron deficiency. The other mechanisms for iron deficiency are issues with the absorption of iron and the influence of iron-poor diets (Table 145-2). For example, the increasing avoidance of dietary meat is leading to an increase in iron deficiency because nonheme iron can be inadequate to maintain iron stores, especially in women. Lactovegetarians are at even higher risk.[5]

Gastrointestinal Causes

Any source of gastrointestinal bleeding (Chapter 121) can cause iron deficiency, but some gastrointestinal diseases have additional adverse effects on iron balance. For example, *Helicobacter pylori* infections can result in iron deficiency because of bleeding from ulcers (Chapter 125), but infection also results in achlorhydria, which impairs the ability to convert iron from its ferric to its ferrous form and thereby decreases the absorption of iron. *Heliobacter pylori* infections may also lead to autoimmune gastritis, which leads to iron deficiency in its early stages and to B_{12} deficiency in its later stages.

Obese patients are often iron deficient, with about 8% of obese patients having elevated hepcidin levels as a marker of reduced iron absorption. After bariatric surgery, the prevalence of iron deficiency can be as high as 50%,

ABSTRACT

Microcytic and hypochromic anemias are anemias in which the size of the red blood cell (mean corpuscular volume or MCV) is reduced due to impaired production of hemoglobin, thereby resulting in a reduced hemoglobin content (mean corpuscular hemoglobin or MCH) and mean corpuscular hemoglobin concentration (MCHC). Iron deficiency anemia is caused by inadequate iron stores, anemia of chronic disease is a consequence of iron sequestration, and inherited microcytic anemias are caused by a variety of mutations in the iron absorption pathway. Thalassemia is caused by reduced synthesis of the normal hemoglobin protein. Finally, the rare sideroblastic anemias are microcytic because of defects in the synthesis of heme. Treatment requires identification of its cause. Iron can be replaced orally or intravenously.

iron-refractory iron deficiency anemia

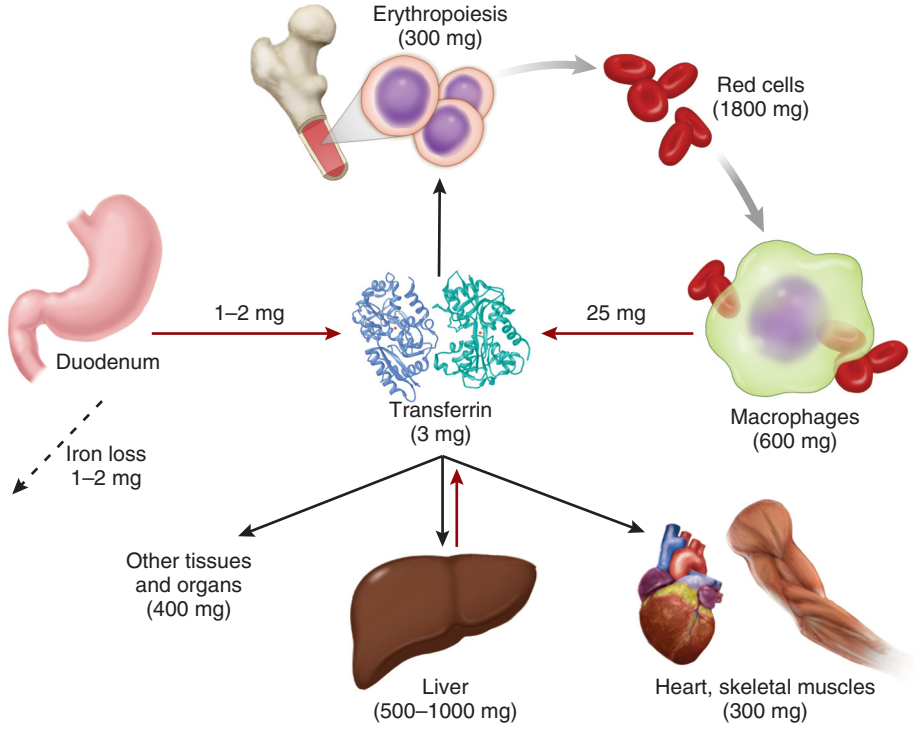

FIGURE 145-1. Iron distribution in the body. Schematic representation of iron distribution in the body. The iron carrier transferrin transports iron to all organs. The average content of iron in different tissues/organs for an adult male is shown in parentheses. Most iron is consumed for hemoglobin synthesis in red blood cells. Iron recycling from macrophages, which clear senescent red cells by phagocytosis, provides most usable iron. Duodenal iron absorption is limited to 1 to 2 mg daily and corresponds to the daily physiologic loss. (From Camaschella C. Microcytic and hypochromic anemias. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020:1035-1040.)

with the prevalence increasing every subsequent year after surgery. Since the main site of gastrointestinal iron absorption is the duodenum, surgeries that bypass this part of the bowel are associated with a higher incidence of iron deficiency. For example, the risk is higher for more complex surgeries, such as the Roux-en-Y, than sleeve gastrectomy.[6]

Athletes are at risk for iron deficiency, with gastrointestinal blood loss as the major cause. Furthermore, exercise-induced hemolysis, caused by foot striking and perhaps also by intense muscle contractions, can lead to urinary losses of iron. Decreased iron absorption may also contribute because levels of hepcidin are often elevated in athletes due to training-induced inflammation.

Patients who have inflammatory bowel disease (Chapter 127) have a high prevalence of iron deficiency because bowel inflammation results in reduced absorption of iron as well as gastrointestinal blood loss. In addition, the marked inflammatory state leads to a rise in hepcidin levels, thereby blocking iron absorption. Celiac disease (Chapter 126) can also be accompanied by severe iron deficiency, owing to reduced absorption of iron, gastrointestinal blood loss, and increased hepcidin levels. Even when on a gluten-free diet, patients may not be able to absorb enough iron to avoid long-term iron deficiency.[7]

Both aspirin and nonsteroidal anti-inflammatory agents can lead to iron deficiency through overt bleeding from ulcers and/or increased subtle gastrointestinal blood loss. For example, a daily aspirin increases blood loss from 0.8 mL/day to 5.0 mL/day. Protein pump inhibitors reduce stomach acid, hinder the conversion of ferric to ferrous iron, and can lead to iron deficiency. This risk of iron deficiency is less with H_2-blockers.

Parasitic infections are a common cause of gastrointestinal blood loss in developing countries. Hookworm infections (Chapter 327) are classically associated with iron deficiency, with each worm capable of ingesting 0.5 mL of blood a day. Other parasites associated with iron deficiency are whipworm (Chapter 327) and schistosomiasis (Chapter 326).

Other Causes

Another source of blood loss is the genitourinary system. Bladder or renal lesions that result in chronic hematuria can lead to iron deficiency over time. In women, a frequent source of excess menstruation is dysfunctional uterine bleeding and fibroids (Chapter 184). In chronic hemolytic disorders (Chapters 146 and 147), ongoing hemoglobinuria can rarely result in iron deficiency.

Patients who have heart failure (Chapter 45) have an increased prevalence of both overt and functional iron deficiency, with rates of true iron deficiency as high as 13 to 42% and an even higher percentage having functional iron deficiency. In patients who are on renal dialysis (Chapter 117), blood loss with dialysis and the use of erythropoiesis-stimulating agents lead to depletion of iron stores. The effective use of erythropoiesis-stimulating agents requires efficient mobilization of stored iron, but this process can be blunted by the inflammation of renal disease.

CLINICAL MANIFESTATIONS

Because iron deficiency anemia often slowly worsens, otherwise healthy patients may tolerate marked anemia. As a result, iron deficiency anemia is often first suggested based on a complete blood count ordered for routing screening. Iron deficiency anemia is usually suspected or diagnosed from results of blood tests pointing to microcytic anemia, low serum iron, and low ferritin.[8]

Iron deficiency can lead to symptoms due to both the lack of iron itself and the resultant anemia. The most common and disabling symptom of iron deficiency anemia is fatigue, which can occur with even modest reductions in iron stores. Older patients with underlying comorbid conditions typically develop dyspnea and may even develop new onset or worsening angina.

A common complaint in iron-deficient women is hair loss, with increased loss reported in women with ferritins under 100 ng/dL. The pattern most associated with iron deficiency is diffuse nonscarring scalp alopecia (Chapter 409). Another common symptom of iron deficiency is cold intolerance, perhaps because iron is important for the effectiveness of thyroid hormone. Restless leg syndrome (Chapter 374), in which patients have leg cramps, unpleasant leg sensations, and the need to move the legs at night, is also a symptom of low iron stores.[9] Some patients report increased bruising and/or generalized pruritus. In advanced iron deficiency, patients may develop glossitis, angular stomatitis, brittle or spoon nails (koilonychia), or dysphagia due to esophageal webs (Plummer-Vinson syndrome).

Pica, which is an unusual craving for eating ice or clay, is a common symptom in patients with iron deficiency. While this overall condition is not specific for iron deficiency, the preference for eating ice may be both sensitive and specific for the condition.

DIAGNOSIS

The serum ferritin level correlates with body iron stores in healthy patients and is the most reliable and cost-effective test to diagnose iron deficiency. Since ferritin is an acute phase reactant, an iron-replete patient may have a very high ferritin level, but it is rare for an iron-deficient patient to have a ferritin level over 100 ng/mL. A ferritin level of less than 15 ng/mL is very specific for iron deficiency, but iron deficiency cannot be excluded in older patients or in patients who have inflammatory conditions unless the ferritin level is greater than 100 ng/mL. Ferritin values under 50 ng/mL should be considered abnormal in a symptomatic patient.

The anemia of iron deficiency is classically a microcytic anemia (Table 145-1) without reticulocytosis (Fig. 145-2), but these findings are neither sensitive nor specific (Table 145-3) since thalassemia and the anemia of inflammation (Chapter 144) can also lead to microcytosis. A low red cell mean corpuscular volume is generally a late finding seen with severe iron deficiency, but concurrent medical issues such as liver disease, folate deficiency, or B_{12} deficiency (Chapter 144) may blunt or obscure the decrease in red cell size.

A serum iron level is not effective as a diagnostic test since it is low in the anemia of inflammation, can be falsely elevated with oral iron intake in iron-deficient patients, and varies markedly from day to day. An elevated total iron binding capacity (TIBC) is specific for iron deficiency, but its sensitivity is low because it is reduced by inflammation, aging, and poor nutrition. Iron saturation percentages are also unreliable because they depend on both the TIBC and serum iron level, so saturation is also low in the anemia of chronic disease. Serum levels of soluble transferrin receptor are increased in iron deficiency, and levels also can be increased in any condition associated with increased red cell mass, such as in hemolytic anemias. The gold standard for iron deficiency is the bone marrow iron stain, but this invasive and expensive procedure is rarely, if ever, indicated.

Determining the Underlying Cause

A priority in care of the patient with iron deficiency is determining the cause. Given that the body has no natural mechanisms for eliminating iron, blood loss must always be assumed.[10] Testing of the stool for blood can identify patients with blood loss; however, most stool tests require 10 mL or more of daily blood loss to be positive, and losses less than 10 mL/day can still lead to iron deficiency. Because of this limitation, any man with unexplained iron deficiency or any iron-deficient woman over age 40 years should undergo both upper and lower gastrointestinal endoscopy to evaluate for occult blood loss (see Fig. 121-6). In problematic cases, capsule endoscopy may be required (Chapter 121).[11] Premenopausal women over age 40 years should also undergo testing, as should any person with gastrointestinal symptoms, family history of colon cancer, weight loss, or blood in the stool. A thorough menstrual history should be also obtained. A urinalysis is important, although occult hematuria is rarely persistent enough to lead to iron deficiency.

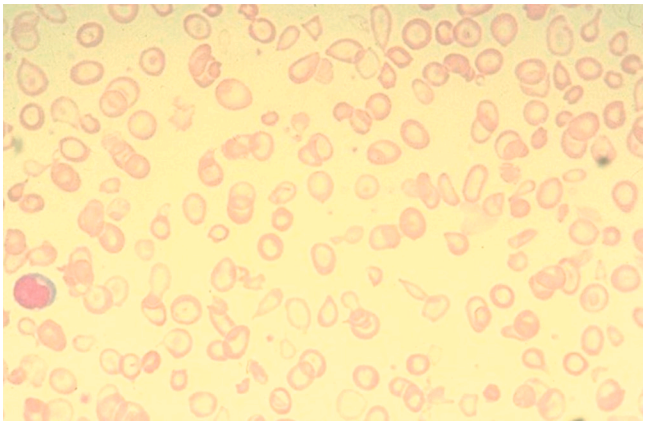

FIGURE 145-2. Microcytic hypochromic blood smear.

Differential Diagnosis

Iron deficiency anemia must be distinguished from α- or ß-thalassemia, in which serum iron and serum ferritin levels are normal or high. A low serum iron level with a high ferritin level is typical of the anemia of chronic inflammation, in which serum hepcidin levels are normal or high, and inflammatory markers such as the erythrocyte sedimentation rate and the C-reactive protein level are usually elevated. Sideroblastic anemia is associated with iron overload and an increased ferritin level; it can be confirmed by finding ringed sideroblasts on bone marrow smears.

TREATMENT

Repletion of iron can ameliorate symptoms of iron deficiency and restore a normal red blood cell mass. Eating a diet higher in bioavailable iron can help treat iron deficiency[A1] and can maintain iron stores, but even the best diet alone is usually inadequate to replete iron stores. Meat is the food that is richest in iron due to its heme iron. Cooking with iron skillets can also increase dietary iron, but the amount of iron enrichment is variable.

Oral Iron Supplementation

Ferrous sulfate (325 mg once daily) is effective for patients without conditions that preclude oral therapy. However, lower doses (15 to 20 mg of elemental iron daily) can be as effective and are better tolerated with fewer gastrointestinal side effects.[12]

Multiple oral iron preparations exist (Table 145-4), and no one compound appears to be superior to another.[A2] If ferrous sulfate is not tolerated, then ferrous gluconate, which has less elemental iron per tablet, can be tried.

The iron supplement is best taken on an empty stomach or with meat protein (cow, pork, and fish) to increase its absorption. Vitamin C may also increase the absorption of iron, whereas concomitant calcium and fiber can decrease its absorption. Tea, which is a potent inhibitor of iron absorption, can reduce absorption by 90%. Coffee also decreases iron absorption by about 60%.

With oral supplementation, the reticulocyte count should rise within 1 week, and hemoglobin concentration should start rising by the second week of therapy. Iron should be continued until iron stores are replete, with a goal ferritin level of 50 to 100 ng/dL.

Gastrointestinal side effects of oral iron are common, with 30 to 50% of patients reporting symptoms that may be related to esophageal erosions and gastritis. The side effects of stomach pain and constipation can hinder compliance. Taking a smaller dose of elemental iron and even decreasing to every other day can maintain effectiveness[A3] while reducing these symptoms. In patients whose iron deficiency does not respond to oral iron, adherence to and tolerability of oral iron should be assessed. Conditions to consider include celiac disease (Chapter 126), autoimmune gastritis (Chapter 125), *Helicobacter pylori* infections, persistent menorrhagia, and ongoing gastrointestinal losses.

TABLE 145-3 DIAGNOSIS OF IRON DEFICIENCY

TEST	IRON DEFICIENCY	ANEMIA OF CHRONIC INFLAMMATION	IRON DEFICIENCY AND INFLAMMATION	SIDEROBLASTIC ANEMIA
Serum iron	Decreased	Decreased	Decreased	Often increased
Mean corpuscular volume	Decreased/Normal	Decreased/Normal	Decreased/Normal	Normal
Total iron-binding capacity	Increased	Decreased	Decreased/Normal	Normal
Saturation (%)	Decreased (usually <16%)	Decreased (usually <30%)	Decreased (usually <20%)	Increased (usually >45%)
Ferritin (μg/L)	Decreased (usually <15 ng/mL)	Increased (usually >200 ng/mL)	Decreased (usually <100 ng/mL)	Increased (usually >200 ng/mL)

TABLE 145-4 COMMONLY PREPARED IRON PREPARATIONS

AGENT	TYPICAL SINGLE DOSE
ORAL	
Ferrous sulfate	325 mg (65 mg elemental iron)
Ferrous gluconate	325 mg (35 mg elemental iron)
Iron bisglycinate	25 mg elemental iron
INTRAVENOUS	
Ferric carboxymaltose	750-1000 mg
Ferric derisomaltose	1000 mg
Ferumoxytol	510-1020 mg
Low molecular weight iron dextran	1000 mg

Intravenous Iron Therapy

Parenteral iron should be used in any iron-deficient patient who is not responding to or cannot tolerate oral iron. If the hemoglobin concentration has not responded within 2 weeks, it is unlikely the patient will respond to oral iron. In patients who have ongoing bleeding, the iron loss may be too great for oral iron to overcome. Bowel issues, such as surgical resection or inflammatory bowel disease, can also lead to resistance to oral iron. *H. pylori* infection and celiac disease lead to impaired absorption of iron. Patients with known absorption problems, such as history of bowel surgery or bariatric procedures, should preferentially receive intravenous iron. In pregnancy, intravenous iron has been shown to be superior to oral iron.[A4]

Replacement iron formulations include low molecular weight iron dextran (given as a 1000 mg single replacement dose over one hour), ferumoxytol (given as 510 mg over 15 minutes, repeated once in 3 to 8 days), ferric carboxymaltose (given as two 750 mg doses a week apart), and ferric derisomaltose (up to 1000 mg over 20 minutes). Patients who need a magnetic resonance imaging scan must inform their doctors if they received ferumoxytol because it can function as a contrast agent. With iron carboxymaltose, about 75% of recipients experience a fall in the serum phosphorus level to less than 2.0 mg/dL,[A5] and symptomatic hypophosphatemia can occur.

All intravenous iron preparations contain carbohydrates that bind the elemental iron to prevent reactions. Nevertheless, a disadvantage of intravenous iron is an infusion reaction, which is not a true allergic reaction but rather is related to the activation of complement by the labile free iron (complement activation-related pseudoallergy). Since these reactions are not allergic in nature, administering a test dose is not helpful. Rates of mild reactions are about 1 in 200, and rates of major reactions are about 1 in 200,000. Reactions that require hospitalization are very rare but can be seen with any iron product.[13] Iron infusion should be administered under the supervision of experienced clinicians who are skilled and equipped to deal with infusion reactions. All patients should be observed for 30 minutes after the infusion. Diphenhydramine premedication should be avoided because it can worsen symptoms.

In general, the infusion is stopped for mild reactions and then resumed at a slower rate once symptoms resolve. For more severe reactions, fluids (e.g., 500 mL of normal saline) and corticosteroids (e.g., 150 to 500 mg of hydrocortisone) are helpful. If patients do not respond or develop anaphylaxis (Chapter 233), they should also be treated with epinephrine intravenously (1 mL or a 1/10,000 solution) or intramuscularly (0.3 to 0.5 mL of a 1/1000 solution), oxygen, and more fluids; such patients should be transferred to an acute care setting.

Formulas that calculate the total iron deficit tend to be unreliable, so the most pragmatic approach is to use a 1000-mg replacement dose. Patients with severe iron deficiency anemia may have deficits that exceed 1 g, so a ferritin level should be checked 2 to 4 weeks after an infusion. If the ferritin is not higher than 50 ng/dL at that time, another iron dose should be given. After a patient receives intravenous iron, the ferritin should be checked every 3 to 4 months; if it falls below 50 ng/dL, the iron infusion should be repeated. Patients with ongoing gastrointestinal bleeding should have the ferritin level checked more often and may require frequent infusions.

Oral iron supplementation in iron-deficient but not anemic women (serum ferritin measurements under 50 ng/mL) improves fatigue. In patients who have heart failure, repletion of deficient iron stores can improve cardiac function and quality of life, and also to reduce hospitalization.[A6–A8] In such patients, intravenous iron replacement appears to be superior to oral replacement.[A9] In patients who have restless leg syndrome (Chapter 374) with abnormal ferritin levels, iron replacement can markedly reduce symptoms.[A10] In patients who are on hemodialysis, proactive iron treatment is preferred over reactive treatment.[A11]

PREVENTION

The recommended dietary iron intake is 8 mg/day for adults and postmenopausal women, 18 mg for premenopausal women, and 27 mg/day during pregnancy. Meats are rich in heme iron, and iron in meat is much more effectively absorbed. Nonmeat sources of iron contain less bioavailable iron, and it is difficult to ingest large enough amounts to meet iron requirements.

PROGNOSIS

The prognosis of iron deficiency is excellent once stores are replete. Some patients, especially those who have had bariatric surgery or inflammatory bowel disease, may require chronic iron infusions.

ANEMIA OF CHRONIC DISEASE (ANEMIA OF INFLAMMATION)

Any type of illness can be accompanied by an anemia that is due to direct results of the inflammatory state. Although this type of anemia especially accompanies cancer and severe infections, it is increasingly recognized as a complication of conditions such as heart failure[14] and chronic pulmonary disease.[15]

PATHOBIOLOGY

Inflammation leads to anemia by several different mechanisms.[16] Inflammatory cytokines such as interleukin (IL)-6 increase the levels of serum hepcidin, which blocks the absorption of iron. The impaired release of iron from its stores results in iron-restricted erythropoiesis. Normally, ferroportin allows export of iron from enterocytes, macrophages, and hepatocytes. However, hepcidin binds to and leads to the degradation of ferroportin, which blocks the export of iron to the blood and to developing red cells. These cytokines also suppress the production of erythropoietin, so serum erythropoietin levels will be lower than predicted for a given degree of anemia. In addition, the half-life of the red cell is shorter.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The degree of anemia varies with the degree of inflammation. Most patients will have hemoglobin concentrations in the 8 to 10 g/dL range, but concentrations can be as low as 7 g/dL. The anemia of inflammation can be microcytic, owing to the impaired delivery of iron to the developing erythrocyte, but it is rare to be less than 70 fL. The anemia can further add to the symptomatic burden of the underlying disorder.

The diagnosis is typically made by excluding other causes for the anemia (e.g., nutritional deficiencies of iron, folate, or vitamin B_{12}, multiple myeloma in older patients, bone marrow disorders) and documenting the presence of adequate iron stores (serum ferritin > 100 ng/dL). Serum levels of erythropoietin are lower than would be expected for the degree of anemia. Due to iron sequestration, the iron saturation percentage is decreased.

TREATMENT

The most effective therapy of anemia of chronic disease is treatment of the underlying disorder. Unless the patient is frankly iron deficient, patients do not benefit from either oral or intravenous iron unless they are also receiving an indicated erythropoiesis-stimulating agent. Such agents are commonly prescribed in chronic kidney disease (Chapters 116 and 117) and sometimes prescribed in cancer patients who are undergoing chemotherapy, but they are not generally used for other causes. In the future, the use of hepcidin antagonists may be of benefit.

SIDEROBLASTIC ANEMIA

The rarest cause of microcytic anemia are the sideroblastic anemias. By definition, ringed sideroblasts must be seen on bone marrow examination. Ringed sideroblasts are abnormal red cell precursors in which aggregates of iron surround the nucleus due to disruption of the synthesis of heme.[17]

Sideroblastic anemia can be acquired or inherited.[18] The most common inherited form is X-linked sideroblastic anemia due to mutations in the *ALAS2* gene. The enzyme product of this gene controls the first step in the synthesis of heme, so mutations lead to disruption of its synthesis. Rarer autosomal recessive forms include mutations in *SLC25A38*, which is needed to import the amino acid glycine that is required for the synthesis of heme, and glutaredoxin 5, which impairs *ALAS2* gene translation.

Acquired forms of sideroblastic anemia can be due to myelodysplastic syndromes (Chapter 167) or to drugs or toxins that interfere with the synthesis of heme. Implicated drugs include ethanol, isoniazid, pyrazinamide, and linezolid. Copper deficiency, either because of inadequate dietary intake or overabundant ingestion of zinc, can lead to ringed sideroblasts.[19]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Given the number of entities that can lead to sideroblastic anemia, presentations can vary. Younger patients presenting with inherited sideroblastic anemia will present with microcytic anemia. In acquired forms, red cells can range from microcytic to macrocytic, but the blood smear will show a population of microcytic red cells. In copper deficiency, patients often have neurologic manifestations such as myelopathy.

Diagnosis is made by a bone marrow examination that shows ringed sideroblasts (Fig. 145-3). Precise diagnosis can be made by use of molecular diagnostic techniques once drugs and toxins have been excluded.

TREATMENT AND PROGNOSIS

Treatment of inherited sideroblastic anemia is supportive with transfusion and management of the subsequent iron overload, although some patients will respond to high-dose vitamin B6 (pyridoxine) or to a stem cell transplant.[20] For acquired forms, discontinuation of the toxic agent is crucial and, as in the case of alcohol-induced sideroblastosis (Chapter 364), may lead to rapid resolution with adequate nutrition. For myelodysplastic syndrome (Chapter 167), treatment of the underlying marrow disease is indicated.

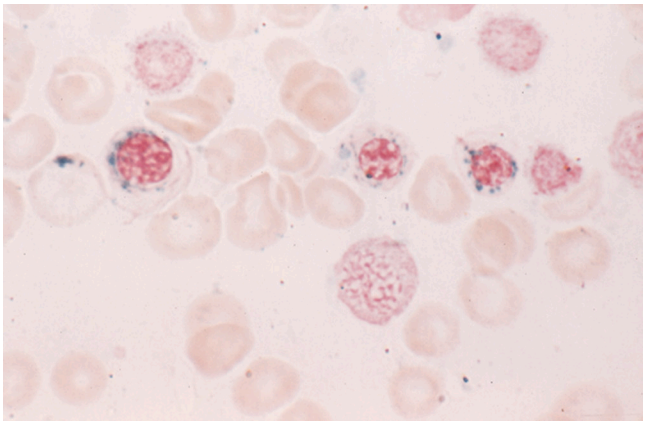

FIGURE 145-3. Ringed sideroblasts. Prussian blue iron stain of the bone marrow shows ringed sideroblasts, which are erythroblasts with perinuclear rings of iron-laden mitochondria. 146 AUTOIMMUNE AND INTRAVASCULAR HEMOLYTIC ANEMIAS

MARC MICHEL

DEFINITION

Hemolytic anemia is defined as an anemia due to a shortened lifespan of mature red blood cells (RBCs) in the peripheral blood. According to the cause, hemolysis and accelerated destruction of RBCs can take place within the vasculature (intravascular hemolysis) and/or in the liver or spleen (extravascular hemolysis). Hemolytic anemia can be the consequence of an intrinsic (intracorpuscular) and often genetically determined defect of the red cell membrane or a red cell constituent (hemoglobin structure or enzyme machinery). Alternatively, hemolytic anemia can result from an extrinsic (extracorpuscular) and typically acquired abnormality that attacks the RBC's membrane (immune, infectious, toxic) (Table 146-1).

Autoimmune hemolytic anemia is a rare acquired autoimmune disease in which autoantibodies directed toward autologous red cell membrane antigens lead to their accelerated destruction.[1] The diagnosis of autoimmune hemolytic anemia is thus based on the presence of a positive direct antiglobulin (Coombs) test and on the absence of any other hereditary or acquired cause of hemolysis.[2] In autoimmune hemolytic anemia, hemolysis is mainly extravascular, but some features of concomitant intravascular hemolysis may be present at onset. In addition to autoimmune hemolytic anemia, other causes of immune-mediated hemolytic anemias that are not mediated by autoantibodies may occur, including some drug-induced hemolytic anemias or post-transfusional hemolytic reactions due to the presence of alloantibodies or to other more complex mechanisms. Paroxysmal nocturnal hemoglobinuria (PNH) is a rare and potentially life-threatening acquired clonal blood disorder with protean manifestations in which RBCs are abnormally vulnerable to activation of complement. The resulting chronic intravascular hemolysis is the hallmark of the classic hemolytic form of the disease, with the release of free hemoglobin contributing to many of its clinical manifestations.

TREATMENT

The most effective therapy of anemia of chronic disease is treatment of the underlying disorder. Unless the patient is frankly iron deficient, patients do not benefit from either oral or intravenous iron unless they are also receiving an indicated erythropoiesis-stimulating agent. Such agents are commonly prescribed in chronic kidney disease (Chapters 116 and 117) and sometimes prescribed in cancer patients who are undergoing chemotherapy, but they are not generally used for other causes. In the future, the use of hepcidin antagonists may be of benefit.

SIDEROBLASTIC ANEMIA

The rarest cause of microcytic anemia are the sideroblastic anemias. By definition, ringed sideroblasts must be seen on bone marrow examination. Ringed sideroblasts are abnormal red cell precursors in which aggregates of iron surround the nucleus due to disruption of the synthesis of heme.[17]

Sideroblastic anemia can be acquired or inherited.[18] The most common inherited form is X-linked sideroblastic anemia due to mutations in the *ALAS2* gene. The enzyme product of this gene controls the first step in the synthesis of heme, so mutations lead to disruption of its synthesis. Rarer autosomal recessive forms include mutations in *SLC25A38*, which is needed to import the amino acid glycine that is required for the synthesis of heme, and glutaredoxin 5, which impairs *ALAS2* gene translation.

Acquired forms of sideroblastic anemia can be due to myelodysplastic syndromes (Chapter 167) or to drugs or toxins that interfere with the synthesis of heme. Implicated drugs include ethanol, isoniazid, pyrazinamide, and linezolid. Copper deficiency, either because of inadequate dietary intake or overabundant ingestion of zinc, can lead to ringed sideroblasts.[19]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Given the number of entities that can lead to sideroblastic anemia, presentations can vary. Younger patients presenting with inherited sideroblastic anemia will present with microcytic anemia. In acquired forms, red cells can range from microcytic to macrocytic, but the blood smear will show a population of microcytic red cells. In copper deficiency, patients often have neurologic manifestations such as myelopathy.

Diagnosis is made by a bone marrow examination that shows ringed sideroblasts (Fig. 145-3). Precise diagnosis can be made by use of molecular diagnostic techniques once drugs and toxins have been excluded.

TREATMENT AND PROGNOSIS

Treatment of inherited sideroblastic anemia is supportive with transfusion and management of the subsequent iron overload, although some patients will respond to high-dose vitamin B6 (pyridoxine) or to a stem cell transplant.[20] For acquired forms, discontinuation of the toxic agent is crucial and, as in the case of alcohol-induced sideroblastosis (Chapter 364), may lead to rapid resolution with adequate nutrition. For myelodysplastic syndrome (Chapter 167), treatment of the underlying marrow disease is indicated.

146 AUTOIMMUNE AND INTRAVASCULAR HEMOLYTIC ANEMIAS

MARC MICHEL

DEFINITION

Hemolytic anemia is defined as an anemia due to a shortened lifespan of mature red blood cells (RBCs) in the peripheral blood. According to the cause, hemolysis and accelerated destruction of RBCs can take place within the vasculature (intravascular hemolysis) and/or in the liver or spleen (extravascular hemolysis). Hemolytic anemia can be the consequence of an intrinsic (intracorpuscular) and often genetically determined defect of the red cell membrane or a red cell constituent (hemoglobin structure or enzyme machinery). Alternatively, hemolytic anemia can result from an extrinsic (extracorpuscular) and typically acquired abnormality that attacks the RBC's membrane (immune, infectious, toxic) (Table 146-1).

Autoimmune hemolytic anemia is a rare acquired autoimmune disease in which autoantibodies directed toward autologous red cell membrane antigens lead to their accelerated destruction.[1] The diagnosis of autoimmune hemolytic anemia is thus based on the presence of a positive direct antiglobulin (Coombs) test and on the absence of any other hereditary or acquired cause of hemolysis.[2] In autoimmune hemolytic anemia, hemolysis is mainly extravascular, but some features of concomitant intravascular hemolysis may be present at onset. In addition to autoimmune hemolytic anemia, other causes of immune-mediated hemolytic anemias that are not mediated by autoantibodies may occur, including some drug-induced hemolytic anemias or post-transfusional hemolytic reactions due to the presence of alloantibodies or to other more complex mechanisms. Paroxysmal nocturnal hemoglobinuria (PNH) is a rare and potentially life-threatening acquired clonal blood disorder with protean manifestations in which RBCs are abnormally vulnerable to activation of complement. The resulting chronic intravascular hemolysis is the hallmark of the classic hemolytic form of the disease, with the release of free hemoglobin contributing to many of its clinical manifestations.

ABSTRACT

Autoimmune hemolytic anemia is a rare acquired autoimmune disease in which autoantibodies directed toward autologous membrane antigens on red blood cells (RBCs) lead to their accelerated destruction. The presence of RBC-bound autoantibodies is demonstrated by a positive direct antiglobulin test, and autoimmune hemolytic anemia is classified into warm or cold autoimmune hemolytic anemia according to the temperature at which autoantibodies bind optimally to RBCs. Autoimmune hemolytic anemia may lead to various degrees of both extravascular and intravascular hemolysis and can sometimes be life-threatening. Paroxysmal nocturnal hemoglobinuria (PNH) is a very rare cause of hemolytic anemia and should be suspected in an adult with an acquired direct antiglobulin test–negative intravascular hemolytic anemia.

TABLE 146-1 MAIN CAUSES OF HEMOLYTIC ANEMIAS

INTRACORPUSCULAR	EXTRACORPUSCULAR
DISORDERS OF THE RBC MEMBRANE	**IMMUNOLOGIC**
Inherited	• Autoimmune HA
• Hereditary spherocytosis	• Alloimmunization
• Hereditary elliptocytosis	• Delayed hemolytic transfusion reaction
• Hereditary stomatocytosis	• Drug-induced HA
Acquired	**MECHANICAL**
• Paroxysmal nocturnal hemoglobinuria	• Thrombotic thrombocytopenic purpura
HEMOGLOBINOPATHY	• Atypical or typical hemolytic-uremic syndrome
Qualitative defect in hemoglobin	• Other microangiopathies
• Sickle cell disease	• HELLP syndrome
• Unstable hemoglobins	• Prosthetic heart valve dysfunction (valve hemolysis)
Quantitative defect in hemoglobin	• Acanthocytosis
• β-Thalassemia	**INFECTIOUS**
• α-Thalassemia	• Malaria
RBC ENZYME ABNORMALITY	• Babesiosis, *Clostridium perfringens*, gram-positive bacteria
• G6PD deficiency	**TOXIC**
• Pyruvate kinase deficiency	• Exogenous: thermal burns; industrial copper, lead poisoning, spider bite, snake bite, mushrooms ingestion.
• Others: pyrimidine 5′ nucleotidase deficiency	• Endogenous: Wilson disease (copper overload)
	• Drug related

G6PD = glucose-6-phosphate dehydrogenase; HA = hemolytic anemia; HELLP = hemolysis, elevated liver, low platelets; RBC = red blood cell.

IMMUNE HEMOLYTIC ANEMIAS

Autoimmune Hemolytic Anemia

EPIDEMIOLOGY

Autoimmune hemolytic anemia can affect both children (mainly before the age of 5 years) and adults, and its estimated overall (not age-adjusted) annual incidence is 2.4 per 100,000 individuals.[3] In children, males tend to be more frequently affected; the female : male sex ratio is 1.5:2 in adults. Median age at onset is 58 years in adults, with more than two thirds of the patients age 40 years and above. This age distribution may be related to the increased frequency of lymphoproliferative malignancies in the elderly, with an age-related increase in secondary autoimmune hemolytic anemia due to lymphoma.

The estimated annual incidence of cold-agglutinin disease, which is a rare form of autoimmune hemolytic anemia, is 0.18/100,000. The median age at diagnosis is 67 years,[4,5] with a female prevalence.

Most cases of autoimmune hemolytic anemias occur sporadically but may be sometimes associated, mostly in children, with an underlying hereditary primary immunodeficiency. Autoimmune hemolytic anemia usually occurs as an isolated immune cytopenia but can sometimes be associated, either concomitantly or sequentially, with immune thrombocytopenia (ITP; Chapter 158) and/or autoimmune neutropenia in the setting of Evans syndrome. Among autoimmune hemolytic anemias, the so-called warm autoimmune hemolytic anemia (see Diagnosis and Classification) accounts for 70 to 80% of all cases and almost 90% of the cases in children. Paroxysmal cold hemoglobinuria is a very uncommon subtype of autoimmune hemolytic anemia seen almost exclusively in children. Autoimmune hemolytic anemia can be primary (or idiopathic) or associated with an underlying disease or condition (secondary autoimmune hemolytic anemia).

PATHOBIOLOGY

The pathogenesis of autoimmune hemolytic anemia is a complex multistep process involving not only the autoantibodies but also various effectors of the immune system, including the complement system and macrophages, as well as B and T lymphocytes.[6] Whereas the mechanisms leading to hemolysis are partially elucidated (antibody-dependent cell-mediated cytotoxicity and complement dependent cytotoxicity being primarily involved), the mechanisms leading to the breakdown of self-tolerance are far from fully understood and are mainly extrapolated from mouse models.

Immunoglobulin G (IgG) anti–red cell autoantibodies mediate the destruction of RBCs outside the circulating blood (extravascular hemolysis). In contrast, when lytic components of the complement system participate in the process, the destruction of red cells usually occurs directly within the circulation (intravascular hemolysis) and/or in the liver.[7]

In warm autoimmune hemolytic anemia, the autoantibody targeting RBCs is mainly of the IgG_1 isotype. It is able to bind to macrophage Fc gamma receptor; therefore, extravascular hemolysis takes place mainly in the reticuloendothelial system of the spleen. Autoantigens on RBC membranes targeted by autoantibody are, by decreasing frequency, (1) peptides from the Rhesus system (in approximately one third of cases); (2) band 3 protein; and (3) glycophorin A, an RBC membrane glycoprotein. In other cases, the antibodies have specificity for antigens in the Kell or Duffy blood group system and very rarely for ABO antigens. In less than 10% of the cases of warm autoimmune hemolytic anemia, no specificity can be found. In contrast to warm autoimmune hemolytic anemia, cold agglutinins are IgM autoantibodies that react at cold temperatures with polysaccharides on the red cell surface and mainly with i and I antigens and less commonly with the Pr glycoprotein and sialylated polysaccharides. Cold agglutinins associated with *Mycoplasma pneumoniae* infection have an anti-I specificity, whereas those related to infectious mononucleosis have anti-i specificity. More recently, infection with the severe acute respiratory syndrome virus coronavirus-2 (SARS-CoV2), whose protein spike shares some homology with ankyrin 3, has also been recognized as a viral trigger of autoimmune hemolytic anemia. In cold agglutinin disease, the cold agglutinins are almost always anti-I monoclonal IgM antibodies with a VH4-34 heavy chain, a heavy chain shape of the antigen-binding surface that favors attachment to polysaccharides.

DIAGNOSIS

Clinical Symptoms

The clinical symptoms of autoimmune hemolytic anemia are those of anemia (e.g., unusual fatigue, exertional dyspnea, tachycardia) and/or those due to active hemolysis (jaundice with or without dark urine, especially when there is intravascular hemolysis). In patients with high-affinity cold agglutinins, exposure to cold can also precipitate episodes of acrocyanosis by inducing massive agglutination of RBCs in the capillary circulation of the hands, feet, or even nose tip and ears. Mild splenomegaly may be present especially in warm autoimmune hemolytic anemia, whereas splenomegaly is uncommon in cold agglutinin disease unless there is an underlying B-cell lymphoma.

General Laboratory Tests

Elevated serum levels of indirect bilirubin and lactate dehydrogenase (LDH) and decreased serum haptoglobin are the usual, albeit nonspecific, features of hemolytic anemia. Laboratory signs of intravascular destruction of RBCs (hemoglobinemia, hemoglobinuria, and hemosiderinuria) are unusual in the setting of autoimmune hemolytic anemia. Once hemolytic anemia has been recognized, the diagnosis of autoimmune hemolytic anemia is usually relatively easy and based first on the identification of anti-RBC autoantibody by means of the direct antiglobulin (Coombs) test, and then on the exclusion of other causes of hemolytic anemia. A careful examination of the peripheral blood smear is essential, keeping in mind that an increase in the number of spherocytes (particularly microspherocytes) can be observed in approximately 30 to 40% of cases of autoimmune hemolytic anemias (Chapter 147).[8]

The Direct Antiglobulin (Coombs) Test

The direct antiglobulin (Coombs) test reveals antibody-coated RBCs central to the diagnosis of autoimmune hemolytic anemia. The indirect antiglobulin (Coombs) test evaluates the presence of incomplete antibodies in the patient's serum. As presently used, the standard antiglobulin reagent contains antibodies to test for the presence of all four classes of IgG and components of complement (usually C3 and C4) on standard gel tubes.

A positive direct antiglobulin test requires cautious interpretation when there are no other features of autoimmune hemolytic anemia. False-positive test results are not unusual. The reported incidence of positive antiglobulin (Coombs) tests in normal blood donors and the general populations of hospitalized patients varies widely—from 1 in 100 to 1 in 15,000. Differences in the technique used to perform the test account for this variation. The usual reason for a false-positive direct antiglobulin test is nonspecific, low-avidity adherence of serum IgG to red cells whereas some patients with systemic lupus erythematosus or B-cell lymphoid malignancies may produce true anti-RBC auto-antibodies without active hemolysis. False-negative direct antiglobulin tests in true autoimmune hemolytic anemia are rare (~5% of all autoimmune hemolytic anemias) and are usually due to low-affinity autoantibodies that spontaneously elute from the red cell surfaces in vitro, or to IgA antibodies, or to amounts of erythrocyte-coating antibodies that are below

the limit of detection by the antiglobulin test. The diagnosis of direct antiglobulin test–negative autoimmune hemolytic anemia can be considered only after the exclusion of other potential causes of hereditary and acquired hemolytic anemia.

Classification of Autoimmune Hemolytic Anemia: Warm versus Cold Autoimmune Hemolytic Anemia

Once the diagnosis of autoimmune hemolytic anemia is established, classification of the type of autoimmune hemolytic anemia involved is essential.[9] According to the direct antiglobulin test pattern and the optimal temperature at which the autoantibody reacts with human RBCs, autoimmune hemolytic anemias (warm and cold) are typically subdivided into four major subtypes: warm autoimmune hemolytic anemia; cold autoimmune hemolytic anemia (including chronic cold agglutinin disease); mixed-type autoimmune hemolytic anemia; and the exceptional paroxysmal cold hemoglobinuria.[10] The great majority of cold-reactive autoantibodies are called "cold agglutinins;" cold hemolysins are much less common. A small proportion (~5%) of patients may exhibit both cold-reactive and warm-reactive autoantibodies, indicating a mixed autoimmune hemolytic anemia type. The distinction between cold autoimmune hemolytic anemia and warm autoimmune hemolytic anemia is very important because the mechanisms of RBC injury, the primary site of hemolysis, and the therapeutic approaches are different. Table 146-2 summarizes the main features of the different types of autoimmune hemolytic anemia.

In warm autoimmune hemolytic anemias, which represent 70 to 80% of all autoimmune hemolytic anemias in adults, the direct antiglobulin test pattern is either solely IgG-positive or IgG plus C_3–positive. Autoantibodies are mainly of the IgG_1 isotype, and they bind and react optimally with RBCs at a temperature of 37° C (range, 35 to 40° C). In warm autoimmune hemolytic anemia, the hemolysis is mainly extravascular and occurs predominantly in the spleen. On the other hand, in autoimmune hemolytic anemia, due to cold autoantibodies, which account for 15 to 20% of AIHAs, the usual direct antiglobulin test pattern is IgG-negative and C3-positive, and circulating cold agglutinins are detectable in the serum at a significant titer (i.e., >1/64). Cold antibodies are almost exclusively of IgM isotype, which are able to activate the classical complement pathway but are seldom found fixed on the RBC membrane in vitro as they are rapidly eluted ex vivo before the test can be performed. Cold antibodies typically react with RBCs at temperatures below 30° C (optimum, 4° C) and lead to various degrees of extravascular hemolysis, predominantly in the liver rather than the spleen. In rare cases of AIHAs (~5 to 10%) known as mixed-type AIHAs, autoantibodies (mostly of IgM isotype) can react with RBCs within a wide range of temperature (thermal amplitude from 4 to 37° C). Last, paroxysmal cold hemoglobinuria is a very uncommon AIHA subtype seen almost exclusively in children; it is due to an IgG hemolysin reacting with autologous RBCs at low temperatures (2 to 10° C) that can be detected only by means of the Donath Landsteiner test, a test available only in few referral laboratories. In addition to these four distinct subtypes of AIHAs, drug-induced hemolytic anemias must be regarded as a distinct entity (see Drug-Induced Hemolytic Anemia). Besides the distinction between warm autoimmune hemolytic anemia and cold autoimmune hemolytic anemia; autoimmune hemolytic anemias are also classified as primary (or idiopathic) or secondary, depending on the presence or absence of an underlying disease or condition promoting immune dysregulation. On average, 50 to 60% of warm autoimmune hemolytic anemias are secondary (see Table 146-3 for associated conditions) and, therefore, a minimal workup must be performed at the time of diagnosis in every patient to search for an underlying disease or condition (Table 146-4). It is important to emphasize that a presumably primary form of warm autoimmune hemolytic anemia can precede by many years the finding of a non-Hodgkin lymphoma; therefore, patients with warm autoimmune hemolytic anemia must be followed beyond remission.

Regarding autoimmune hemolytic anemias due to cold autoantibodies, in children and young adults, these are mainly secondary to either bacterial (*M. pneumoniae* infection) or viral (Ebstein-Barr virus or cytomegalovirus) infection, whereas in adults aged over 50, although rare, chronic cold agglutinin disease is by far the main cause of cold autoimmune hemolytic anemia. Although cold agglutinin disease has long been considered as a primary (i.e., idiopathic) form of autoimmune hemolytic anemia, it is now recognized that about 90% of cases of cold agglutinin disease are associated with a monoclonal

TABLE 146-2 MAIN CHARACTERISTICS OF VARIOUS TYPES OF AUTOIMMUNE HEMOLYTIC ANEMIA

AUTOIMMUNE HEMOLYTIC ANEMIA TYPE	EPIDEMIOLOGY/ TYPE OF HEMOLYSIS	RATE OF SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA	AUTOANTIBODY ISOTYPE	OPTIMAL TEMPERATURE	DIRECT ANTIGLOBULIN TEST PATTERN	ELUATE	AUTOANTIBODY SPECIFICITY (TARGETED ANTIGENS)
Warm autoimmune hemolytic anemia	~70-80% of all autoimmune hemolytic anemia Adult > children (mean age 3 years), mostly EV hemolysis, subacute onset (rarely abrupt with associated IV hemolysis)	~50% of the cases (see Table 146-3)	IgG >> IgA, IgM	37° C	IgG ± C_3	IgG	Antigens of the Rh system, band 3, glycophorin, A
Cold agglutinin syndrome	~20-30% of all autoimmune hemolytic anemia cases in adults Age >50 years EV ± IV hemolysis	Mainly secondary monoclonal IgM kappa gammopathy in 90% of the cases ± features of definite clonal B-cell lymphoproliferative disorder	IgM >>> IgA or IgG Cold agglutinins titer >1/500	4° C	C_3	negative	I antigen> i >> Pr
Cold transient autoimmune hemolytic anemia	Children, young adults IV hemolysis	Infections (*Mycoplasma pneumoniae*, Ebstein-Barr virus, etc.)	Polyclonal IgM Cold agglutinins titer ≥1/64	4° C	C_3	negative	I > i antigens
Paroxysmal cold hemoglobinuria	Children (rare), exceptional in adults Acute IV hemolysis	Infections (*Mycoplasma pneumoniae* virus)	IgG (Donath-Landsteiner hemolysin)	>30° C	C_3	negative	P + c antigens (biphasic hemolysins)
Mixed-type autoimmune hemolytic anemia	Adult Mainly EV hemolysis	Mainly B-cell lymphoma	IgG, IgM ± AF ~ 1/500	Wide range (4°-37° C)	IgG ± C_3	IgG	Polyreactivity

EV = extravascular; Ig = immunoglobulin G; IV = intravascular.

TABLE 146-3 MAIN DISORDERS OR CONDITIONS ASSOCIATED WITH WARM AUTOIMMUNE HEMOLYTIC ANEMIA

Hematologic disorders and lymphoproliferative diseases:
- Chronic lymphoid leukemia,* acute lymphoblastic leukemia,† LGL leukemia
- B-cell lymphoma,* Hodgkin lymphoma
- Angioimmunoblastic T-cell lymphoma
- Castleman disease
- Myelodysplasias, myelofibrosis

Solid tumors: thymoma/ovarian dermoid cyst/carcinoma

Autoimmune and inflammatory diseases
- Systemic lupus erythematosus, antiphospholipid syndrome
- Rheumatoid arthritis
- Ulcerative colitis, pernicious anemia/thyroiditis
- Myasthenia gravis
- Autoimmune hepatitis, giant cell hepatitis*
- Sarcoidosis
- Eosinophilic fasciitis

Infections:
- Virus: Epstein-Barr virus,* hepatitis C, cytomegalovirus, SARS-CoV-2
- Bacteria: tuberculosis/brucellosis/syphilis/babesiosis

Drugs

Primary immunodeficiencies
- Common variable immunodeficiency
- Hyper-IgM syndrome,† ALPS†
- CTLA4† or LRBA deficiency†
- IPEX syndrome,† APECED syndrome†

Others
- Pregnancy
- Postallogenic bone marrow transplantation or liver or small bowel transplant*
- Rosai-Dorfman disease

*Diseases that can also be associated with cold autoimmune hemolytic anemia.
†Seen almost exclusively in childhood.
ALPS = autoimmune lymphoproliferative syndrome; APECED = autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; CTLA4 = cytotoxic T lymphocyte–associated protein 4; IgM = immunoglobulin M; IPEX = immune dysregulation, polyendocrinopathy, enteropathy X-linked syndrome; LGL = large granular lymphocytes; LRBA = lipopolysaccharide-responsive and beige-like anchor protein; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.

TABLE 146-4 RECOMMENDED WORKUP IN WARM AUTOIMMUNE HEMOLYTIC ANEMIA

1. Antinuclear antibodies (± anti-DNA antibodies if ANA-positive)
2. Anticardiolipin antibodies and lupus anticoagulant*
3. Serum protein electrophoresis and immunoelectrophoresis
4. Immunophenotyping of peripheral lymphocytes (flow cytometry)
5. CT scan of the chest, abdomen, and pelvis (in the absence of obvious SLE of APS)
6. Bone marrow biopsy: recommended in the presence of hypogammaglobulinemia and/or monoclonal gammopathy and/or abnormal lymphadenopathy on the CT imaging

*Especially in case of a previous episode of venous and/or arterial thrombosis or in case of recurrent miscarriage in women and systematically before splenectomy.
ANA = antinuclear antibodies; APS = antiphospholipid syndrome; CT = computed tomography; SLE = systemic lupus erythematosus.

IgM kappa and with other features of indolent clonal B cell lymphoproliferative disorder. As a result, it must be distinguished from Waldenström macroglobulinemia (Chapter 173) or lymphoplasmacytic lymphoma in the bone marrow (Chapter 171). Hemolytic anemia is seldom very severe in the setting of cold agglutinin disease, and it is classically exacerbated by exposure to cold or infections.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

There are several mechanisms by which a drug can induce hemolytic anemia, and true drug-induced autoimmune hemolytic anemias are rare. Many drugs or drug metabolites have the potential to elicit antidrug antibodies. Drugs that form covalent bonds with proteins in the red cell membrane can bind antidrug antibodies to the red cell surface, thereby causing a positive direct antiglobulin test and, in some cases, initiating antibody-mediated destruction of red cells. Other drugs, such as the cephalosporins, can bind to red cell membranes and take up IgG nonspecifically from plasma. In these cases, there is no antidrug antibody. The diagnosis of drug-induced immune-mediated hemolytic anemia should be considered if the patient has a history of taking a suspected medication, there is acute complement-mediated hemolysis, only complement components are detectable on the red cell surface, or the patient's serum reacts with red cells in the presence of the suspected drug. Some drugs can induce true autoantibodies against red cells. Fludarabine, a purine nucleoside analogue used in the treatment of chronic lymphocytic leukemia, and monoclonal antibodies against tumor necrosis factor-α (infliximab and adalimumab), T cells (alemtuzumab), α4 integrin (natalizumab), and interleukin-2 receptor (daclizumab) also have this property, the cause of which is unknown. Notably, there is no definitive way of distinguishing drug-induced autoimmune hemolytic anemia from primary autoimmune hemolytic anemia. Immune checkpoint inhibitors, mostly anti-PD1 agents but also to a lesser extent anti-PDL1 and anti-CTLA4 monoclonal antibodies, which are currently used worldwide to treat various cancers, have become an important and increasing cause of drug-induced autoimmune hemolytic anemias.

TREATMENT

Supportive Care and Transfusion

Regardless the type of autoimmune hemolytic anemia, folic acid supplementation (5 to 10 mg/day) is warranted in patients with active autoimmune hemolytic anemia and increased erythropoiesis to prevent its depletion, which may be misinterpreted as a treatment failure. RBC transfusions are also indicated in patients with disabling symptoms of anemia and/or a significant underlying cardiovascular disorder (e.g., coronary artery disease or heart failure). Although younger patients may tolerate a stable hemoglobin level as low as 6 g/dL, maintaining a hemoglobin level of at least 8 g/dL is usually recommended in patients with major comorbidities. It is important for the managing physician to understand that no patient with symptomatic autoimmune hemolytic anemia should be denied blood transfusions because of an "incompatible crossmatch." The blood bank should be informed of the patient's status. Indeed, the patient's positive direct antiglobulin test almost always interferes with compatibility testing, so the role of the blood bank is to provide packed red cells that are the least incompatible ones in regard to the specificity of the patient's autoantibody. Close communication and cooperation between the clinician and the specialist in transfusion medicine are therefore essential for reducing the risks associated with transfusion in patients with autoimmune hemolytic anemia. Because transfused RBCs can be destroyed by the patient's autoantibodies, rapid transfusion of large volumes of RBCs must be avoided because they can have serious consequences. This risk is increased if the patient also has alloantibodies induced by previous transfusions or pregnancy. Units of packed RBCs should therefore not be administered at a rate that exceeds 1 mL/kg/hour. In cold autoimmune hemolytic anemia and cold agglutinin disease, prewarmed (at a temperature close to 37° C) packed RBCs are recommended. Plasma exchange is sometimes used for patients with life-threatening autoimmune hemolytic anemia, but there is no robust evidence supporting its efficacy and safety in the literature.

In transfusion-dependent patients with inadequate reticulocytosis, the transient off-label use of an erythropoiesis-stimulating agent by specialists may provide a 70% response rate for increasing the hemoglobin level and avoiding a transfusion.[11] Plasma exchanges can be temporarily helpful in cases of severe hemolysis and/or in preparation for surgery (e.g., cardiac surgery) that requires cold exposure.[12]

Treatment of Transient (Acute) Cold Autoimmune Hemolytic Anemias

In cases of transient cold autoimmune hemolytic anemias induced by an infection, the onset is usually abrupt, and the degree of anemia may be profound and sometimes life-threatening, requiring transfusion of prewarmed packed RBCs, which must not be postponed (Fig. 146-1). In addition to supportive care, the use of antibiotics is justified in case of pneumonia due to *M. pneumoniae*. A short course of corticosteroids can sometimes be considered in case of severe cold autoimmune hemolytic anemia secondary to a viral infection (Epstein-Barr virus) in order to reduce the duration of anemia, but this practice is neither consensual nor evidence-based.

Management of Chronic Cold Agglutinin Disease

The management of cold agglutinin disease has long been only supportive and symptomatic (see Fig. 146-1). Avoidance of exposure to cold is still the mainstay in management of cold agglutinin disease, especially to avoid cold-induced circulatory symptoms, but this measure is often not sufficient to avoid episodes of hemolysis. In cases of infections and other acute phase reactions, the levels of both C3 and C4 increase due to their enhanced production, resulting in exacerbation of complement-dependent cytotoxicity directed toward autologous RBCs and increased hemolysis. Consequently, prompt treatment of febrile infections or other illnesses as well as the prevention of infection by influenza and/or pneumococcal vaccines are strongly recommended in patients

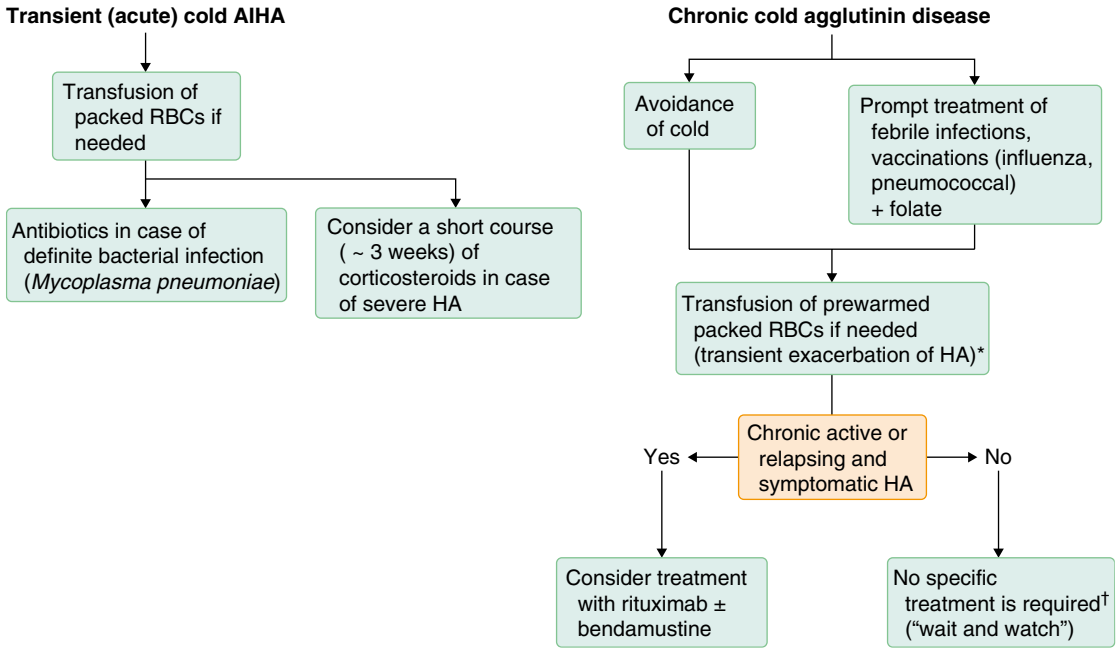

FIGURE 146-1. **Proposed algorithm for the management of cold autoimmune hemolytic anemias (AIHAs). *The transient use of erythropoiesis-stimulating agents can be considered off-label, †unless the underlying B cell–clonal lymphoproliferative disorder requires specific management. HA = hemolytic anemia; RBCs = red blood cells.**

with cold agglutinin disease. In case of exacerbation of hemolysis and severe anemia, transfusion of prewarmed packed RBCs must be considered because patients with cold agglutinin disease are often elderly with significant comorbid conditions. Whereas cold agglutinin disease is usually considered a relatively indolent and slowly progressive lymphoproliferative disorder with a relatively good prognosis, transfusion dependency may be observed in some patients with recurrent episodes of active hemolysis.

For patients with active or relapsing symptomatic episodes of cold hemolytic anemia that warrants treatment, rituximab either alone or in combination with bendamustine[A1] offers the best response rate (up to 75% response), but the toxicity of bendamustine and the increased risk of severe infection is a limitation for frail elderly patients. Another potential option for patients who require transfusions is sutimlimab,[13] which is a selective upstream inhibitor of the classical complement pathway (given at 45 to 60 mg/kg intravenously weekly for 4 weeks, then every 2 weeks).[A2] Some responses also have been reported in smaller studies with bortezomib plus dexamethasone or with ibrutinib.

In transfusion-dependent patients with normal or only slightly elevated reticulocyte counts, the transient use of an erythropoiesis-stimulating agent off-label may be useful as a transfusion-sparing strategy. Plasma exchange can be temporarily helpful in cases of severe hemolysis and/or in preparation for surgery requiring cold exposure such as lung-heart surgery.

Management of Primary Warm Autoimmune Hemolytic Anemias

First-Line Treatment: Corticosteroids

Primary warm autoimmune hemolytic anemias usually have a chronic course, and except for the few patients with mild compensated hemolysis with a normal or almost normal hemoglobin level, treatment is usually needed (Fig. 146-2). In contrast to cold agglutinin disease, corticosteroids are the cornerstone of therapy in warm autoimmune hemolytic anemias and should be given as first-line treatment. Intravenous immunoglobulin (IVIG) has only little efficacy in warm autoimmune hemolytic anemias and should be considered (at 2 g/kg over 2 days) only as potential rescue therapy for severe, transfusion-dependent autoimmune hemolytic anemia in the absence of response to corticosteroids. The corticosteroid regimen is usually based on oral prednisone or prednisolone at an initial daily dose of 1 to 2 mg/kg daily. By analogy with other autoimmune diseases, the use of intravenous methylprednisolone at a dose of 250 to 1000 mg/day for 1 to 3 days may be considered in patients with profound anemia, although no clinical trials supporting its superior efficacy are available. The starting dose of oral prednisone is usually maintained for 3 to 4 weeks and then tapered progressively if at least a partial response is achieved. There is no consensus concerning the total duration of treatment, but because the likelihood of early relapse is high when the treatment is prematurely stopped, corticosteroids should be maintained for at least 3 months after a complete response is achieved (defined by normalization of hemoglobin with no evidence of active hemolysis). Except for children, the use of alternate-day prednisone before stopping the treatment is not recommended. The efficacy of corticosteroids can take a few days to 2 weeks, so blood transfusions may be necessary at autoimmune hemolytic anemia onset, especially in case of severe anemia in young children or elderly adults for maintaining a "safe" hemoglobin level. After 2 to 3 weeks of treatment with corticosteroids, a clinically significant response is observed in 80 to 85% of the cases. Except for the few patients who are truly refractory to corticosteroids, the major issue that clinicians have to deal with when treating patients with warm autoimmune hemolytic anemia is that approximately 50 to 60% of them are found to be dependent on corticosteroids to suppress hemolysis. Thus, flares of relapses of warm autoimmune hemolytic anemia may occur either within weeks after withdrawal of corticosteroids or even on treatment when the dose of daily prednisone is decreased below a threshold, which is usually between 10 to 15 mg daily, a dose that is associated with several long-term adverse effects. Overall, only one third of patients can be considered to be in complete remission off-treatment 1 year after the onset of disease.

Second-Line Treatment

Rituximab

The efficacy of rituximab, the chimeric monoclonal antibody that targets the CD20 antigen on B lymphocytes, was first shown in refractory warm autoimmune hemolytic anemia in children with a response rate reaching up to 100% in some studies. In adults, rituximab was also shown to have significant efficacy in primary warm autoimmune hemolytic anemias in randomized trials, with a 75% overall response rate at 1 year.[A3,A4] The usual dose is 375 mg/m^2 by intravenous infusion once a week for 4 weeks, but other regimens such as fixed doses of 1000 mg 2 weeks apart as in rheumatoid arthritis can be used. Safety is usually good, although late-onset neutropenia and opportunistic infections such as *Pneumocystis jiroveci* pneumonia may rarely occur, so primary prophylaxis (Table 146-4) with trimethoprim-sulfamethoxazole (160 mg/800 mg) three times per week (Chapter 313) is wise when patients with autoimmune hemolytic anemia treated are with rituximab. Taken together, the data from the literature clearly support, whenever possible, the use of rituximab (off-label) as an early second-line treatment and before splenectomy for patients with warm autoimmune hemolytic anemia who have had no or little response to corticosteroids and for elderly patients with comorbidities such as diabetes who are at high risk for developing corticosteroid-induced side effects. When rituximab is administered before splenectomy, vaccination against *Streptococcus pneumoniae, Haemophilus influenzae* type B, and/or *Neisseria meningitidis* should be administered whenever possible 2 weeks before rituximab because splenectomy may be required thereafter (see Chapter 154 for specific recommendations).

Splenectomy

Splenectomy has long been the preferred second-line option for primary warm autoimmune hemolytic anemias. The rate of sustained response after splenectomy is approximately 60 to 70%, but clear predicting factors for response are still lacking. The perioperative risk of laparoscopic splenectomy is low and acceptable, with a mortality rate of less than 1%. The most feared complications, even after the laparoscopic procedure, remain the rare but unpredictable risk of overwhelming sepsis and the risk of postoperative thromboembolic complications, especially in the splanchnic veins. Perioperative low-molecular-weight heparin is therefore recommended in patients who have warm autoimmune hemolytic anemia and who undergo splenectomy and especially in those who also have positive antiphospholipid antibodies. The best time for splenectomy

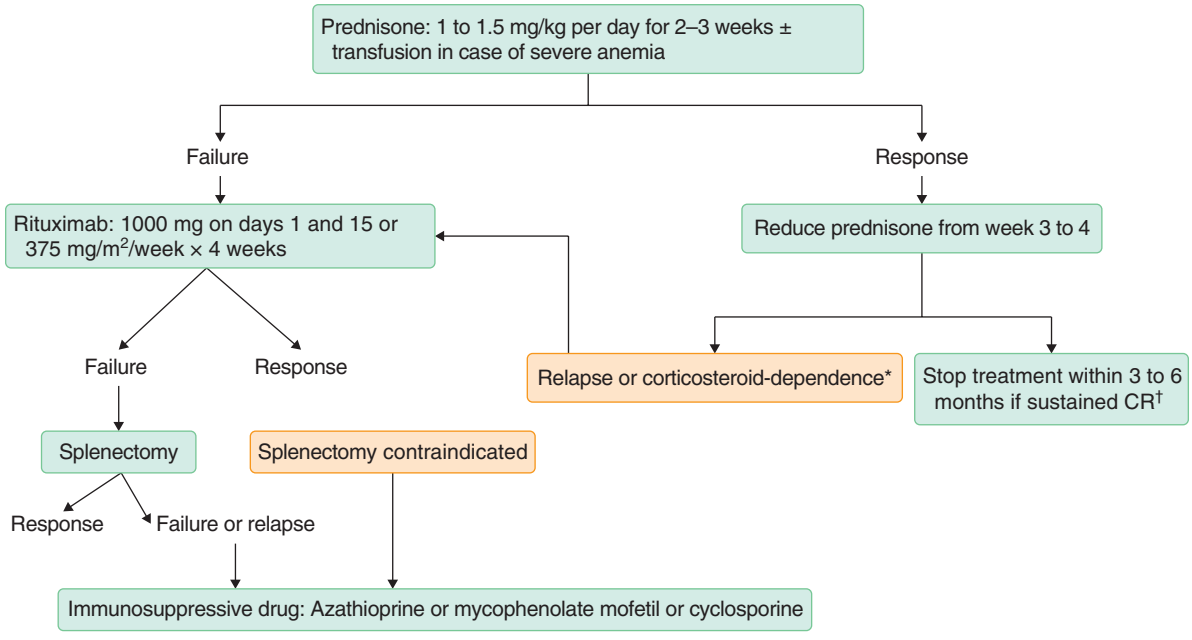

FIGURE 146-2. Proposed algorithm for the treatment of primary warm-reactive autoimmune hemolytic anemia in adults. *Need to maintain daily prednisone at more than 10 mg to maintain at least a partial remission (i.e., hemoglobin level ≥10 g/dL with at least a 2-g increase from baseline). †Complete remission (CR) = hemoglobin level >12 g/dL without hemolysis.

is controversial now that alternatives such as rituximab are available at least in some countries. In children aged less than 5 to 7 years, this procedure should be avoided or delayed as long as possible. In adults, it must be considered early in the course of the disease in patients who have failed to respond to both corticosteroids (or need high and unacceptable doses to maintain at least a partial remission) and rituximab.

Danazol

In patients dependent on corticosteroids, the use of danazol, an attenuated androgen analogue, at 400 to 800 mg/day can be helpful as a corticosteroid-sparing strategy in adults requiring a dose of daily prednisone greater than 15 mg to maintain a remission. However, because of its common androgenic side effects, its use is usually limited in female patients, and its potential liver toxicity makes long-term use difficult also in men.

Other Treatment Lines

Immunosuppressive and Cytotoxic Agents

In patients with refractory warm autoimmune hemolytic anemia in whom splenectomy and rituximab have failed or in patients those who are reluctant to undergo splenectomy or are not suitable candidates for splenectomy, the management is mainly based on experience and mostly retrospective data in the literature, as opposed to controlled, prospective, comparison trials. The efficacy of azathioprine, cyclophosphamide, and to a lesser extent cyclosporine and mycophenolate mofetil has been reported in small case series. The choice depends on the efficacy/safety ratio individualized for each patient. These drugs should be reserved for patients who have failed to respond to rituximab and to splenectomy or are not suitable candidates for splenectomy. For multirefractory patients, promising results have been reported with the combination of bortezomib and dexamethasone under expert supervision.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

DEFINITION

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare and potentially life-threatening clonal blood disorder with protean manifestations caused by an acquired somatic mutation in the phosphatidylinositol glycan (*PIG-A*) gene. In pluripotent hematopoietic stem cells, the mutation in *PIG-A* leads to a deficiency of glycosylphosphatidylinositol (GPI) anchors and GPI-anchored proteins, including the complement regulatory proteins CD55 and CD59 normally expressed on the surface of RBCs. PNH RBCs are therefore highly vulnerable to activation of complement on their surfaces (especially in case of fever, acidosis, or hypoxia) and the formation of the membrane attack complex (Chapter 37). The resulting chronic intravascular hemolysis is the hallmark of the classic hemolytic form of the disease, and the release of free hemoglobin contributes to most of its clinical manifestations (dysphagia, recurrent abdominal pain, erectile dysfunction).

EPIDEMIOLOGY

PNH can occur at any age but is most common between 10 and 50 years. The mean age at diagnosis is about 34 years (median age is about 40), and the female : male ratio is close to 1. Median survival after diagnosis is approximately 20 years. It is a rare disorder with an estimated prevalence in the population of about one per million in the population. There is no sex preference, and a family history of PNH is highly unusual.

PATHOBIOLOGY

PNH is due to a somatic mutation that causes a defect in the red cell membrane. The disease begins in a single hematopoietic stem cell when the *PIG-A* gene on the short arm of the active X chromosome acquires a mutation. The *PIG-A* gene encodes PIG-A, an enzyme that is essential for the synthesis of GPI. The location of *PIG-A* on the X chromosome allows a single mutation in the gene to affect GPI synthesis. This lipid normally forms a peptide link with the C-terminal amino acid of numerous proteins, anchoring them to the red cell membrane. Molecular genetic studies indicate that the PNH clone upregulates genes that make the PNH clone resistant to apoptosis and immune attack. The mutation in a hematopoietic stem cell affects *PIG-A* in blood cells of all lineages. Almost 150 different mutations of *PIG-A* have been identified. Most of them inactivate *PIG-A* and cause total loss of GPI in the descendants of the carrier stem cell. Red cells with complete deficiency of GPI are termed *PNH III erythrocytes*, and those with partial deficiency are called *PNH II erythrocytes*. The coexistence of PNH III and PNH II red cells in the same patient indicates the presence of two mutant clones. A small number of hematopoietic stem cells in normal people bear the *PIG-A* mutation; they have no proliferative advantage and persist in small numbers. In normal blood, the frequency of *PIG-A*–deficient cells is about 1 in 50,000 red cells. In contrast to those with PNH, however, the deficient cells in normal subjects arise from committed hematopoietic cells. The presence of *PIG-A*–deficient cells in normal subjects suggests that PNH involves not only the *PIG-A* mutation but also a second step, perhaps a mutation, that allows expansion of the mutated clone.

Functional Consequences of Deficiency of GPI

The membrane inhibitor of reactive hemolysis (CD59, or protectin) and CD55, an inhibitor of C3 convertase, are two of the many proteins that GPI normally anchors to the red cell. They prevent polymerization of C9, the final step in assembly of the membrane attack complex that begins with cleavage of C5 to C5b. Deficiencies of CD59 and CD55 allow unimpeded assembly of the membrane attack complex on the erythrocyte surface, thereby initiating intravascular hemolysis. A variety of nonspecific factors, such as a reduction in the pH of blood, can activate complement. The morning hemoglobinuria

that occurs in some cases of PNH is probably the result of subtle acidification of blood during sleep.

CLINICAL MANIFESTATIONS

Classically, some patients with PNH arise in the morning and pass dark urine. The typical paroxysms of hemoglobinuria occur on a background of chronic, low-grade intravascular hemolysis that causes constant hemosiderinuria in PNH. About one third of cases evolve into aplastic anemia (Chapter 151). Transformation to acute myelogenous leukemia is a rare event. Abdominal pain, dysphagia, and erectile dysfunction are additional clinical features. The basis of these symptoms is probably scavenging by free plasma hemoglobin of endogenous nitric oxide, a regulator of vasomotor and smooth muscle tone. In about one third of cases, venous thrombosis occurs in unusual sites and can cause intra-abdominal splanchnic vein thrombosis involving the hepatic veins (Budd-Chiari syndrome), the portal veins, or less frequently cerebral vein thrombosis (Chapter 140). Splenomegaly is uncommon; hepatomegaly and ascites point to the complication of intra-abdominal venous thrombosis. Hemosiderinuria is the result of chronic intravascular hemolysis. Subtle or overt signs of bone marrow damage (leukopenia and thrombocytopenia) are frequent. The extent of red cell destruction in PNH depends on the number of PNH red cells in blood, the level of GPI on the red cell membrane (PNH III cells are devoid of GPI), and the surface activation of complement. The anemia is often aggravated by iron deficiency caused by chronic urinary iron loss in the form of hemosiderinuria. A direct antiglobulin test–negative hemolytic anemia associated with iron deficiency should raise the suspicion of PNH. The basis of the tendency to develop venous thrombosis is unclear. Hypercoagulability caused by the release of prothrombotic materials in red cell and platelet membranes (which are also abnormal in PNH) and impaired fibrinolysis have been implicated. Nitric oxide scavenging by free plasma hemoglobin may also damage endothelial cells and cause aggregation of platelets.

DIAGNOSIS

The diagnosis of PNH is suspected in case of an acquired and Coombs-negative intravascular hemolytic anemia and can be established by flow cytometry demonstrating a deficiency of GpI-linked proteins (CD24/CD57 and CD14) on both neutrophils and monocytes, as well as CD59 on RBCs. Another reagent with utility in flow cytometry is aerolysin, a bacterial protein that binds to the GPI anchor. Data strongly suggest that the fluorescent aerolysin variant (FLAER) is the best and most reliable reagent to study GPI-linked antigens on leukocytes, helpful for diagnosing PNH.

The clone size in PNH is usually correlated with the degree of intravascular hemolysis.

TREATMENT

Eculizumab, a humanized monoclonal antibody against C5, reduces the signs of intravascular hemolysis, the requirement for transfusions, and the incidence of thrombosis in PNH.[A5] In PNH, it is usually given at a dose of 600 mg every week for 4 weeks, followed 1 week later by a 900-mg dose, and then at 900 mg every other week.[14,15] Complement blockade is not always complete. Before being treated with eculizumab, every patient should be vaccinated against *Meningococcus A, B,* and *C* and, in many countries, a long-term prophylaxis with oral penicillin is also strongly recommended. Beyond transfusion-dependent hemolytic anemia, the occurrence of disease-related venous thrombosis is also a strong indication for eculizumab in the setting of PNH in combination with anticoagulation. Ravulizumab (given as a single weight-based loading dose of 2400 to 3000 mg followed by 3000 to 3600 mg every 8 weeks starting 2 weeks later) is another complement inhibitor that also binds to C5, has a much longer terminal half-life compared with eculizumab, and can provide equivalent results.[A6,A7] Crovalimab is a subcutaneous C5 inhibitor that may prove useful, especially in patients who are resistant to eculizumab and ravulizumab.[16] Subcutaneous pegcetacoplan (1080 mg subcutaneously twice weekly), which targets complement protein C3 rather than C5, can inhibit extravascular as well as intravascular hemolysis and may provide even better disease control than the C5 inhibitors.[A8] Combined inhibition of both C3 and C5 under expert supervision may become an option in persistent cases.[17] Hematopoietic stem cell transplantation is curative but is reserved for patients who have some pancytopenia that does not respond to complement therapy.

PROGNOSIS

With current therapy, long-term survival is expected. However, progression to bone marrow failure (Chapter 151) is associated with a poorer prognosis.

HEMOLYTIC TRANSFUSION REACTIONS

The cause of hemolytic transfusion reactions (Chapter 162) is intravascular lysis of the donor's red cells by antibodies (alloantibodies or isoantibodies) in the recipient that bind to one or more blood group antigens on the transfused cells. The recipient's isoantibodies can be natural anti-A or anti-B antibodies, or they can be induced by previous transfusions or pregnancy. Whether IgM or IgG, the isoantibodies trigger the assembly of lytic complement components on the surface of the donor's red cells. The rapid formation of large amounts of C3a and C5a fragments causes hypotension and bronchospasm. Renal failure is a consequence of severe, prolonged hypotension; the main renal lesion is renal cortical ischemia secondary to shunting of blood away from the kidneys. Hemoglobin itself is not nephrotoxic. The signs and symptoms of a hemolytic transfusion reaction are nonspecific and include fever, back pain, urticaria, dyspnea, hypotension, and evidence of disseminated intravascular coagulation. These nonspecific signs appear and worsen during administration of the transfusion. Immediate steps must be taken to stop the transfusion, submit the transfused blood and a sample of the patient's blood to the blood bank, and order tests of plasma and urine for free hemoglobin. Hydration is key to prevent renal failure. Intravenous fluid, usually normal saline, should be started at once and be combined with a diuretic (usually furosemide) in amounts needed to sustain a urine flow rate of at least 100 mL/hour. Patients with sickle cell disease (Chapter 149) are at high risk of delayed hemolytic transfusion reaction, a complication that can be life-threatening and require prompt management (Chapter 162).[18]

OTHER CAUSES OF INTRAVASCULAR HEMOLYSIS

Conditions in which vascular abnormalities (e.g., valve hemolysis), toxins (e.g., venomous snake bites), infections (e.g., malaria, babesiosis, clostridial sepsis), or drugs damage RBCs, cause them to lose pieces of membrane, and ultimately fragment into free hemoglobin-releasing particles should be considered in the differential diagnosis of intravascular hemolysis (Tables 146-2 and 146-3). Most of these conditions are readily apparent from the history and physical examination. Treatment focuses on the underlying cause of the hemolysis.

147 HEMOLYTIC ANEMIAS: RED BLOOD CELL MEMBRANE AND METABOLIC DEFECTS

PATRICK G. GALLAGHER

The mature erythrocyte differs from all other cells in the body. Lacking a nucleus, DNA, RNA, and ribosomes, it cannot synthesize RNA, DNA, or protein. It does not divide, it has no mitochondria, it cannot perform the Krebs cycle, and it lacks an electron transport system for oxidative phosphorylation. After enucleation, the reticulocyte, the precursor of the mature erythrocyte, leaves the marrow and enters the circulation equipped with a full complement of enzymes, transporters, signaling molecules, and all other proteins necessary to perform the essential functions of the red blood cell (RBC) during its lifespan.

The erythrocyte membrane accounts for only about 1% of the total weight of an RBC, yet it plays a critical role in the maintenance of normal RBC homeostasis through a number of mechanisms. These include retention of vital compounds and removal of metabolic waste, regulation of erythrocyte metabolism and pH, and import of iron required for hemoglobin (Hb) synthesis during erythropoiesis. The membrane maintains a slippery exterior so that erythrocytes do not aggregate or adhere to endothelial cells. The membrane skeleton, a network of proteins on the inner surface of the RBC, provides the strength and flexibility needed to maintain the normal shape and deformability of the erythrocyte.

The principal functions of erythrocyte metabolism in the mature erythrocyte include maintenance of adequate supplies of adenosine triphosphate (ATP), production of reducing substances to act as antioxidants, and control of oxygen affinity of Hb by production of adequate amounts of 2,3-diphosphoglycerate (2,3-DPG). Because the mature erythrocyte has lost its ability to perform oxidative phosphorylation, its energy is supplied by anaerobic glycolysis though the Embden-Meyerhof pathway, by oxidative glycolysis through the hexose monophosphate shunt, and through nucleotide salvage pathways.

THE ERYTHROCYTE MEMBRANE

NORMAL FUNCTION

Composed of a lipid bilayer and an underlying cortical membrane skeleton (Fig. 147-1), the membrane provides the erythrocyte the deformability and stability required to withstand its travels through the circulation. In one circulatory cycle throughout the body, an erythrocyte is subjected to high shear stress in the arterial system, dramatic size and shape changes in the microcirculation with capillary diameters as small as 7.5 μm, and marked fluctuations in tonicity, pH, and Po_2.[1]

Membrane Lipids

Red blood cell membrane lipids are asymmetrically distributed across the bilayer membrane, reflecting a steady state involving a constant exchange of phospholipids between the two bilayer hemileaflets. Glycolipids and cholesterol are intercalated between the phospholipids in the bilayer with their long axes perpendicular to the bilayer plane. Glycolipids, located in the external half of the bilayer with their carbohydrate moieties extending into the aqueous phase, carry several important RBC antigens and serve other significant functions. Phospholipids are asymmetrically organized; choline phospholipids, phosphatidylcholine, and sphingomyelin are primarily in the outer half of the bilayer, whereas amino phospholipids, phosphatidylethanolamine, and phosphatidylserine (PS) are in the inner half of the bilayer. In pathologic states such as thalassemia, sickle cell disease, and diabetes, loss of phospholipid asymmetry with externalization of PS leads to activation of blood clotting through conversion of prothrombin to thrombin and facilitates macrophage attachment to erythrocytes, marking them for destruction. Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol de novo and depend on lipid exchange and fatty acid acylation as mechanisms for phospholipid repair and renewal.

Membrane Proteins

Membrane proteins are classified as either *integral*, penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or *peripheral*, interacting with integral proteins or lipids at the membrane surface but not penetrating into the bilayer core. Integral membrane proteins include the glycophorins, Rh proteins, Kell and Duffy antigens, and transport proteins such as band 3 (AE1, anion exchanger 1, SLC4A1), Na^+,K^+-ATPase, Ca^{2+}-ATPase, and Mg^{2+}-ATPase. Numerous membrane receptors and antigens are present on integral membrane proteins. Peripheral membrane proteins are on the cytoplasmic membrane face and include enzymes such as glyceraldehyde-3-phosphate dehydrogenase and the structural proteins of the spectrin-actin–based membrane skeleton.

Integral Membrane Proteins

Band 3, the major integral protein of the RBC, has two primary functions: ion transport and maintenance of protein–protein interactions. Band 3 mediates chloride–bicarbonate exchange and provides a binding site for glycolytic enzymes, Hb, and the skeletal proteins ankyrin, protein 4.1, and protein 4.2.

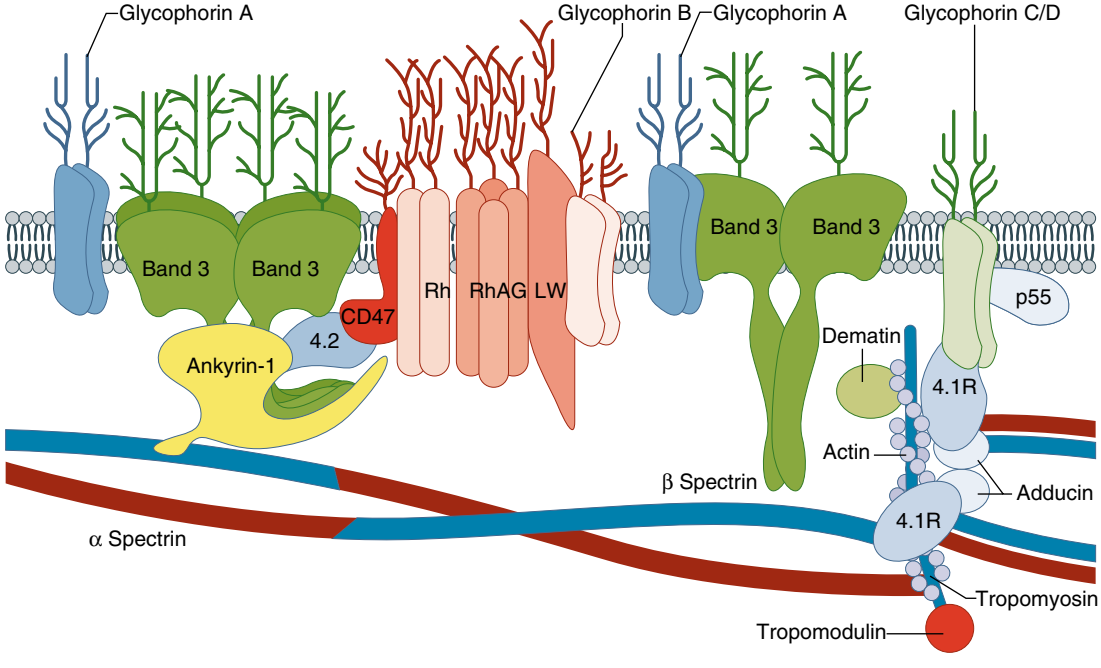

FIGURE 147-1. The erythrocyte membrane. A model of the major proteins of the erythrocyte membrane is shown: α and β spectrin, ankyrin, band 3 (the anion exchanger), 4.1 (protein 4.1) and 4.2 (protein 4.2), actin, and glycophorin. LW = Landsteiner Wiener glycoprotein; Rh = Rhesus polypeptide; RhAG = Rh-associated glycoprotein. (From Perrotta S, Gallagher PG, Mohandas N. Hereditary spherocytosis. *Lancet*. 2008;372:1411-1426.)

ABSTRACT

Disorders of the erythrocyte membrane and erythrocyte metabolism comprise an important group of inherited hemolytic anemias. Abnormalities of proteins of the membrane and its underlying cytoskeleton compromise the strength and flexibility of the erythrocyte needed to maintain the normal shape and deformability needed to survive its travels through the circulation. Qualitative and quantitative membrane protein defects lead to various abnormalities of erythrocyte shape associated with varying degrees of hemolysis. In many cases, red blood cell shape abnormalities provide a clue to the pathobiology and diagnosis of the underlying disorder. Disorders of erythrocyte volume homeostasis associated with abnormalities in membrane proteins are now beginning to be understood. Abnormalities of metabolism are particularly crippling to the erythrocyte, because without a nucleus or mitochondria, the cell is left to depend on the array of proteins available after enucleation to maintain its metabolic functions. These include maintaining adequate supplies of energy via production of ATP, producing reducing substances to allow antioxidant production and activity, and controlling oxygen affinity of hemoglobin. Clinical, laboratory, and genetic manifestations of metabolic disorders of the erythrocyte are heterogeneous.

KEYWORDS

membrane
metabolism
spherocytosis
elliptocytosis
pyropoikilocytosis
stomatocytosis

A single *N*-glycan chain attached to an asparagine in the membrane spanning domain of band 3 is composed of *N*-acetyl-d-lactosamine units arranged in an unbranched, linear fashion in fetal erythrocytes (i antigen) and in a branched fashion in adult cells (I antigen).

The glycophorins are the next most abundant family of integral membrane proteins. They provide most of the negative surface charge required by RBCs to avoid sticking to each other and to the vascular wall. They are involved in transmembrane signaling and carry receptors for *Plasmodium falciparum*, a number of viruses and bacteria, and several blood group antigens.

Peripheral Membrane Proteins

Spectrin is the major component of the membrane skeleton. It is composed of two subunits, α and β spectrin, that are structurally related but functionally distinct. Spectrin is highly flexible and assumes a variety of conformations, an unusual property that may be critical for normal membrane pliancy. The spectrin-based membrane skeleton is linked to the plasma membrane through the actin–protein 4.1 junctional complex; through spectrin–ankyrin interactions; and through binding of a multiprotein complex containing Rh proteins, Rh-associated glycoproteins, CD47, LW, glycophorin B, and protein 4.2 to ankyrin. Protein 4.1, a protein necessary for normal membrane stability, interacts with spectrin, actin, and other proteins of the RBC membrane. Ankyrin serves as the primary linkage protein for the high-affinity binding of spectrin to the inner membrane through interactions with the cytoplasmic domain of band 3. Protein 4.2 is a peripheral membrane protein that helps link the skeleton to the lipid bilayer through interactions with ankyrin and band 3.

Erythrocyte membrane disorders result from alterations in the quantity or quality (or both) of individual proteins and their dynamic interactions with each other. Disruption of the vertical protein–protein interactions of the membrane, that is, the spectrin-ankyrin–band 3 linkage or the band 3–protein 4.2 interaction, leads to uncoupling of the membrane skeleton from the lipid bilayer. This leads to membrane instability with loss of lipids and some integral membrane proteins, resulting in loss of membrane surface area and the phenotype of spherocytosis. Disruption of the horizontal interactions of membrane skeleton proteins, including perturbation of spectrin self-association or junctional complex protein–protein interactions, leads to membrane instability, altered membrane deformability and mechanical properties, and the phenotype of elliptocytosis.

Erythrocyte membrane disorders also result from abnormal cation permeability or disturbed erythrocyte hydration (see later section on "Hereditary Stomatocytosis Syndromes.")

DISORDERS OF THE ERYTHROCYTE MEMBRANE

Hemolytic anemias caused by defects in the erythrocyte membrane comprise an important group of hereditary anemias. Hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis are the most common disorders among this group.[2] Detailed clinical studies carried out years ago have now been complemented by biochemical and genetic studies, providing a better understanding of the pathogenesis of these disorders as well as the normal biology of the erythrocyte membrane.

HEREDITARY SPHEROCYTOSIS

DEFINITION

Hereditary spherocytosis is a group of disorders characterized by spherical erythrocytes on the peripheral blood smear (Fig. 147-2A). Clinical, laboratory, and genetic heterogeneity characterize this group of disorders.

EPIDEMIOLOGY

Hereditary spherocytosis affects approximately one in 2000 to 4000 individuals of northern European ancestry.[3] Found worldwide, it is much more common in Whites than individuals of African ancestry.

PATHOBIOLOGY

The primary defect in hereditary spherocytosis is the loss of erythrocyte membrane surface area caused by defects in erythrocyte membrane proteins,

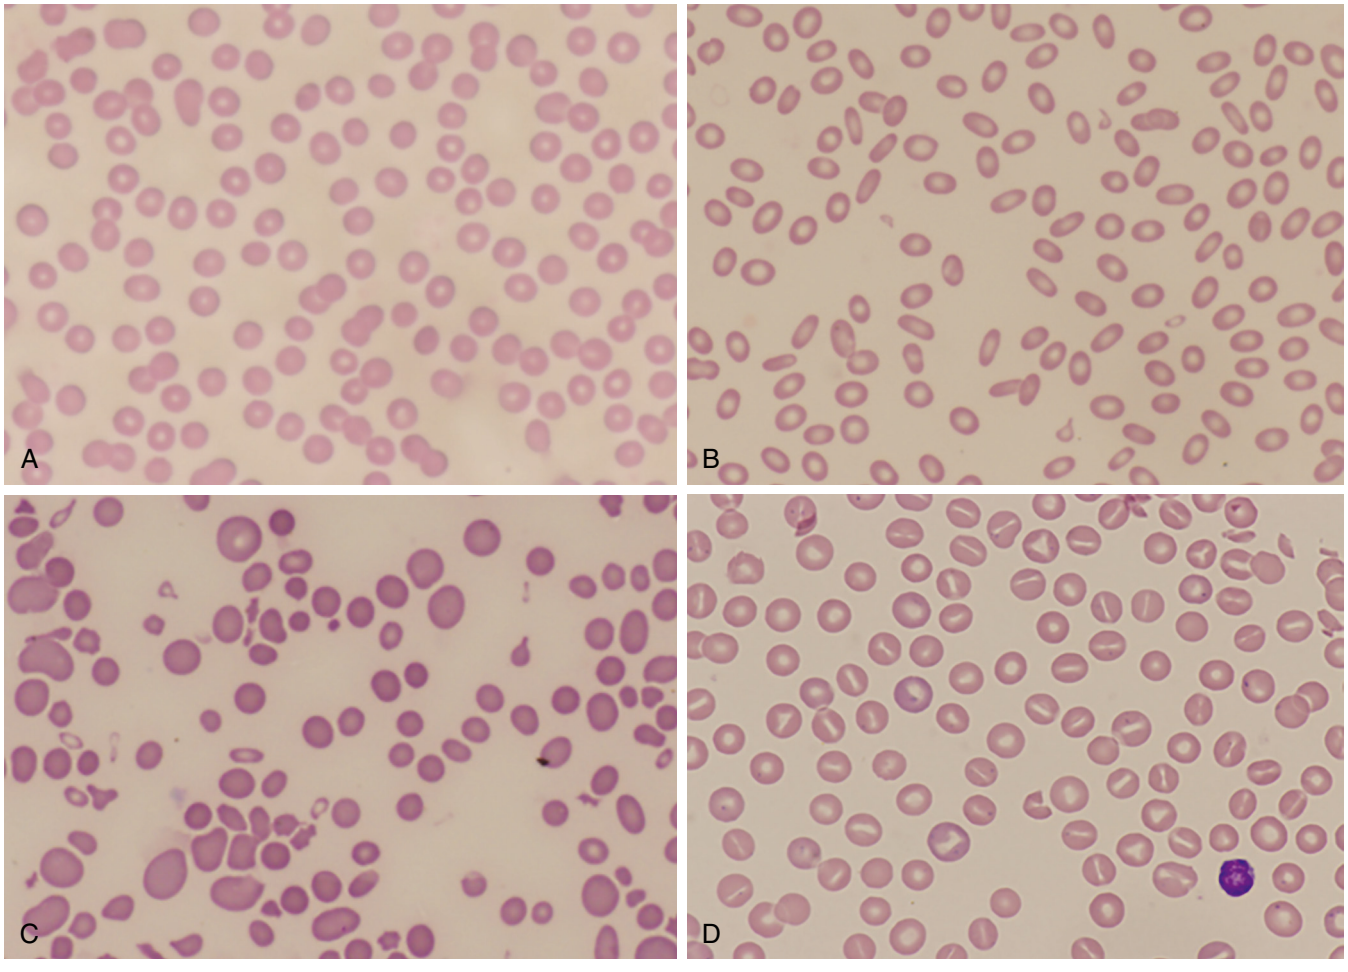

FIGURE 147-2. Peripheral blood smears in disorders of erythrocyte shape. A, Hereditary spherocytosis. Characteristic small spherocytes lacking central pallor are seen. **B,** Hereditary elliptocytosis. Smooth, cigar-shaped elliptocytes are seen. **C,** Hereditary pyropoikilocytosis. Pronounced microcytosis, poikilocytosis, fragmentation of erythrocytes, and elliptocytes are seen. **D,** Hereditary stomatocytosis.

including α spectrin, β spectrin, ankyrin, band 3, and protein 4.2. Qualitative or quantitative defects of one or more of these membrane proteins lead to membrane instability, which, in turn, leads to membrane loss. In approximately two thirds of hereditary spherocytosis patients, inheritance is autosomal dominant. In the remaining patients, inheritance is nondominant owing to either a de novo mutation or autosomal recessive inheritance. Cases with autosomal recessive inheritance are caused by defects in either α spectrin or protein 4.2. Rare cases of homozygous hereditary spherocytosis have been reported, resulting in fetal death or severe hemolytic anemia. In most cases, hereditary spherocytosis mutations are "private," that is, each individual has a unique mutation, implying that there is no selective evolutionary advantage to hereditary spherocytosis.

The spleen plays a critical, albeit secondary, role in the pathophysiology of hereditary spherocytosis. Splenic destruction of poorly deformable spherocytes is the primary cause of hemolysis experienced by hereditary spherocytosis patients. Abnormal erythrocytes are trapped in the splenic microcirculation and ingested by phagocytes. Moreover, the splenic environment is hostile to erythrocytes, with low pH, low glucose, and low ATP concentrations and high local concentrations of toxic free radicals produced by adjacent phagocytes, all contributing to membrane damage.

CLINICAL MANIFESTATIONS

The clinical manifestations of the spherocytosis syndromes vary widely[4] and are determined by the density and deformability of the abnormal red cells.[5] The classic triad of hereditary spherocytosis is anemia, jaundice, and splenomegaly. Rarely, patients may have severe hemolytic anemia presenting in utero or shortly after birth and continuing through the first year of life. These patients may require multiple blood transfusions, and in some cases, splenectomy in infancy. Many patients with hereditary spherocytosis escape detection throughout childhood. In these patients, the diagnosis of hereditary spherocytosis is not made until they are being evaluated for unrelated disorders later in life or when complications related to anemia or chronic hemolysis occur. Although the lifespan of an erythrocyte in these patients may be shortened to only 20 to 30 days, they adequately compensate for their hemolysis with increased bone marrow erythropoiesis.

Chronic hemolysis leads to the formation of bilirubinate gallstones (Chapter 141), the most frequently reported complication in patients with hereditary spherocytosis. Although gallstones have been observed in early childhood, most appear in adolescents and young adults.

Other complications of hereditary spherocytosis include aplastic, hemolytic, and megaloblastic crises. Aplastic crises occur after virally-induced bone marrow suppression and present with anemia, jaundice, fever, and vomiting. The most common etiologic agent in these cases is parvovirus B19 (Chapter 342). Hemolytic crises, usually associated with viral illnesses and occurring before 6 years of age, are generally mild and present with jaundice, increased spleen size, and a decrease in hematocrit. Megaloblastic crises occur in hereditary spherocytosis patients with increased folate demands, such as the pregnant patient, growing children, or patients recovering from an aplastic crisis.

Uncommon manifestations of hereditary spherocytosis include skin ulceration, gout, chronic leg dermatitis, cardiomyopathy, spinal cord dysfunction, movement disorders, and extramedullary erythropoiesis. In patients with untreated severe hereditary spherocytosis, poor growth and findings attributable to extramedullary hematopoiesis, such as hand and skull deformities, may be observed.

DIAGNOSIS

Patients with hereditary spherocytosis may present at any age, usually with anemia, hyperbilirubinemia, or an abnormal blood smear. In evaluating a patient with suspected hereditary spherocytosis, particular attention should be paid to the family history, including questions about anemia, jaundice, gallstones, and splenectomy. The initial laboratory investigation should include a complete blood count with a peripheral smear, reticulocyte count, direct antiglobulin test (Coombs test), and serum bilirubin. When the peripheral smear or family history is suggestive of hereditary spherocytosis, flow cytometric analysis of eosin-5-maleimide–labelled erythrocytes (EMA binding) or an incubated osmotic fragility test (discussed later) should be obtained. Rarely, additional, specialized testing is required to confirm the diagnosis.

Overall, laboratory findings in hereditary spherocytosis are heterogeneous. Erythrocyte morphology (Chapter 143) is distinctive but not diagnostic (Fig. 147-2A). Typical hereditary spherocytosis patients have blood smears with easily identifiable spherocytes lacking central pallor. Some patients present with only a few spherocytes on peripheral smear, but others present with numerous small, dense spherocytes and bizarre erythrocyte morphology. Specific morphologic findings have been identified in patients with certain membrane protein defects such as pincered erythrocytes (band 3) or spherocytic acanthocytes (β spectrin). When examining a peripheral blood smear in a case of suspected spherocytosis, it is important to have a high-quality smear with the erythrocytes well separated and some cells with central pallor in the field of examination because spherocytes are a common artifact on peripheral blood smears. Other disorders with spherocytes on peripheral blood smear are listed in Table 147-1.

TABLE 147-1 DISORDERS WITH SPHEROCYTES ON PERIPHERAL BLOOD FILM

Autoimmune hemolytic anemia
Thermal injuries
Microangiopathic and macroangiopathic hemolytic anemias
Hepatic disease
Clostridial septicemia
Transfusion reactions with hemolysis
Poisoning with certain snake, spider, and *Hymenoptera* venoms
Severe hypophosphatemia
Heinz body anemias
ABO incompatibility (neonates)

The mean corpuscular hemoglobin concentration (MCHC) is increased (between 34.5 and 38) in patients with hereditary spherocytosis owing to relative cellular dehydration. The mean corpuscular volume (MCV) is usually normal or slightly decreased. Many cell counters provide a histogram of MCHCs claimed to be accurate enough to identify nearly all patients with hereditary spherocytosis.

In a normal erythrocyte, a redundancy of cell membrane gives the cell its characteristic discoid shape and provides it abundant surface area. In spherocytes, there is a decrease in surface area relative to cell volume, resulting in their abnormal shape. This change is reflected in the increased osmotic fragility found in these cells. Osmotic fragility is tested by adding increasingly hypotonic concentrations of saline to RBCs. Normal erythrocytes are able to increase their volume by swelling, but spherocytes, which are already at maximal volume for surface area, burst at higher saline concentrations than normal. Approximately one fourth of hereditary spherocytosis individuals will have a normal osmotic fragility on freshly drawn RBCs, with the osmotic fragility curve approximating the number of spherocytes seen on peripheral smear. However, after incubation at 37° C for 24 hours, hereditary spherocytosis RBCs lose membrane surface area more readily than normal because their membranes have become leaky and unstable. Thus, incubation accentuates the defect in hereditary spherocytosis erythrocytes and brings out the defect on osmotic fragility, making incubated osmotic fragility the standard test in diagnosing hereditary spherocytosis (Fig. 147-3, *bottom panel*). When the spleen is present, a subpopulation of very fragile erythrocytes that have been conditioned by the spleen form the tail of the osmotic fragility curve. This tail disappears after splenectomy. The osmotic fragility test suffers from poor sensitivity, with as many as 20% of mild cases of hereditary spherocytosis missed after incubation. It is unreliable in patients who have small numbers of spherocytes and in patients who have been recently transfused. It is abnormal in other conditions in which spherocytes are present.

Eosin-5-maleimide (EMA) binding is a flow cytometry–based test used in the diagnosis of hereditary spherocytosis.[6] EMA is a fluorescent dye that binds to band 3 and Rh-related proteins in the erythrocyte membrane. In hereditary spherocytosis, the mean fluorescence of EMA-stained erythrocytes is lower compared with control because of the reduction of band 3 and related proteins, typically decreased to approximately 65% of normal (Fig. 147-3, *top panel*). Although primary defects of band 3 protein are seen in only about 25% of hereditary spherocytosis patients, decreased fluorescence intensity is also observed in the erythrocyte membranes of hereditary spherocytosis patients with defects in other membrane proteins such as ankyrin and spectrin. This is thought to be attributable to transmission of long-range effects of mutant protein defects across the membrane lattice, ultimately influencing the amount of EMA binding to band 3. EMA binding has good sensitivity and specificity and is simple and rapidly performed.[7]

Specialized testing is available for studying difficult cases or cases in which additional information is desired. Useful tests for these purposes include structural and functional studies of erythrocyte membrane proteins, such as protein

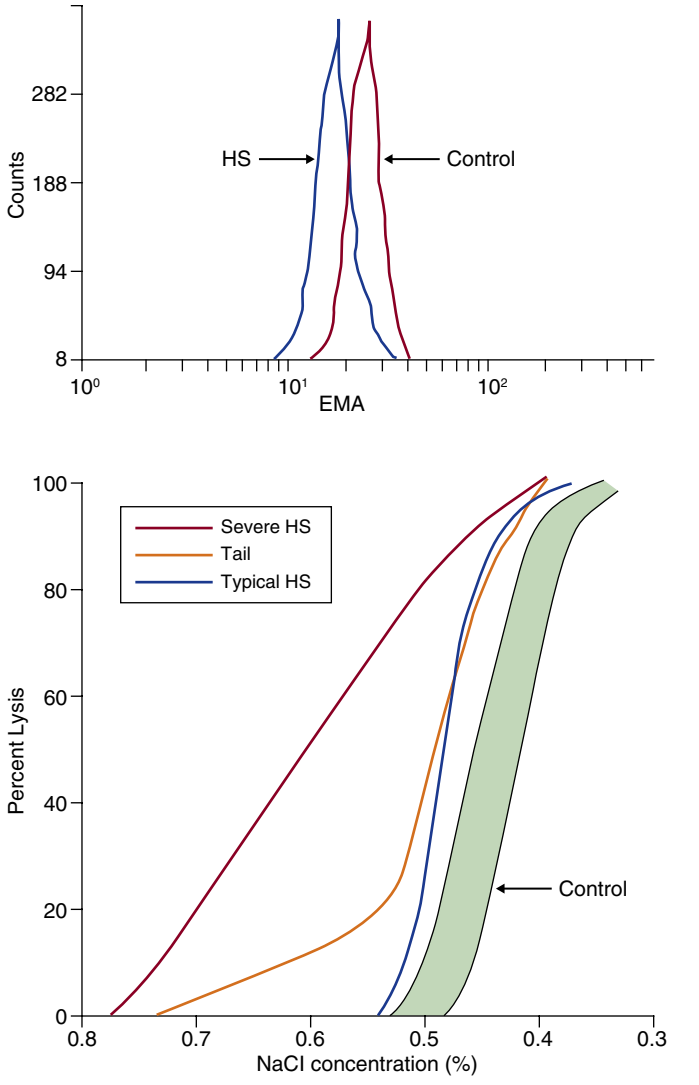

FIGURE 147-3. Testing in hereditary spherocytosis. *Top panel*, Eosin-5-maleimide (EMA) binding. Histogram of fluorescence of EMA-labeled erythrocytes from a normal control and a patient with typical hereditary spherocytosis. Decreased fluorescence is observed from hereditary spherocytosis (HS) erythrocytes. *Bottom panel*, Osmotic fragility curves in hereditary spherocytosis. The *shaded region* is the normal range. Results representative of both typical and severe spherocytosis are shown. A tail, representing fragile erythrocytes conditioned by the spleen, is common in spherocytosis patients prior to splenectomy. (From Gallagher PG. Abnormalities of the erythrocyte membrane. *Pediatr Clin North Am* 2013;60:1349-1352.)

quantitation, limited tryptic digestion of spectrin, spectrin, and ion transport. Membrane deformability may be examined using an ektacytometer.

Genetic diagnosis of hereditary spherocytosis has become widely available and the associated costs continue to decrease. The precise role of molecular diagnosis is evolving. Next-generation sequencing panels could become a cost-effective approach to molecular diagnosis of hereditary hemolytic anemia, especially when the family history is uninformative or when routine laboratory testing fails to identify the causative hemolytic process.[8] In difficult cases, such as when there is transfusion dependence, genetic testing may be diagnostic. Some experts recommend genetic testing to verify the diagnosis prior to splenectomy.

Other laboratory manifestations in hereditary spherocytosis are manifestations of ongoing hemolysis. Increased serum bilirubin, increased lactate dehydrogenase, increased urinary and fecal urobilinogen, and decreased serum haptoglobin reflect increased erythrocyte destruction. Because of the high risk for gallstones, routine interval ultrasonography to detect gallstones is recommended even if patients are asymptomatic.

After diagnosing a patient with hereditary spherocytosis, family members should be examined for presence of the disease. This can be of great epidemiologic importance, particularly for very old and very young patients. Prenatal diagnosis of hereditary spherocytosis has been made in a few cases, but this is rarely necessary.

TREATMENT AND PROGNOSIS

Splenic sequestration and destruction is the primary determinant of erythrocyte survival in hereditary spherocytosis patients. Splenectomy cures or alleviates anemia in most patients, reducing or eliminating the need for transfusions. The risk for cholelithiasis is also decreased to nearly background levels. After splenectomy, spherocytes remain in the peripheral blood, but their lifespan becomes near normal.

In the past, splenectomy was routinely performed in all patients with hereditary spherocytosis.[9] However, the risk of overwhelming post-splenectomy infection; the emergence of penicillin-resistant pneumococci; and the growing recognition of the increased risk of post-splenectomy cardiovascular disease (particularly thrombosis, pulmonary hypertension, and increased risk of atherosclerosis) have led to reevaluation of the role of splenectomy in the treatment of hereditary spherocytosis (Chapter 154).[10,11] In addition, with growing globalization, the important role of the spleen in protection of individuals living in or traveling to geographic regions where parasitic diseases such as malaria or babesiosis occur have reemerged. When splenectomy is considered, health care providers, the patient, and family members must review and weigh the benefits of splenectomy against the immediate and long-term risks of the procedure. Considering the risks and benefits, a reasonable approach is to splenectomize all patients with severe spherocytosis and all patients who have significant signs or symptoms of anemia, including growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors. Other candidates for splenectomy are older patients who have hereditary spherocytosis and also have vascular compromise of vital organs. Whether patients with moderate hereditary spherocytosis and compensated, asymptomatic anemia should undergo splenectomy is controversial.

When splenectomy is indicated, laparoscopic splenectomy has become the method of choice. This technique results in less postoperative discomfort, a quicker return to preoperative diet and activities, shorter hospitalization, decreased costs, and smaller scars. Even massive spleens can be removed laparoscopically because the spleen is placed in a large bag, diced intraoperatively, and eliminated through suction catheters. Partial splenectomy was initially advocated for infants and young children with significant anemia associated with erythrocyte membrane disorders to allow for palliation of hemolysis and anemia while maintaining some residual splenic immune function. This procedure is now being suggested by some for most hereditary spherocytosis patients.[12] Guidelines, which reflect changes in current opinion about surgical management, include (1) preference for a laparoscopic approach, (2) performance of splenectomy ideally after the age of 6 years, (3) no indication for extended thrombosis prophylaxis after splenectomy for hereditary spherocytosis, and (4) avoidance of splenectomy in patients with some forms of hereditary stomatocytosis because of an increased risk of venous thromboembolism.

Before splenectomy (Chapter 154), patients should be immunized with vaccines against pneumococcus, *Haemophilus influenzae* type B, and meningococcus. Post-splenectomy care includes counseling of patients (or parents) to seek prompt medical care in case of febrile illness, to seek medical care after dog or cat bites, and to receive prophylaxis if traveling to malaria-endemic areas. Use of routine antibiotics after splenectomy for prevention of pneumococcal sepsis is controversial and data are lacking to indicate or refute their prescription. Many providers prescribe daily oral penicillin prophylaxis, 250 to 500 mg twice a day, for 2 or more years post-splenectomy. Before splenectomy and post-splenectomy if hemolysis does not abate, hereditary spherocytosis patients should take folic acid (1 mg/day orally) to prevent folate deficiency.

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

DEFINITION

Hereditary elliptocytosis is characterized by the presence of elliptical or oval cigar-shaped erythrocytes on peripheral blood smears of affected individuals (see Fig. 147-2B).

EPIDEMIOLOGY

Hereditary elliptocytosis has been estimated to occur in approximately one in 2000 to 4000 individuals. The true incidence of hereditary elliptocytosis is unknown because its clinical severity is heterogeneous, and many patients are asymptomatic. It is common in African Americans and people of Mediterranean ancestry, presumably because elliptocytes confer some resistance to malaria. In parts of Africa, the incidence of hereditary elliptocytosis approaches one in 100.

PATHOBIOLOGY

The principal defect in hereditary elliptocytosis is mechanical weakness or fragility of the erythrocyte membrane skeleton. Qualitative and quantitative defects in a number of RBC membrane proteins have been described in hereditary elliptocytosis, including α spectrin, β spectrin, protein 4.1, and glycophorin C. Most defects occur in spectrin, the principal structural protein of the erythrocyte membrane skeleton. αβ Spectrin heterodimers self-associate

into tetramers and higher order oligomers that are critical for erythrocyte membrane stability as well as erythrocyte shape and function. Most spectrin defects in hereditary elliptocytosis impair the ability of spectrin dimers to self-associate into tetramers and oligomers, thereby disrupting the membrane skeleton. Structural and functional defects of protein 4.1 appear to disrupt the spectrin–actin contact in the membrane skeleton. Glycophorin C variants are also deficient in protein 4.1. The precise pathobiology of how elliptocytes are formed in these syndromes is unclear.

Genetically, hereditary elliptocytosis is heterogeneous with multiple genetic loci. A wide variety of mutations have been described in the α spectrin, β spectrin, protein 4.1, and glycophorin C genes, including point mutations, gene deletions and insertions, and messenger RNA processing defects. Several mutations have been identified in a number of individuals of the same genetic background, suggesting a "founder effect" for these mutants, which supports the hypothesis that there has been genetic selection for elliptocytosis because these RBCs confer some resistance to malaria. Most cases of hereditary elliptocytosis are inherited in an autosomal dominant pattern, with rare cases of de novo mutations.

CLINICAL MANIFESTATIONS

The clinical presentation of hereditary elliptocytosis is heterogeneous, ranging from asymptomatic carriers to patients with severe, life-threatening anemia. Most patients with hereditary elliptocytosis are asymptomatic and are diagnosed incidentally during testing for unrelated conditions. Asymptomatic carriers have been identified who possess the same molecular defect as an affected hereditary elliptocytosis relative but who have normal peripheral blood smears. The erythrocyte lifespan is decreased in only about 10% of patients. This subset of patients with hereditary elliptocytosis and decreased erythrocyte lifespan experience hemolysis, anemia, splenomegaly, and intermittent jaundice. Many of these patients have parents with typical hereditary elliptocytosis and thus are homozygotes or compound heterozygotes for defects inherited from each of the parents. Symptoms may vary among members of the same family; indeed, they may vary in the same individual at different times.

HEREDITARY PYROPOIKILOCYTOSIS

Hereditary pyropoikilocytosis is a rare cause of anemia with distinctive erythrocyte morphology on peripheral blood smear (see Fig. 147-2C) and has a picture similar to that seen in patients with severe burns. Patients typically present in infancy with severe anemia and peripheral blood smear findings of elliptocytosis, poikilocytosis, pyknocytosis, and fragmentation. Microspherocytosis is common, and the MCV is usually very low (50 to 70 fL). Most patients are of African ancestry. At least one third of hereditary pyropoikilocytosis patients have a parent or sibling with typical hereditary elliptocytosis, as they share common mutations in the self-association site of spectrin. Patients with hereditary pyropoikilocytosis tend to experience severe hemolysis and anemia in infancy that gradually improves, evolving toward typical hereditary elliptocytosis later in life.

DIAGNOSIS

Cigar-shaped elliptocytes on peripheral blood smear are the hallmark of hereditary elliptocytosis (see Fig. 147-2B). These normochromic, normocytic elliptocytes vary in number from a few to 100%. The likelihood of hemolysis does not correlate with the number of elliptocytes present. Ovalocytes, spherocytes, stomatocytes, and fragmented cells may also be seen. In some cases, pyknocytes may be prominent. Elliptocytes may be seen in association with other disorders, including megaloblastic anemias, hypochromic microcytic anemias (iron deficiency anemia and thalassemia), myelodysplastic syndromes, and myelofibrosis; however, elliptocytes generally make up fewer than one third of RBCs in these conditions. History and additional laboratory testing usually clarify the diagnosis of these disorders. In typical cases, the incubated osmotic fragility is normal, but in severe hereditary elliptocytosis and hereditary pyropoikilocytosis, incubated osmotic fragility is increased, and EMA binding is decreased.

Other laboratory findings in hereditary elliptocytosis are similar to those found in other hemolytic anemias and are nonspecific markers of increased erythrocyte production and destruction. The reticulocyte count generally is less than 5% but may be higher when hemolysis is severe.

Similar to hereditary spherocytosis, specialized laboratory procedures are available to study the erythrocyte membranes of hereditary elliptocytosis and hereditary pyropoikilocytosis patients. These studies are not routinely required to make the diagnosis of hereditary elliptocytosis or hereditary pyropoikilocytosis, but they may be helpful in studying problematic cases and in elucidating the underlying molecular defects.

TREATMENT

Therapy is rarely needed in patients with hereditary elliptocytosis. In rare cases, occasional RBC transfusions may be required. In cases of severe hereditary elliptocytosis and hereditary pyropoikilocytosis, splenectomy has been palliative because the spleen is the site of erythrocyte sequestration and destruction. Many practitioners think that the same indications for splenectomy in hereditary spherocytosis should be applied to patients with symptomatic hereditary elliptocytosis or hereditary pyropoikilocytosis. Post-splenectomy patients with hereditary elliptocytosis or hereditary pyropoikilocytosis experience increased hematocrits, decreased reticulocyte counts, and improvement in clinical symptoms. Similar post-splenectomy guidelines as outlined for hereditary spherocytosis should be followed.

Patients should be followed for signs of decompensation during acute illnesses. Interval ultrasonography to detect gallstones should be performed. In patients with significant hemolysis, folate (1 mg/day orally) should be administered daily.

HEREDITARY STOMATOCYTOSIS SYNDROMES

Red blood cell hydration is primarily determined by the intracellular concentration of monovalent cations. A net increase in sodium and potassium ions causes water to enter, forming *stomatocytes* (see Fig. 147-2D) or *hydrocytes*, but a net loss of sodium and potassium produces dehydrated RBCs, or *xerocytes*. Numerous descriptions of congenital or familial hemolytic anemias associated with abnormal cation permeability and, in some cases, disturbed RBC hydration have been reported.[13] These span the range from severe hydrocytosis to severe xerocytosis. In many cases, the molecular bases of this group of disorders are unknown. An unusual characteristic of the stomatocytosis syndromes is a predisposition to thrombosis after splenectomy. Acquired stomatocytosis has been associated with acute alcoholism and hepatobiliary disease, vinca alkaloid administration, neoplasms, and cardiovascular disease. Stomatocytosis is also sometimes observed as a processing artifact.

Overhydrated Hereditary Stomatocytosis (Hydrocytosis)

This group of disorders is characterized by stomatocytes, erythrocytes with a mouth-shaped (stoma) area of central pallor on peripheral blood smear (see Fig. 147-2D), severe hemolysis, macrocytosis (110-150 fL), elevated erythrocyte sodium concentration, reduced potassium concentration, and increased total Na^+ and K^+ content. The excess cations expand cell water, producing large, osmotically fragile cells with low MCHCs (24 to 30%). The clinical severity of overhydrated hereditary stomatocytosis is variable; some patients experience hemolysis and anemia, but others are asymptomatic. Missense mutations in the Rh-associated glycoprotein (*RHAG*) and in band 3 (*SLC4A1*) have been identified in discrete subsets of hydrocytosis patients.

Dehydrated Hereditary Stomatocytosis (Xerocytosis)

Blood smears from patients with dehydrated hereditary stomatocytosis exhibit contracted and spiculated RBCs, dessicytes, a variable number of stomatocytes, and target cells. Most patients have nearly normal erythrocyte morphology, with only a few target cells and an occasional echinocyte or stomatocyte. The MCV (95-115 fL) and MCHC are increased, and the osmotic fragility is reduced (i.e., resistance to osmotic lysis). The characteristic biochemical abnormality is a decreased potassium concentration and total monovalent cation content. Dominantly inherited mutations in PIEZO1 are found in most xerocytosis patients. PIEZO proteins are the recently identified pore-forming subunits of channels that mediate mechanotransduction in mammalian cells. In erythrocytes, PIEZO1 carries the Er blood group antigens.[14] Association of PIEZO variants with changes in erythrocyte hydration suggest that these proteins play an important role in erythrocyte volume homeostasis. A few hereditary xerocytosis patients have been found to have mutations in the Gardos channel, encoded by *KCNN4*, important in the pathogenesis of erythrocyte dehydration in sickle cell disease.

Intermediate Syndromes and Hereditary Stomatocytosis Variants

Hydrocytosis and xerocytosis represent the extremes of a broad spectrum of RBC permeability defects. In fact, families with features of both conditions have been reported. Some patients with severe permeability defects have little or no hemolysis. The proportion of stomatocytes and the degree of sodium influx do not correlate with each other, and neither correlates with the amount of hemolysis or anemia.

ERYTHROCYTE METABOLISM

NORMAL METABOLISM

The primary functions of the erythrocyte, gas transport and exchange, are maintained without a net change in energy state. However, several critical functions of the erythrocyte depend on the production and expenditure of energy. As erythrocytes age, glucose utilization and ATP levels fall, leading to decreased membrane deformability and, ultimately, a shortened lifespan. Lower potassium levels, higher sodium levels, and decreased membrane lipids are also seen in ATP-deficient, aging erythrocytes.

Erythrocytes do not undergo oxidative phosphorylation and do not store glycogen; thus, they must constantly catabolize glucose from the blood stream through the Embden-Meyerhof pathway and the hexose monophosphate shunt as a source of energy (Fig. 147-4). Erythrocytes incorporate glucose from the plasma through facilitated transfer, with erythrocyte glucose levels rapidly equilibrating with changes in blood glucose levels. Glucose is the preferred carbohydrate of the RBC, but fructose and mannose are metabolized almost as readily. Inside the erythrocyte, glucose is converted to glucose-6-phosphate or to fructose by sorbitol. Glucose-6-phosphate follows one of three pathways: (1) most (≈90%) enters the Embden-Meyerhof pathway, where it is converted into lactate, pyruvate, and ATP; (2) some (≈5 to 10%) enters the hexose monophosphate shunt to produce reduced intermediates and ribulose 5-phosphate, the latter of which eventually enters the Embden-Meyerhof pathway; and (3) a tiny fraction (<1%) is converted to glucose-1-phosphate and then to glycogen.

Embden-Meyerhof Pathway

The Embden-Meyerhof pathway of glycolysis is the primary source of ATP, 2,3-DPG and nicotinamide adenine dinucleotide, reduced form (NADH) in erythrocytes (see Fig. 147-4). Most of the energy generated by erythrocytes is through the Embden-Meyerhof pathway followed by storage as high-energy phosphates such as ATP or as reducing energy in the form of glutathione or pyridine nucleotides (NADH and nicotinamide adenine dinucleotide phosphate, reduced form [NADPH]). This pathway metabolizes about 90% of erythrocyte glucose with the catabolism of 1 mole of glucose yielding 2 moles of ATP and 2 moles of lactate. Two moles of ATP per mole of metabolized glucose seems insignificant compared with the Krebs cycle of intermediary metabolism, in which 1 mole of glucose metabolized produces 38 moles of ATP. However, this ATP production is adequate to renew 150 to 200% of the total RBC ATP every hour.

The Embden-Meyerhof pathway is also the primary source of NADH, a necessary cofactor for NADH methemoglobin reductase, which maintains heme iron in the reduced state. Without this reaction, heme iron would be oxidized to methemoglobin, which is not a functional oxygen transporter.

Finally, the Rapoport-Luebering shunt of the Embden-Meyerhof pathway (see Fig. 147-4) produces 2,3-DPG, a compound found in high concentrations in erythrocytes but in low concentrations in other cells. After it is formed, under physiologic conditions of pH and solute concentrations, 2,3-DPG binds reversibly to tetramers of deoxyhemoglobin with greater affinity than it does to oxyhemoglobin. By binding to deoxyhemoglobin, it allosterically upregulates the release of the remaining oxygen bound to the Hb, enhancing the ability of erythrocytes to release oxygen near tissues that need it most.

Hexose Monophosphate Shunt (Pentose Phosphate Pathway)

In the hexose monophosphate shunt (see Fig. 147-4), glucose-6-phosphate undergoes oxidation followed by a series of reactions to yield

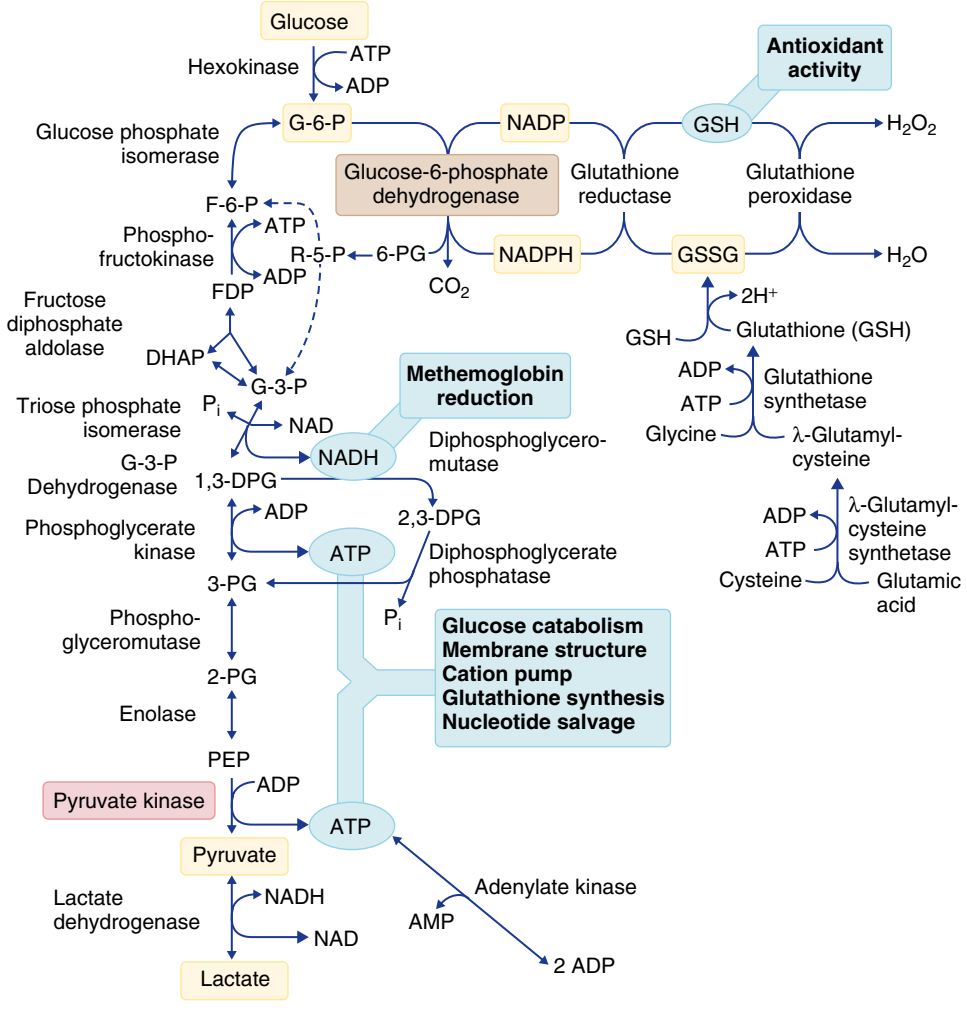

FIGURE 147-4. Pathways of energy metabolism in the erythrocyte. Glucose-6-phosphate may be degraded anaerobically to lactate through the Embden-Meyerhof pathway or oxidatively through the hexose monophosphate shunt. Pentose phosphates (R-5-P) can reenter anaerobic glycolysis as fructose-6-phosphate (F-6-P) and glyceraldehyde-3-phosphate (G-3-P) after conversion by enzymes of the terminal pentose phosphate pathway or as a product of adenosine or inosine degradation. 2,3-Diphosphoglycerate (2,3-DPG) may be generated instead of adenosine triphosphate (ATP) through diversion of triose through the Rapoport-Luebering shunt. Glutathione may be synthesized directly from constituent amino acids; its cycling from oxidized (GSSG) to reduced forms (GSH) depends on reduced pyridine cofactor (NADPH) generation. ADP = adenosine diphosphate; DHAP = dihydroxyacetone phosphate; FDP = fructose-1,6-diphosphate; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = nicotinamide adenine dinucleotide phosphate, reduced form; PEP = polyestradiol phosphate.

fructose-6-phosphate and glyceraldehyde-3-phosphate, intermediates in the glycolytic pathway. The hexose monophosphate shunt is the primary source of erythrocyte NADPH, with 2 moles of NADPH produced for each mole of glucose metabolized. NADPH is required for the reduction of oxidized glutathione and some protein sulfhydryl groups.

Mature erythrocytes synthesize large amounts of reduced glutathione. Glutathione protects erythrocytes from oxidants, including hydrogen peroxide (H_2O_2), superoxide anions (O_2^-), and hydroxyl radicals (OH), which are produced as byproducts of the oxidation of heme by oxygen. Oxidants are also produced by activated phagocytes (e.g., during infection) and by erythrocytes after exposure to certain agents. When oxidants accumulate, they damage cellular proteins and lipids. Detoxification of H_2O_2 is significantly enhanced by glutathione peroxidase. Glutathione is converted to oxidized glutathione and to mixed disulfides with protein thiols. Glutathione levels are restored by glutathione reductase. In this process, NADPH is oxidized to nicotinamide adenine dinucleotide phosphate (NADP), which stimulates the hexose monophosphate shunt to regenerate NADPH. After oxidant stress, hypoxia, or acidosis, erythrocytes can increase the amount of glucose metabolized through the hexose monophosphate shunt up to 10- to 20-fold to generate increased amounts of reduced glutathione. The tight coupling of glutathione metabolism with the hexose monophosphate shunt protects the mature erythrocyte from oxidative stress.

DISORDERS OF ERYTHROCYTE METABOLISM

Congenital nonspherocytic hemolytic anemia traditionally includes erythrocyte disorders not due to defects of the RBC membrane or hemoglobin, immune-mediated disease, or other diseases such as paroxysmal nocturnal hemoglobinuria. Congenital nonspherocytic hemolytic anemia is a heterogeneous group of disorders associated with various metabolic abnormalities of the erythrocytes, including enzymopathies of glucose, glutathione, and nucleotide metabolism. Similar to the membrane disorders, clinical, biochemical, and genetic heterogeneity are typical within the enzymopathies. Hemolysis may develop as a result of either enzyme or antioxidant deficiency or dysfunction (e.g., abnormal substrate or cofactor binding), altered activation or inhibition characteristics, or decreased stability or specific activity.

Peripheral blood smears in congenital nonspherocytic hemolytic anemia, with the exception of pyrimidine 5′-nucleotidase deficiency, are unremarkable. Osmotic fragility of fresh erythrocytes is normal. Response to splenectomy is variable. Inheritance is heterogeneous. A thorough family history is important and may be of assistance in determining the diagnosis. Manifestations of the metabolic defect are usually confined to the erythrocyte but may occasionally involve nonerythroid cells.

Definitive diagnosis of metabolic abnormalities of the erythrocyte depends on qualitative or quantitative assays of specific enzyme activity or identification of the specific genetic mutation by DNA analysis. Results of enzyme assays should be interpreted with caution because they only sample surviving RBCs in the peripheral blood and the metabolic milieu of these cells is not necessarily comparable to cells already hemolyzed; in vitro enzyme assay conditions may not accurately reflect the in vivo environment; transfusions before the assay may obscure the underlying metabolic defect; and leukocyte contamination may lead to spurious results. Finally, average enzyme activity may not accurately reflect activity in subpopulations of erythrocytes. This is particularly true when there is reticulocytosis, which may yield artificially elevated mean enzyme activity owing to higher enzyme levels found in reticulocytes.

DISORDERS OF THE EMBDEN-MEYERHOF PATHWAY

Defects of the Embden-Meyerhof pathway are inherited in an autosomal recessive fashion, and usually hemolysis is seen only in homozygotes or compound heterozygotes. Heterozygotes, whose erythrocytes contain less than normal amounts of mutant enzyme, are clinically normal. An exception is phosphoglycerate kinase deficiency, an X-linked disorder with hemolysis found only in males. In this group of disorders, hemolysis is chronic, is not typically influenced by drugs or other inciting agents, and is attributed to insufficient levels of erythrocyte ATP. Splenomegaly from trapping of mutant erythrocytes is common. The hostile splenic environment contributes to the shortened erythrocyte lifespan. When performing specific diagnostic enzyme assays, measurement of glycolytic intermediates may assist in diagnosis because concentrations of intermediates are increased upstream of a defect and decreased downstream of a defect.

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency accounts for approximately 90% of inherited defects of the Embden-Meyerhof pathway and is the second most common inherited erythrocyte enzymopathy associated with anemia after glucose-6-phosphate dehydrogenase (G6PD) deficiency (see later). Pyruvate kinase deficiency is found worldwide, but it is most common in individuals of northern European descent.

PATHOBIOLOGY

Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate, generating ATP. Deficient or defective pyruvate kinase leads to decreased levels of erythrocyte ATP, disturbing many cellular processes such as signaling and maintenance of water and ion content, leading to energy failure and dehydration. Upstream catabolites accumulate in the erythrocyte, including 2,3-DPG, which shifts the oxygen dissociation curve to the right, enhancing tissue oxygenation and ameliorating some of the physiologic effects of anemia. Early pyruvate kinase-deficient reticulocytes retain the ability to use oxidative phosphorylation to produce ATP, bypassing their defect. This ability is lost as reticulocytes mature and is markedly dampened in the hypoxic environment of the spleen.

Pyruvate kinase deficiency is inherited in an autosomal recessive manner. Affected individuals are homozygous or compound heterozygotes for pyruvate kinase defects. Heterozygotes are clinically normal or exhibit very minimal hemolysis. Mutation studies reveal a wide range of variants, with a few mutations enriched in certain populations.[15]

CLINICAL MANIFESTATIONS

Clinical manifestations in pyruvate kinase deficiency are heterogeneous, ranging from asymptomatic to transfusion-dependent hemolytic anemia.[16] More severely affected patients present in infancy or early childhood with anemia, jaundice, and splenomegaly. Occasionally, patients may escape detection until later in life when complications related to anemia and chronic hemolysis occur such as cholelithiasis or aplastic crisis or when the diagnosis is made during evaluation of the patient for another condition.

DIAGNOSIS

The peripheral blood smear demonstrates normocytic, normochromic erythrocytes, sometimes with spiculations (Fig. 147-5A). Poikilocytes and acanthocytes may also be seen. Reticulocytosis is common. Osmotic fragility of fresh erythrocytes is usually normal. Occasional patients exhibit a population of osmotically fragile cells after incubation.

NADH fluorescence is a commonly used screening test for pyruvate kinase deficiency. PEP and NADH are mixed with the patient's blood, incubated, and spotted on filter paper, and fluorescence is measured. Direct enzyme assay, which uses PEP as substrate for pyruvate kinase, performed on leukocyte-free hemolysate, is the gold standard for the diagnosis of pyruvate kinase deficiency. This detects all but the few rare patients with dysfunctional, thermolabile enzyme variants without enzyme deficiency. Leukocytes must be carefully depleted from the samples because they contain more than 300 times the pyruvate kinase activity of erythrocytes. Genetic diagnosis for pyruvate kinase deficiency is now widely available. Molecular diagnosis is particularly helpful in patients after transfusion, when prenatal diagnosis is desired, and when sample shipping and preparation precludes direct enzyme assay. To ascertain the diagnosis most accurately using molecular techniques, study of parental DNA is required, unless the patient is homozygous for a deleterious mutation, to determine if the variants detected are in *cis* or *trans* for precise diagnosis.

TREATMENT

Most patients require expectant management, with only rare transfusions, such as during an aplastic episode.[17] Mitapivat, an oral, small-molecule allosteric activator of pyruvate kinase in red cells,[18] can increase the hemoglobin level in adults with pyruvate kinase deficiency and a missense *PKLR* mutation.[A1] In severe cases, patients may be transfusion dependent. In these cases, splenectomy typically lessens hemolysis and ameliorates the anemia. After splenectomy, some patients develop marked reticulocytosis, up to 50 to 70%. This paradoxical reticulocytosis is attributed to increased reticulocyte survival after removal of the hostile splenic environment.

Other Disorders of the Embden-Meyerhof Pathway

Other abnormalities of the Embden-Meyerhof pathway have been described. Hexokinase deficiency is quite uncommon, with great phenotypic variability in reported cases. Severely affected patients have had anemia beginning in infancy and may require blood transfusions. Glucose phosphate isomerase (GPI) deficiency is the third most common hemolytic enzymopathy. GPI deficiency

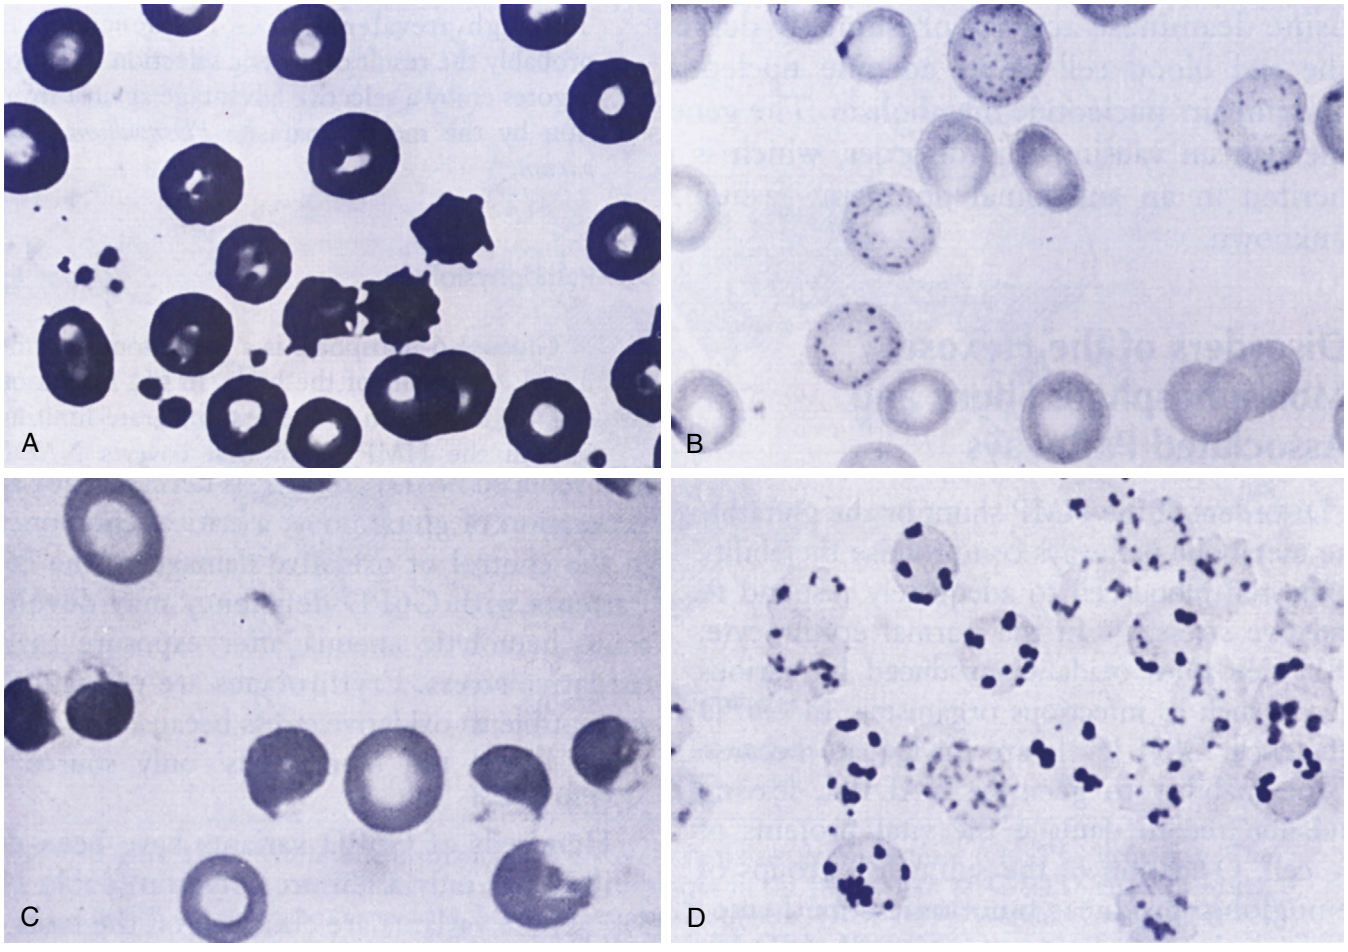

FIGURE 147-5. **Peripheral blood smears in erythrocyte enzymopathies. Philadelphia: JB Lippincott; 1995:1877-1896.)

usually presents in infancy or early childhood with moderate to severe hemolytic anemia. Rare cases of GPI deficiency may also be complicated by neurologic symptomatology. Phosphofructokinase deficiency may involve erythrocytes, muscle, or both. The presentation is usually in adolescence with exertional myopathy. Hemolytic anemia has been described in isolated cases of 2,3-bisphosphoglycerate mutase deficiency and phosphoglycerate kinase deficiency.

DISORDERS OF NUCLEOTIDE METABOLISM

Mature erythrocytes lack the ability to synthesize purine and pyrimidine nucleotides de novo. However, they are able to form some nucleotides through salvage pathways.

Pyrimidine 5′-Nucleotidase Deficiency

Pyrimidine 5′-nucleotidase degrades the pyrimidine nucleotides of RNA to cytidine and uridine, which can diffuse out of the cell. When pyrimidine 5′-nucleotidase is deficient, nondiffusible, partially degraded RNAs accumulate, leading to the marked basophilic stippling characteristic of pyrimidine 5′-nucleotidase-deficient erythrocytes (see Fig. 147-5B). These accumulated pyrimidine nucleotides inhibit the transport of oxidized glutathione out of RBCs, leading to high levels of erythrocyte glutathione. Clinically, the patient has mild to moderate hemolytic anemia and splenomegaly. The cause of the hemolysis remains cryptic. Typically, splenectomy does not ameliorate the hemolysis and anemia.

DISORDERS OF THE HEXOSE MONOPHOSPHATE SHUNT (PENTOSE PHOSPHATE PATHWAY) AND ASSOCIATED PATHWAYS

Disorders of the hexose monophosphate shunt or of the glutathione metabolic pathways (see Fig. 147-4) compromise the ability of the RBC to respond adequately to oxidative stress. In normal erythrocytes, glutathione detoxifies oxidants produced by various agents and infection. In G6PD-deficient erythrocytes, because of the inability to generate NADPH, glutathione levels are inadequate, leaving the cell susceptible to oxidant stress. Oxidation of Hb sulfhydryl groups leads to the production of methemoglobin and intracellular Hb precipitates called *Heinz bodies*. Heinz bodies (see Fig. 147-5D), usually visualized on peripheral blood smears with supravital stains such as methyl violet, attach to and damage the erythrocyte membrane. They induce clustering of immunoglobulins and band 3 protein, marking the erythrocyte for opsonization by phagocytes and eventual removal from the circulation. Heinz bodies are "pitted" from circulating cells by the spleen and are commonly seen on smears of patients after splenectomy. "Bite cells," erythrocytes with localized invaginations, possibly at the site of Heinz body injury or removal, are seen during acute hemolytic episodes (Chapter 143). In addition to damage from Heinz body formation, glutathione-deficient erythrocytes undergo peroxidation of membrane phospholipids and oxidative cross-linking of spectrin, decreasing membrane deformability and further promoting splenic trapping.

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is the most common inherited disorder of erythrocyte metabolism, affecting more than 400 million people worldwide.[19,20] The high prevalence of G6PD deficiency is thought to be attributable to genetic selection because G6PD-deficient erythrocytes have a selective advantage against invasion by the malaria parasite *Plasmodium falciparum*.

EPIDEMIOLOGY AND PATHOBIOLOGY

G6PD is the initial and rate-limiting step in the hexose monophosphate shunt (see Fig. 147-4), which converts NADP into NADPH. NADPH is required for the generation of glutathione, a critical constituent in the prevention of oxidative damage to the cell. G6PD-deficient patients may develop acute hemolytic anemia after exposure to oxidative stress. Although G6PD is a ubiquitous enzyme, erythroid cells are particularly susceptible to oxidative stress because the hexose monophosphate shunt is their only source of NADPH.

Hundreds of G6PD variants have been described, but only a few are common. Variants are classified on the basis of biochemical characteristics, electrophoretic mobility, ability to use substrate analogue, Km for NADP and G6PD, pH

TABLE 147-2 FEATURES OF G6PD VARIANTS

VARIANT	GENOTYPE	ENZYME ACTIVITY (% OF NORMAL)	ENZYME THERMAL STABILITY	ENZYME THERMAL ACTIVITY (K_{CAT} S^{-1})	ENZYME CATALYTIC CLASSIFICATION	WHO CLINICAL DISTRIBUTION
G6PD B	None	100	Normal	275	IV	Worldwide
G6PD A+	Val68Met	85	Normal	247	IV	Africa
G6PD A-	Val68Met, Asn126AsP	10-23	Low	137	III	Africa

activity profile, and thermal stability. The normal enzyme, Gd^B, is present in 99% of White Americans and 70% of African Americans. A normal variant, Gd^{A+}, found in 20% of African Americans, has a faster electrophoretic mobility than Gd^B. Gd^{A-}, the most common variant associated with hemolysis, is found in about 10% of African Americans and in many Africans. Gd^{A-} has decreased catalytic ability compared with Gd^{A+}. Gd^{Med}, the second most common variant associated with hemolysis, is common in the Mediterranean area, in India, and in Southeast Asia, with a prevalence of up to 5 to 50%. Gd^{Med} exhibits markedly decreased catalytic activity. Gd^{Canton}, a variant common in Asian populations, produces a clinical syndrome similar to Gd^{A-}. Features of several G6PD variants are shown in Table 147-2.

Gd^B activity decreases as normal cells age, with a half-life of approximately 60 days. Despite very low levels of or no active G6PD, older erythrocytes maintain the ability to produce NADPH and maintain a glutathione response to oxidative stress. The Gd^{A-} variant has a half-life of only 13 days, so young cells have a normal amount of enzyme activity, but older RBCs are grossly deficient. Because of this heterogeneity in G6PD levels, individuals with the Gd^{A-} variant experience only limited hemolysis after oxidant exposure.

More than 100 mutations in the *G6PD* gene, localized to Xq28, have been described. Most mutations are amino acid substitutions that influence enzyme kinetics, stability, or both, with a few rare deletions and splicing mutations described. Because it is X-linked, G6PD deficiency primarily affects males. Males have only one G6PD allele and express only one G6PD type. Females can express one or two G6PD types. The Lyon hypothesis specifies that only one X chromosome is active in any given cell; thus, any given cell in a heterozygous female is either normal or deficient. In females who are heterozygous for G6PD deficiency, average G6PD activity may be normal or mildly, moderately, or severely reduced, depending on the degree of lyonization. G6PD-deficient erythrocytes in heterozygous females are susceptible to the same oxidant stress as G6PD-deficient cells in males, but, typically, the overall degree of hemolysis is less because there is a smaller population of vulnerable cells.

CLINICAL MANIFESTATIONS

G6PD deficiency is divided into five classes based on clinical severity and degree of enzyme deficiency. Class I is characterized by congenital nonspherocytic hemolytic anemia without precipitating cause and severe G6PD deficiency. Class II is characterized by intermittent hemolysis and severe G6PD deficiency. Class III is characterized by hemolysis after oxidant stress and mild G6PD deficiency. Class II and III together represent more than 90% of G6PD variants. Classes IV and V are clinically asymptomatic. The most clinically significant syndromes of G6PD deficiency are acute hemolytic anemia; neonatal jaundice; and rarely, congenital nonspherocytic hemolytic anemia.

Acute hemolytic anemia is the most dramatic clinical presentation of G6PD deficiency with acute intravascular hemolysis after exposure to an oxidative stress. Oxidative stresses include ingestion of certain drugs such as primaquine or sulfa-containing compounds, exposure to naphthalene (mothballs), ingestion of fava beans, or infection, the latter being the most common cause of hemolysis. Table 147-3 lists drugs that should be avoided in G6PD-deficient patients. Presenting symptoms include irritability, fever, nausea, abdominal pain, and diarrhea within 48 hours of oxidant exposure. Hemoglobinuria, jaundice, and anemia ensue. The spleen and liver may be enlarged and tender. Cases with severe anemia may precipitate congestive heart failure. Laboratory findings include a normochromic, normocytic anemia with anisocytosis and reticulocytosis. Poikilocytes and bite cells may be seen. Heinz bodies, a classic finding in G6PD deficiency, may be seen but are an inconsistent finding because these damaged cells are rapidly cleared from the circulation in the spleen. Additional laboratory findings may include hemoglobinuria and the presence of free Hb in the blood.

TABLE 147-3 AGENTS TO BE AVOIDED BY GLUCOSE-6-PHOSPHATE DEHYDROGENASE–DEFICIENT PATIENTS*

ANTIMALARIALS

Primaquine (people with the African A^- variant may take it at reduced dosage, under surveillance)
Pamaquine
Chloroquine (may be used under surveillance when required for prophylaxis or treatment of malaria)

SULFONAMIDES AND SULFONES

Sulfanilamide
Sulfapyridine
Sulfadimidine
Sulfacetamide (Albucid)
Acetyl sulfisoxazole (Gantrisin)
Salicylazosulfapyridine (Salazopyrin)
Dapsone
Sulfoxone
Glucosulfone sodium (Promin)
Sulfamethoxazole-trimethoprim (Bactrim, Septra)

OTHER ANTIBACTERIAL COMPOUNDS

Nitrofurans—nitrofurantoin, furazolidone, nitrofurazone
[Nalidixic acid]
Chloramphenicol
p-Aminosalicylic acid

ANALGESICS

Acetylsalicylic acid (aspirin): moderate doses can be used
Acetophenetidin (Phenacetin)
Safe alternative: Paracetamol

ANTHELMINTICS

β-Naphthol
Stibophen
Niridazole

MISCELLANEOUS

Vitamin K analogues (1 mg of menaphthone can be given to babies)
Naphthalene (moth balls)
Probenecid
Dimercaprol (BAL)
Methylene blue
Arsine†
Phenylhydrazine†
Acetylphenylhydrazine†
Toluidine blue
Mepacrine

*Drugs in bold print should be avoided by people with all forms of glucose-6-phosphate dehydrogenase (G6PD) deficiency. Drugs in normal print should be avoided, in addition, by G6PD-deficient people of Mediterranean, Middle Eastern, and Asian origin. Items in normal print and within square brackets apply only to people with the African A^- variant.
†These drugs or chemicals may cause hemolysis in normal people if given in large doses. Many other drugs may produce hemolysis in certain individuals.

Another clinically significant syndrome of G6PD deficiency is neonatal jaundice. Jaundice is seldom present at birth, with the peak incidence of onset between days 2 and 3 of life. The severity of hyperbilirubinemia is variable. It may be severe, resulting in kernicterus or even death. In most cases, however, hyperbilirubinemia is adequately treated with phototherapy. In neonatal jaundice, it is important to note that the anemia is very rarely severe. The etiology of neonatal jaundice remains controversial. Neonatal jaundice is increased in G6PD-deficient infants who also carry a polymorphism of the uridine diphosphoglucuronyl transferase (*UDPGT1*) gene associated with Gilbert syndrome.

Chronic nonspherocytic hemolytic anemia is associated with uncommon variants of G6PD deficiency, usually mutant enzymes unable to maintain basal NADPH production. Presentation may be in the neonatal period when neonatal jaundice is accompanied by anemia in a male. The degree of chronic anemia in congenital nonspherocytic hemolytic anemia caused by G6PD deficiency has been variable. Some patients have compensated hemolysis, but others require intermittent transfusions. Transfusion dependence occurs in the most severe cases.

G6PD deficiency, which suppresses the antioxidant system, has been suggested to worsen severity of COVID-19 infection which activates pro-oxidant responses. This association was not identified in a genome-wide association study of patients with severe COVID-19.[21] This possible association needs to be further explored in clinical trials.

DIAGNOSIS

The G6PD reaction (glucose-6-phosphate + $NADP^+ \rightarrow$ 6-phosphogluconolactone + NADPH + H^+) reduces $NADP^+$ to NADPH. Formation of NADPH and NADH can be observed directly because they fluoresce in the visible spectrum when illuminated with long-wave ultraviolet light. Based on this observation, several simple screening tests performed using inexpensive long-wave ultraviolet light have been devised, and rapid testing has a very high sensitivity. However, these tests are semiquantitative, categorizing a sample as normal or deficient. They are unreliable after an acute hemolytic episode and do not typically detect female heterozygotes. Positive screening test results should be confirmed by spectrophotometric assay or DNA studies because of the risk of false-positive results.

Definitive assay of the enzyme depends on direct spectrophotometric measurement of NADPH production. Although more sensitive than screening tests, this still requires 20 to 30% G6PD-deficient cells to obtain an abnormal result. Sensitivity can be increased by comparing the level of G6PD deficiency with levels of other age-dependent erythrocyte enzymes, especially when testing is temporally in close proximity to an acute hemolytic episode. The cyanide-ascorbate test measures the ability of erythrocytes to prevent the oxidation of Hb by ascorbate. Using intact erythrocytes, as few as 10 to 15% deficient cells can be detected, making this test useful for detecting female heterozygotes and males after a hemolytic episode. This test also detects other perturbations of the hexose monophosphate shunt or glutathione metabolism. Genetic testing can be performed in difficult cases or when a molecular diagnosis is desired.[22]

TREATMENT

The best treatment for an individual with acute hemolytic anemia is careful prescription of medications and avoidance of inciting agents (see Table 147-3).[23,24] Outside of acute hemolytic episodes, these patients do not require any special therapy. Acute hemolytic anemia episodes are managed with particular attention to hematologic, cardiopulmonary, and renal complications of hemolysis. Management of neonatal jaundice does not differ from that recommended for other causes of neonatal hyperbilirubinemia. In congenital nonspherocytic hemolytic anemia, management is expectant. Exposure to oxidant stresses should be avoided. Blood transfusions may be necessary during acute hemolytic episodes. In severe cases of congenital nonspherocytic hemolytic anemia, splenectomy may ameliorate the anemia.

DISORDERS OF GLUTATHIONE METABOLISM

Defects of glutathione metabolism may be associated with hemolysis. Erythrocytes from patients lacking glutathione synthetase or γ-glutamylcysteine synthetase, enzymes involved in glutathione synthesis, have very low levels of glutathione. Clinically, these disorders resemble G6PD deficiency. There is mild to moderate chronic hemolytic anemia with increased susceptibility to oxidant stress.

148 THE THALASSEMIAS

MARIA DOMENICA CAPPELLINI

DEFINITION

The thalassemias, or more comprehensively the thalassemia syndromes, are a heterogeneous group of inherited hemolytic anemias characterized by deficient or absent production of one of the globin chains of hemoglobin. This deficiency leads to an imbalance in the synthesis of globin chains, an imbalance that is the hallmark of all the thalassemia syndromes.

EPIDEMIOLOGY

Taken together, the thalassemias are the most common recessive single-gene disorders in the world, with approximately 270 million or more people carrying one recessive gene. Each year, more than 40,000 children are born with one of the thalassemia syndromes, and about half of these individuals will become transfusion dependent. The extremely high frequency of the hemoglobin disorders compared with other monogenic diseases reflects natural selection mediated by the relative resistance of carriers against *Plasmodium falciparum* malaria (Chapter 316). Other factors that may be involved include the widespread practice of consanguineous marriage, increased maternal age in poorer countries, gene drift, and founder effects. For these reasons, the thalassemias are most frequent in southeastern and southern Asia,[1] in the Middle East, in the Mediterranean countries, and in northern and central Africa. However, as the result of recent mass migrations from the Middle East, Africa, and South East Asia, thalassemias are now encountered worldwide.

PATHOBIOLOGY

Normal adult red cells contain 97% adult hemoglobin (HbA: $\alpha_2\beta_2$), with approximately 2.5% of the minor component HbA_2 ($\alpha_2\delta_2$) and a small amount of fetal hemoglobin (HbF: $\alpha_2\gamma_2$). Because the stable tetramer $\alpha_2\beta_2$ is the major component of hemoglobin after birth, the two main forms of thalassemia are α-thalassemias and β-thalassemias. Because β-chain synthesis is fully activated only after birth, it follows that β-thalassemias are not expressed as a disease in intrauterine life; rather, they are manifested as γ-chain synthesis declines during the first year of life. In contrast, because α chains are shared by both fetal and adult hemoglobin, α-thalassemias are manifested in both fetal and adult life.

The thalassemia syndromes can be classified based on their genetics, clinical phenotypes, and transfusion requirements (Table 148-1).[2] Patients with transfusion-dependent β-thalassemia (β-thalassemia major or severe HbE–β-thalassemia) require lifelong, regular transfusions for survival, whereas patients with non–transfusion-dependent β-thalassemia (β-thalassemia intermedia or mild to moderate HbE–β-thalassemia) require no transfusions, occasional transfusions because of specific circumstances (e.g., pregnancy, surgery, or acute infection), or frequent transfusions but for a limited period (e.g., to support a growth spurt during childhood or manage a clinical complication).[3]

Genetics

Six different types of globin chains (α, β, γ, δ, ε, ζ) are found in normal human hemoglobin at different stages of development. In the very early embryo, hemoglobin synthesis is restricted to the yolk sac and the production of hemoglobins Gower 1 ($\zeta_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$). Subsequently, at about

Another clinically significant syndrome of G6PD deficiency is neonatal jaundice. Jaundice is seldom present at birth, with the peak incidence of onset between days 2 and 3 of life. The severity of hyperbilirubinemia is variable. It may be severe, resulting in kernicterus or even death. In most cases, however, hyperbilirubinemia is adequately treated with phototherapy. In neonatal jaundice, it is important to note that the anemia is very rarely severe. The etiology of neonatal jaundice remains controversial. Neonatal jaundice is increased in G6PD-deficient infants who also carry a polymorphism of the uridine diphosphoglucuronyl transferase (*UDPGT1*) gene associated with Gilbert syndrome.

Chronic nonspherocytic hemolytic anemia is associated with uncommon variants of G6PD deficiency, usually mutant enzymes unable to maintain basal NADPH production. Presentation may be in the neonatal period when neonatal jaundice is accompanied by anemia in a male. The degree of chronic anemia in congenital nonspherocytic hemolytic anemia caused by G6PD deficiency has been variable. Some patients have compensated hemolysis, but others require intermittent transfusions. Transfusion dependence occurs in the most severe cases.

G6PD deficiency, which suppresses the antioxidant system, has been suggested to worsen severity of COVID-19 infection which activates pro-oxidant responses. This association was not identified in a genome-wide association study of patients with severe COVID-19.[21] This possible association needs to be further explored in clinical trials.

DIAGNOSIS

The G6PD reaction (glucose-6-phosphate + $NADP^+ \rightarrow$ 6-phosphogluconolactone + NADPH + H^+) reduces $NADP^+$ to NADPH. Formation of NADPH and NADH can be observed directly because they fluoresce in the visible spectrum when illuminated with long-wave ultraviolet light. Based on this observation, several simple screening tests performed using inexpensive long-wave ultraviolet light have been devised, and rapid testing has a very high sensitivity. However, these tests are semiquantitative, categorizing a sample as normal or deficient. They are unreliable after an acute hemolytic episode and do not typically detect female heterozygotes. Positive screening test results should be confirmed by spectrophotometric assay or DNA studies because of the risk of false-positive results.

Definitive assay of the enzyme depends on direct spectrophotometric measurement of NADPH production. Although more sensitive than screening tests, this still requires 20 to 30% G6PD-deficient cells to obtain an abnormal result. Sensitivity can be increased by comparing the level of G6PD deficiency with levels of other age-dependent erythrocyte enzymes, especially when testing is temporally in close proximity to an acute hemolytic episode. The cyanide-ascorbate test measures the ability of erythrocytes to prevent the oxidation of Hb by ascorbate. Using intact erythrocytes, as few as 10 to 15% deficient cells can be detected, making this test useful for detecting female heterozygotes and males after a hemolytic episode. This test also detects other perturbations of the hexose monophosphate shunt or glutathione metabolism. Genetic testing can be performed in difficult cases or when a molecular diagnosis is desired.[22]

TREATMENT

The best treatment for an individual with acute hemolytic anemia is careful prescription of medications and avoidance of inciting agents (see Table 147-3).[23,24] Outside of acute hemolytic episodes, these patients do not require any special therapy. Acute hemolytic anemia episodes are managed with particular attention to hematologic, cardiopulmonary, and renal complications of hemolysis. Management of neonatal jaundice does not differ from that recommended for other causes of neonatal hyperbilirubinemia. In congenital nonspherocytic hemolytic anemia, management is expectant. Exposure to oxidant stresses should be avoided. Blood transfusions may be necessary during acute hemolytic episodes. In severe cases of congenital nonspherocytic hemolytic anemia, splenectomy may ameliorate the anemia.

DISORDERS OF GLUTATHIONE METABOLISM

Defects of glutathione metabolism may be associated with hemolysis. Erythrocytes from patients lacking glutathione synthetase or γ-glutamylcysteine synthetase, enzymes involved in glutathione synthesis, have very low levels of glutathione. Clinically, these disorders resemble G6PD deficiency. There is mild to moderate chronic hemolytic anemia with increased susceptibility to oxidant stress.

148 THE THALASSEMIAS

MARIA DOMENICA CAPPELLINI

DEFINITION

The thalassemias, or more comprehensively the thalassemia syndromes, are a heterogeneous group of inherited hemolytic anemias characterized by deficient or absent production of one of the globin chains of hemoglobin. This deficiency leads to an imbalance in the synthesis of globin chains, an imbalance that is the hallmark of all the thalassemia syndromes.

EPIDEMIOLOGY

Taken together, the thalassemias are the most common recessive single-gene disorders in the world, with approximately 270 million or more people carrying one recessive gene. Each year, more than 40,000 children are born with one of the thalassemia syndromes, and about half of these individuals will become transfusion dependent. The extremely high frequency of the hemoglobin disorders compared with other monogenic diseases reflects natural selection mediated by the relative resistance of carriers against *Plasmodium falciparum* malaria (Chapter 316). Other factors that may be involved include the widespread practice of consanguineous marriage, increased maternal age in poorer countries, gene drift, and founder effects. For these reasons, the thalassemias are most frequent in southeastern and southern Asia,[1] in the Middle East, in the Mediterranean countries, and in northern and central Africa. However, as the result of recent mass migrations from the Middle East, Africa, and South East Asia, thalassemias are now encountered worldwide.

PATHOBIOLOGY

Normal adult red cells contain 97% adult hemoglobin (HbA: $\alpha_2\beta_2$), with approximately 2.5% of the minor component HbA_2 ($\alpha_2\delta_2$) and a small amount of fetal hemoglobin (HbF: $\alpha_2\gamma_2$). Because the stable tetramer $\alpha_2\beta_2$ is the major component of hemoglobin after birth, the two main forms of thalassemia are α-thalassemias and β-thalassemias. Because β-chain synthesis is fully activated only after birth, it follows that β-thalassemias are not expressed as a disease in intrauterine life; rather, they are manifested as γ-chain synthesis declines during the first year of life. In contrast, because α chains are shared by both fetal and adult hemoglobin, α-thalassemias are manifested in both fetal and adult life.

The thalassemia syndromes can be classified based on their genetics, clinical phenotypes, and transfusion requirements (Table 148-1).[2] Patients with transfusion-dependent β-thalassemia (β-thalassemia major or severe HbE–β-thalassemia) require lifelong, regular transfusions for survival, whereas patients with non–transfusion-dependent β-thalassemia (β-thalassemia intermedia or mild to moderate HbE–β-thalassemia) require no transfusions, occasional transfusions because of specific circumstances (e.g., pregnancy, surgery, or acute infection), or frequent transfusions but for a limited period (e.g., to support a growth spurt during childhood or manage a clinical complication).[3]

Genetics

Six different types of globin chains (α, β, γ, δ, ε, ζ) are found in normal human hemoglobin at different stages of development. In the very early embryo, hemoglobin synthesis is restricted to the yolk sac and the production of hemoglobins Gower 1 ($\zeta_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$). Subsequently, at about

ABSTRACT

The thalassemia syndromes are a heterogeneous group of inherited hemolytic anemias characterized by deficient or absent production of one of the globin chains of hemoglobin. This deficiency leads to an imbalance in globin chain synthesis, an imbalance that is the hallmark of all the thalassemias. Underlying molecular defects in the α- or β-globin gene clusters form the basis of the various inherited forms of α- or β-thalassemias. The clinical manifestations of thalassemia syndromes are extremely variable and depend on the degree of imbalance in the production of globin chains. The clinical spectrum of α-thalassemias correlates well with the number of the affected α genes, that is, from normal to the loss of all four genes. The β-thalassemias are quite heterogeneous and are characterized by a reduced output of the β chains of adult hemoglobin. The clinical classification includes thalassemia major (transfusion dependent), thalassemia intermedia (of intermediate severity, non–transfusion dependent), and thalassemia minor (asymptomatic). The severity of the clinical manifestations correlates well with the degree of imbalance of globin chains; depending on the β-globin gene defects and their interaction, the production of β-globin chains is quantitatively reduced to different degrees, thereby resulting in accumulation of excess unmatched α-globin chains in the erythroid precursors.

TABLE 148-1 GENETIC AND CLINICAL CLASSIFICATIONS OF THE THALASSEMIAS

	GENETIC	CLINICAL	TRANSFUSION REQUIREMENT
α-Thalassemias	α^0 α^+ Deletion (−α) Nondeletion (α^T)	α-Minor HbH disease Hydrops fetalis	No transfusion Occasional transfusions NA
β-Thalassemias	β^0 β^+ Variant with high HbA_2 Normal HbA_2 Silent Dominant Unlinked to β-gene cluster	β-Minor Thalassemia intermedia Thalassemia major	No transfusions Occasional transfusions Regular transfusions
δβ-Thalassemias	$(\delta\beta)^0$ $(\delta\beta)^+$ $(^A\gamma\delta\beta)^0$	δβ-Minor Thalassemia intermedia	Occasional transfusions
HPFH	Deletion Nondeletion Unlinked to β-gene cluster	Silent increase in HbF	No transfusions

HbA = adult hemoglobin; HbF = fetal hemoglobin; HbH = hemoglobin H; HPFH = hereditary persistence of fetal hemoglobin.

8 weeks of gestation, the fetal liver takes over, synthesizing predominantly HbF ($\alpha_2\gamma_2$) and a small amount (<10%) of HbA. Between about 18 weeks and birth, the bone marrow progressively replaces the liver as the major site of red cell production; this shift is accompanied in the later stages of gestation by a reciprocal switch in production of HbA rather than HbF, so that HbF production drops to less than 2% by the end of the first year of life.

The globin genes are encoded in separate gene clusters. The α cluster (ζ,α_2,α_1) lies at the telomere of chromosome 16, whereas the β cluster ($\varepsilon,^G\gamma$ and $^A\gamma,\delta,\beta$) lies at chromosome 11p15.5. In both clusters, the genes are aligned 5′ to 3′ in the order in which they are expressed during development. Both sets of genes are under the regulation of enhancer-like elements (hypersensitive site [HS]–40 for α cluster and locus control region for β cluster) that lie some distance away at the 5′ end of the cluster. Deletion of these enhancer elements results in inactivation of any related globin gene. There are two α genes/alleles (α_2 and α_1) that differ by a few nucleotides in intron 2 and the 3′ untranslated region but nevertheless produce identical protein products. The output of the α_2 gene exceeds that of the α_1 gene by two- to three-fold.

The region around a DNase1 hypersensitive site at 40 kilobases (kb) upstream of the ζ-globin gene (HS-40) is the major regulator of α-globin gene expression. The β cluster contains a single pseudo-β gene, whereas the β cluster enhancer consists of five elements marked by erythroid-specific DNase1 hypersensitive sites lying 6 to 20 kb upstream of the ε-globin gene, with each element containing several binding sites for erythroid-specific and other transcription factors. All together, these elements are known as the locus control region, and each element contributes to the overall locus control region activity. In addition, there is an erythroid-specific hypersensitive site approximately 20 kb downstream of the β-globin gene; when the cluster is activated, the upstream and downstream hypersensitive sites are brought into proximity with the gene promoters to activate their transcription.

The individual globin genes share many general features; for example, each consists of three coding sequence exons separated by two introns in identical position but of variable length for a total length of approximately 1500 nucleotides. This structure has been highly conserved throughout evolution. The upstream regions flanking the first exon contain a number of sequence motifs that are necessary for specifying correct transcriptional initiation. A TATA box is found at 30 base pairs upstream of the initiation site together with one or more CCAAT sites at 70 base pairs upstream. The gene promoters also contain a CACCC or CCGCCC box that binds erythroid Krüppel-like factor (EKLF) 1, and some have binding sites for erythroid transcription factor GATA-1. In model systems, mutations introduced into such sequences lead to reduction in the level of transcription.

All the thalassemias have a similar pattern of inheritance; in most cases, the gene defects are transmitted in a mendelian autosomal recessive fashion. Thus, the severe, symptomatic varieties usually result from the interaction of more than one genetic determinant, for example, compound heterozygosity or homozygosity. The inheritance of α-thalassemia is more complicated because it involves the products of the linked pairs of α genes (αα) (see Clinical Manifestations).

Molecular Basis of Thalassemias

The α- and β-thalassemias are divided into disorders in which no chains are produced from the affected chromosomes (α^0 and β^0) and disorders in which the output of the chains is reduced (α^+ and β^+). For the α-thalassemias, the most common molecular defects are deletions of one or both α genes, which are designated −α and − −, respectively. The single α gene is thought to have arisen by crossover between two misaligned α genes on the homologous chromosome that can give rise to chromosomes with either single (−α) or triplicated (ααα) α-globin genes. To date, more than 40 different deletions that involve both α genes, resulting from illegitimate or nonhomologous recombination, have been reported. The lengths of deletion vary from 5.2 to more than 40 kb; the most common are those from Southeast Asia, the Mediterranean, and the Philippines, designated $--^{SEA}$, $--^{MED}$, and $--^{FIL}$, respectively. Nondeletion types of α-thalassemia (α^α) are much less common than the deletion forms; in most cases, they result from single oligonucleotide mutations in regions where the α gene sequence is critical for normal expression. Because expression of the α_2 gene is two to three times greater than that of the α_1 gene, it is not surprising that most of the nondeletion mutants predominantly affect expression of the α_2 gene. The mutations may affect the initiation codon or splicing signals, cause frame shifts, or introduce premature stop codons. At least five single-nucleotide variants affect the natural termination codon (TAA) of the α_2-globin gene. Among these, hemoglobin Constant Spring ($\alpha^{cs}\alpha$) is the most common and extensively studied. Finally, there are several α-globin variants that are so unstable that they undergo rapid, post-synthetic degradation. In such situations, β chains remain in excess within the red cell, and the patient carriers of these α-chain variants, by definition, have α-thalassemia. To date, 17 unstable α variants have been shown to produce the phenotype of α-thalassemia to a greater or lesser extent.

Like the α-thalassemias, the β-thalassemias are classified as β^0 (in which no β-globin is produced) and β^+ (in which some but less than normal β-globin is produced). In some cases, the defects in β-chain production are so mild that they are designated β^{++}. So far, more than 400 different thalassemic mutations of the β-globin gene have been reported; most are point mutations within the gene or its immediate flanking sequence. A few β-thalassemia mutations that segregate independently of the β-globin gene cluster have been described, presumably involving *trans*-acting regulatory factors. The distribution of alleles is highly variable from one population to another; but within each population, only a few alleles are common. The nondeletion forms of β-thalassemia account for most β-thalassemia alleles. An updated list of mutations (including transcriptional mutations, RNA processing mutations, and mutations affecting translation) is accessible at the Globin Gene Server website (http://globin.cse.psu.edu).

Simple deletions of the β-globin gene are rare, ranging in size from 290 base pairs to more than 60 kb. The 619–base pair deletion at the 3′ end of the β gene is relatively common among Sind and Punjabi populations in India and Pakistan. The remaining deletions are restricted to single families, are necessarily β^0-thalassemias, and interestingly are associated with unusually high levels of HbA_2 in heterozygotes. Large deletions that affect the entire β-globin gene cluster $(\varepsilon\gamma\gamma\delta\beta)^0$ are rare and restricted to single families. Finally, some highly unstable β-chain variants may be manifested as a dominant form of β-thalassemia.

The δβ-thalassemias and hereditary persistence of fetal hemoglobin are the result of deletions affecting various parts of the β-globin locus. These deletions are partially compensated by an increased expression of the γ genes that raises the level of HbF. The length of deletion accounts for different forms of δβ-thalassemia, including both $^G\gamma$ and $^A\gamma$ genes or only $^A\gamma$, and varies from 9 to 100 kb. Hemoglobin Lepore is a hybrid of δ and β chains resulting from a crossover between the two misaligned genes; this hemoglobin is synthesized inefficiently and gives rise to a form of δβ-thalassemia. Deletions of δ and β genes are also the molecular basis for many forms of hereditary persistence of fetal hemoglobin that, usually have higher levels of compensatory HbF production than the δβ-thalassemias. Hereditary persistence of fetal hemoglobin also can be caused by point mutations in the promoter region upstream from the transcription start site in either the $^G\gamma$ or $^A\gamma$ genes that alter the binding of one or more transcription factors. Genetic studies have identified three major quantitative trait loci that account for 20 to 50% of the common variation in

HbF levels in patients with β-thalassemia and sickle cell disease as well as in healthy adults.

CLINICAL MANIFESTATIONS

The clinical manifestations (phenotype expression) of thalassemia syndromes are extremely variable and depend on the degree of globin chain imbalance.[5]

α-Thalassemias

There are two major classes of α-thalassemias: α^0, in which both α genes are inactivated (− −/); and α^+, in which only one of the pair is defective because of α gene deletion or mutation (−α or $\alpha\alpha^T$). The clinical spectrum of α-thalassemias correlates well with the number of the affected α genes, that is, from normal to the loss of all four genes.

The α-thalassemias are common in areas where β-thalassemias are also found at a high frequency. Thus, the coinheritance of α- and β-thalassemia trait may occur and even ameliorate the hematologic parameters. In families in which α- and β-thalassemias are present, genotyping is essential. The unstable mutant Hb^{CT} causes a severe reduction in α_2-globin expression from the affected chromosome; therefore, the carriers and particularly the homozygotes have a more severe phenotype than α-thalassemia minor but not as severe as most cases of HbH disease.

α-Thalassemia Minor

The inheritance of a normal allele (αα) with one of the α^+ or α^0 alleles most frequently results in α-thalassemia minor (− −/αα; −α/αα; $-\alpha^T/\alpha\alpha$; $\alpha^T\alpha/-\alpha;-\alpha/-\alpha$). In general, carriers of such genotypes have lower levels of total hemoglobin, mean corpuscular volume, and mean cell hemoglobin but higher red blood cell counts than normal. The greatest differences are seen in mean cell hemoglobin, which is usually less than 26 pg. The peripheral blood smear shows various degrees of hypochromia with some target cells and occasional poikilocytes (Chapter 143). In carriers of α^0-thalassemia (− −/αα), it is possible to generate a few red cell HbH inclusions (β_4). The carriers of nondeletional forms ($\alpha\alpha^T/\alpha\alpha$) show slightly more marked hematologic changes than those for deletional forms. The hemoglobin constitution of adult carriers of α^+- or α^0-thalassemia is indistinguishable from normal but has slightly lower levels of HbA_2. Traces of hemoglobin Bart (γ_4) in the neonatal period are detectable in a large proportion of neonates with α-thalassemia, and they decline during the first 6 months after birth.

Hemoglobin H Disease

HbH disease most frequently results from the co-presence of α^+- and α^0-thalassemia, and not surprisingly most patients originate from the populations of southeastern Asia, the Mediterranean, and the Middle East. HbH disease is a diagnosis attributed to subjects older than 6 months having a sufficient globin imbalance to produce detectable levels of HbH (>1 to 2%) in their peripheral blood together with inclusion bodies (β_4 tetramers) in their red cells on peripheral smear. The clinical phenotypes encompass a wide spectrum from mild clinical manifestations to thalassemia intermedia and are included in the so-called non–transfusion-dependent thalassemias. The predominant features of HbH disease are a hypochromic, microcytic anemia with jaundice, and hepatosplenomegaly. Because the main mechanism of the anemia is hemolysis rather than dyserythropoiesis, only a few patients have clinical evidence of an expanded erythron. The most common complication of HbH disease is the development of hypersplenism due to severe splenomegaly (Chapter 154). Other complications include gallstones, leg ulcers, increased risk for infection, folic acid deficiency, and increased risk for venous thrombosis mainly after splenectomy. Hemoglobin levels range in different series from 3 to 12 g/dL, with fluctuations that may occur after exposure to an oxidant drug, infection, or transient aplasia possibly due to intercurrent viral infection. Rarely, patients with HbH disease require regular blood transfusions. The anemia is associated with reticulocytosis and typical thalassemic changes of the red cell indices. The relative amount of HbH varies from 1 to 40%. The values of HbA_2 are always reduced. The peripheral blood film shows hypochromia with variable anisopoikilocytosis, target cells, and basophilic stippling. The characteristic feature of HbH disease is that it is always possible to generate multiple inclusions in the red cells after incubation with brilliant cresyl blue. The bone marrow shows marked erythroid hyperplasia.

Hydrops Fetalis

The most severe form of α-thalassemia is hydrops fetalis, in which all four α-globin genes are deleted (genotype − −/− −). Because α-globin chains are absent during gestation, hemoglobin Bart (γ_4) becomes the dominant hemoglobin. Because of its high oxygen affinity, hemoglobin Bart is unable to deliver oxygen to tissues, and the intrauterine consequences are progressive severe anemia, severe ineffective erythropoiesis with marked extramedullary erythropoiesis, massive organomegaly, heart failure, severe hypoalbuminemia, and edema. The hemoglobin levels range from 3 to 20 g/dL; the peripheral blood film is characterized by marked anisopoikilocytosis, large hypochromic macrocytes, and many nucleated red cells. The hemoglobin consists almost entirely of hemoglobin Bart (80 to 90%), with some remaining HbH and Portland. Mothers of these infants often have a history of previous neonatal deaths. Without medical care, women carrying these fetuses may have delivery and postpartum complications (e.g., retained placenta, eclampsia, sepsis) (Chapter 221).

Several reports describe α-thalassemia in association with intellectual disability (so-called ATR-16 syndrome). These conditions are mainly due to large deletions (one or two megabases) of the tip of chromosome 16, including the α-globin gene cluster. However, several cases have no deletions or other apparent abnormalities of the α-globin gene cluster. It has been shown that these patients with a peculiar phenotype characterized by severe mental retardation, dysmorphic facies, genital abnormalities, and α-thalassemia have a disorder that maps to the X chromosome (ATR-X syndrome).

β-Thalassemias

The β-thalassemias, which include a considerably heterogeneous group of disorders of hemoglobin synthesis, are characterized by a reduced output of the β chains of adult hemoglobin.[6] The clinical classification includes thalassemia major (transfusion dependent), thalassemia intermedia (of intermediate severity, non–transfusion dependent), and thalassemia minor (asymptomatic) (Fig. 148-1 and see Table 148-1). The severity of the clinical manifestations correlates well with the degree of imbalance of globin chains. Depending on the β-globin gene defects and their interaction, the production of β-globin chains is quantitatively reduced to different degrees, whereas the synthesis of α-globin continues as normal. The result is an accumulation of excess unmatched α-globin chains in the erythroid precursors. The free α-globin chains, which are not able to form stable tetramers, precipitate in the erythroid precursors where they form inclusion bodies that damage the red cell membrane, thereby causing premature destruction of erythroid precursors in the bone marrow (ineffective erythropoiesis). Ineffective erythropoiesis leads to a sequence of events responsible for bone marrow expansion, anemia, hemolysis, splenomegaly, and increased iron absorption. Any factor that reduces the degree of chain imbalance and the magnitude of α-chain excess, such as coinheritance of α-thalassemia or an innate ability to increase fetal hemoglobin, will ameliorate the clinical expression of the disease (Fig. 148-2).[7]

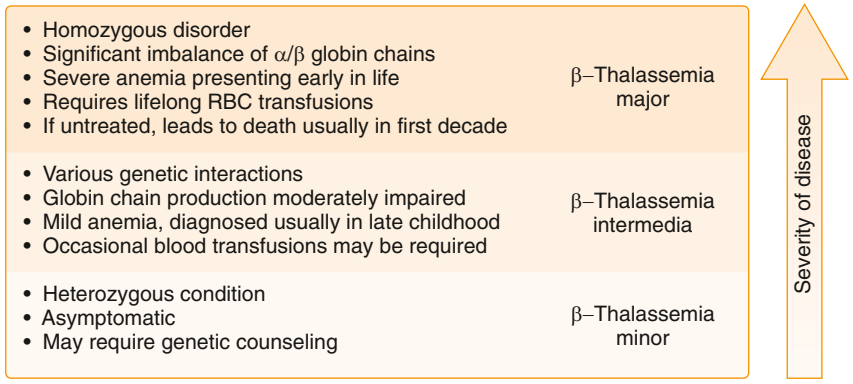
β-Thalassemia Minor

Thalassemia minor is the heterozygous state of β-thalassemia. Subjects with thalassemia minor are "carriers" of a single β-globin gene defect, and they are usually asymptomatic except for a mild microcytic anemia. The carriers are usually identified incidentally[8] during an intercurrent illness, in the course of a family study, or as part of a population survey. Carriers of β-thalassemia may have a triplicated α-gene allele: its coinheritance may cause a mild thalassemia intermedia phenotype due to the excess of α chains production.

The anemia is mild, microcytic, and hypochromic, and it is usually associated with a diagnostic elevation (>3.5%) in the level of HbA_2. However, coincidental iron deficiency can lower elevated HbA_2 levels to the normal range. Carriers of β-thalassemia with normal HbA_2 also have been observed in settings in which an individual with mild thalassemia intermedia was found to have one parent with typical β-thalassemia minor with elevated HbA_2, whereas the other showed either minimal or no hematologic abnormalities and normal HbA_2. Subjects with normal HbA_2 are usually carriers of silent β^{++} mutations (β^{++}). The blood smear shows characteristic microcytosis and hypochromia, with some variation in size and shape of the red cells. The presence of target cells is variable. The hematologic features are remarkably similar among different ethnic groups.

β-Thalassemia Intermedia

Thalassemia intermedia, which is a non–transfusion-dependent thalassemia disorder, describes patients with anemia, splenomegaly, and a wide spectrum of clinical severity without the full manifestations found in thalassemia major.[9] Mildly affected patients, who are almost completely asymptomatic until adult life, experience only mild anemia and spontaneously maintain hemoglobin levels between 7 and 10 g/dL. Patients with more severe thalassemia intermedia



A

	Thalassemia major more likely	Thalassemia intermedia more likely
Clinical		
Presentation (years)	< 2	> 2
Hb levels (g/dL)	< 7	7–10
Liver/spleen enlargement	Severe	Moderate to severe
Hematologic		
HbF (%)	> 50	10–50 (may be up to 100%)
HbA2 (%)	> 3.5	< 4
Genetic		
Parents	Both carriers of high HbA2 β-thalassemia	One or both atypical carriers: high HbF β-thalassemia, borderline HbA2
Molecular		
Type of β-chain mutation	Severe	Mild/silent
Coinheritance of α-thalassemia	No/rare	Yes
Hereditary persistence of fetal hemoglobin	No	Yes
δβ-thalassemia	No	Yes
Gy XmnI polymorphism	No	Yes

B

In between is a wide spectrum of clinical phenotypes labeled thalassemia intermedia because of different genetic interactions characterized by moderate to severe transfusion-independent anemia. B, Tentative criteria to differentiate thalassemia major from thalassemia intermedia at presentation. HbA = adult hemoglobin; HbF = fetal hemoglobin; RBC = red blood cell.**

generally present between the ages of 2 and 6 years; although they are able to survive without regular transfusion therapy, growth and development can be retarded. Most thalassemia intermedia patients are homozygotes or compound heterozygotes for mild to moderate β-gene mutations (β^+/β^+;β^0/β^+); less commonly, only a single β-globin gene is affected. Because the clinical severity of the disease is dictated by the different extent of globin chain imbalance, at least three different mechanisms may promote the mild clinical characteristics of thalassemia intermedia compared with thalassemia major: inheritance of mild or silent β-gene mutations; coinheritance of determinants associated with increased γ-chain production, which contributes to neutralizing the large proportion of unbound α chains; and coinheritance of α-thalassemia, which reduces the synthesis of α chains, thereby reducing the α/non-α chain imbalance.

Three main factors are responsible for the clinical sequelae in patients with thalassemia intermedia: degree of ineffective erythropoiesis, chronic anemia, and iron overload.[10] The ineffective erythropoiesis primarily depends on the underlying molecular defects and is due to precipitation of free α chains in erythroid precursors in the bone marrow, where they cause membrane damage and premature cell death. The degree of ineffective erythropoiesis is the primary determinant of the anemia of thalassemia intermedia; peripheral hemolysis of mature, circulating red cells, and an overall reduction in hemoglobin synthesis are secondary. Hemolysis and damaged red cells that expose negatively charged membrane phosphatidyl-serine residues have been linked to the development of a hypercoagulable state and increased risk for pulmonary hypertension (Chapter 69) in patients with thalassemia intermedia.

Chronic anemia and chronic ineffective erythropoiesis lead to an inappropriate increase in gastrointestinal iron absorption, thereby resulting in iron overload even in the absence of blood transfusion. The mechanism is a reduced expression of hepcidin, a hepatic peptide that plays a central role in iron homeostasis (Chapter 196). Moreover, the growth and differentiation factor 15 (GDF15), which is secreted by erythroid precursors and overexpressed in the presence of ineffective erythropoiesis, may suppress the synthesis of hepcidin. Erythroferrone, secreted by erythroblasts, may also play a role in hepcidin regulation. Taken together, ineffective erythropoiesis (leading to increased GDF15) and chronic anemia/hypoxia result in hepcidin suppression, increased dietary iron absorption from the gut, and increased release of recycled iron from the reticuloendothelial system, thereby leading to an iron overload situation similar to that observed in patients with hereditary hemochromatosis syndromes (which also are characterized by impaired hepcidin production; Chapter 196).

As a consequence of these pathophysiologic processes, several complications are seen in patients with thalassemia intermedia but not with thalassemia major, especially in non-splenectomized patients. Cholelithiasis is much more common in thalassemia intermedia than in thalassemia major because of ineffective erythropoiesis and peripheral hemolysis. Extramedullary hematopoiesis, as a compensatory mechanism, leads to the formation of erythropoietic tissue masses that primarily involve the spleen, liver, lymph nodes, and vertebrae. These masses may cause neurologic problems, such as spinal cord compression (sometimes causing paraplegia) and intrathoracic masses. Leg ulcers that are rare in well-transfused patients with thalassemia major are common in adult patients with thalassemia intermedia. Thrombotic risk is definitely increased in patients with thalassemia intermedia, especially after splenectomy. Although stroke is rare in thalassemia intermedia, asymptomatic brain damage, including ischemia,

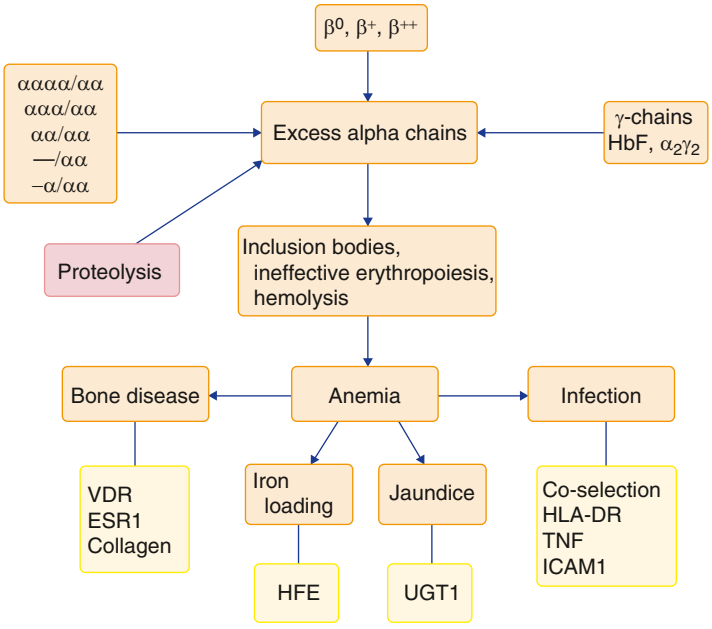


FIGURE 148-2. Pathophysiology of β-thalassemias and modifiers of globin chain imbalance. The severity of ineffective erythropoiesis is dependent on the degree of excess free α chains that result primarily from three different mechanisms: (1) inheritance of severe, mild, or silent β-chain mutations; (2) coinheritance of determinants associated with increased γ-chain production; and (3) coinheritance of α-thalassemia. A phenotype of thalassemia intermedia may result from the increased production of α-globin chains by a triplicated (αααα) or quadruplicated (ααααα) α genotype associated with β heterozygosity. Inheritance of polymorphisms or mutations of genes involved in bone, iron, and bilirubin metabolism as well as in infection may contribute to modify the clinical course of the disease. ESR1 = estrogen receptor 1; HbF = fetal hemoglobin; HFE = hereditary hemochromatosis gene; HLA = human leukocyte antigen; ICAM1 = intercellular adhesion molecule 1; TNF = tumor necrosis factor; UGT1 = UDP-glucose : glycoprotein glucosyltransferase 1; VDR = vitamin D receptor.

has been documented by magnetic resonance imaging (MRI) and computed tomography. Pulmonary hypertension (Chapter 69) is prevalent in thalassemia intermedia patients (approximately 60%) and is thought to be the primary cause of heart failure in this patient population. Liver disease due to viral infection is less frequent than in thalassemia major; however, abnormal liver enzymes are frequently observed in patients with thalassemia intermedia, primarily because of hepatocyte damage resulting from iron overload. In some of the oldest patients with thalassemia intermedia, long-term overload has resulted in cirrhosis (Chapter 139) and hepatocellular carcinoma (Chapter 181), similar to what may be found in hereditary hemochromatosis (Chapter 196).

β-Thalassemia Major

The major forms of β-thalassemia (still sometimes called Cooley anemia) are disorders in which life can be sustained only by regular blood transfusions. This condition usually results from the homozygous state or from the compound heterozygous state for severe β-gene mutations (β^0). The typical forms of thalassemia major become manifested during the first year of life, during which γ chains are switched off but not replaced by β-chain synthesis. Left untreated, these infants are incapable of maintaining a hemoglobin level above 5 g/dL, show marked bone deformities and growth retardation, and are considered as "transfusion-dependent thalassemia patients." They develop the "thalassemic" facies due to frontal bossing of the skull and protrusion of the jaws and cheekbones. The magnitude of the increase in erythropoiesis may result in extramedullary masses arising usually from the sternum and ribs. Progressive hepatosplenomegaly, which is a constant finding, leads to pancytopenia. The early childhood of the untreated or inadequately treated thalassemia major patients is interspersed with various complications, including recurrent infections, spontaneous fractures, gallstones, and leg ulcers.[11]

Heart failure in thalassemia major is multifactorial but is thought to be principally related to chronic anemia and the toxic effects of iron overload in the myocardium (Chapters 47 and 196). Liver disease is due to iron overload (Chapter 196), but other genetic modifiers may affect the outcome of complications in different ways. For example, the presence of a polymorphic variant in the UGT1A1 promoter responsible for Gilbert syndrome (Chapter 133) may increase the predisposition to cholelithiasis, which is already a common complication in thalassemia. Likewise, polymorphisms in genes involved in iron homeostasis or bone metabolism may affect negatively or positively the degree of iron overload or the osteopenia and osteoporosis (Chapter 225), respectively (see Fig. 148-2).[12] Environmental factors, including social conditions, nutrition, and the availability of medical care, have also been implicated in the variable severity of clinical manifestations of thalassemia major.

δβ-Thalassemia and Hereditary Persistence of Fetal Hemoglobin

The clinical manifestations of $(\delta\beta)^0$-thalassemias are similar to those of non–transfusion-dependent thalassemia intermedia, whereas the heterozygotes are distinguished from β-thalassemia heterozygotes by normal levels of HbA_2 together with an increased HbF level of 5 to 20%. Homozygotes for Hb_{Lepore} may have phenotypes similar to either thalassemia major or thalassemia intermedia. Subjects affected by deletion or nondeletion forms of hereditary persistence of fetal hemoglobin are usually asymptomatic.

Any of the β-thalassemia defects may be coinherited with β-chain variants (HbS, HbC, HbE) and cause a clinically relevant β-thalassemia phenotype of different severity. These variants further illustrate that β-thalassemia syndromes have a wide clinical spectrum and that specific therapeutic approaches may completely change the clinical course and the natural history of these disorders (Fig. 148-3).

Hemoglobin E and Hemoglobin E Thalassemias

Hemoglobin E (HbE) is caused by a substitution of glutamic acid by lysine at codon 26 of the β-globin gene. It is a common mutation, especially in the Indian subcontinent and Southeast Asia and among people who have emigrated from those regions. The frequency of HbE approaches 60% in many regions of Thailand, Laos, and Cambodia. HbE results in reduced synthesis of the β-E chain and therefore has the phenotype of a mild form of β-thalassemia. HbE trait has little clinical significance; it may be associated with slight microcytosis without anemia, but it could be mistaken for iron deficiency without appropriate laboratory testing. Homozygous HbEE individuals have mild anemia and microcytosis, occasional splenomegaly, and peripheral blood smears showing red cell changes similar to those seen in thalassemia trait, including target cells. In this condition, hepcidin is suppressed, thereby leading to iron accumulation—even in the absence of blood transfusions and certainly worsened by them.

HbE interacts with different forms of α-thalassemia to produce a wide variety of clinical disorders.[13] Its coinheritance with β-thalassemia, a condition called HbE/β-thalassemia, is the most common severe form of β-thalassemia in Asia and globally represents about 50% of the clinically severe β-thalassemias.

DIAGNOSIS

The diagnosis of thalassemia may be required in a patient with an appropriate, suggestive clinical picture or for the identification of a heterozygote subject as part of a family study or population screening program. The general approach is common to any form of thalassemia, regardless of presentation (Fig. 148-4). The primary evaluation is based on the red cell indices by electronic cell counter and the red cell morphology on a well-stained blood film. Individuals with mean corpuscular volume below 80 fL and mean corpuscular hemoglobin below 27 pg with normal iron parameters require further investigation. The red blood cell number is usually higher than normal. In the presence of anemia with thalassemic red cell changes, the next step is the evaluation of hemoglobin fractions (HbA, HbA_2, HbF, or hemoglobin variants) by electrophoresis on cellulose acetate at alkaline pH or, even better, by high-performance liquid chromatography that enables the precise measurement of HbA_2, HbF, and HbA and the provisional identification of a large number of hemoglobin variants, including HbE. An HbA_2 level above 3.5% associated with hypochromic microcytic red cells is diagnostic of β-thalassemia minor. HbA_2 values between 3.2 and 3.5% (borderline) should be interpreted with care because they could be due to interaction of more than one thalassemic defect (α and β), a silent β mutation, or concomitant iron deficiency. If iron deficiency is present, it should be corrected and the HbA_2 estimation repeated. The majority of individuals with thalassemic red cell indices with normal or low HbA_2 and normal HbF will be α^0-thalassemia carriers or α^+-thalassemia homozygotes. Carriers of α^0-thalassemia may have a few red cells with HbH inclusions. Microcytosis with low or normal HbA_2 levels with elevated HbF (2 to 20%) indicates heterozygosity for δβ-thalassemia. Patients with hereditary persistence of fetal hemoglobin usually have normal red blood cell indices but increased levels of HbF with different intercellular distribution (homogeneous or

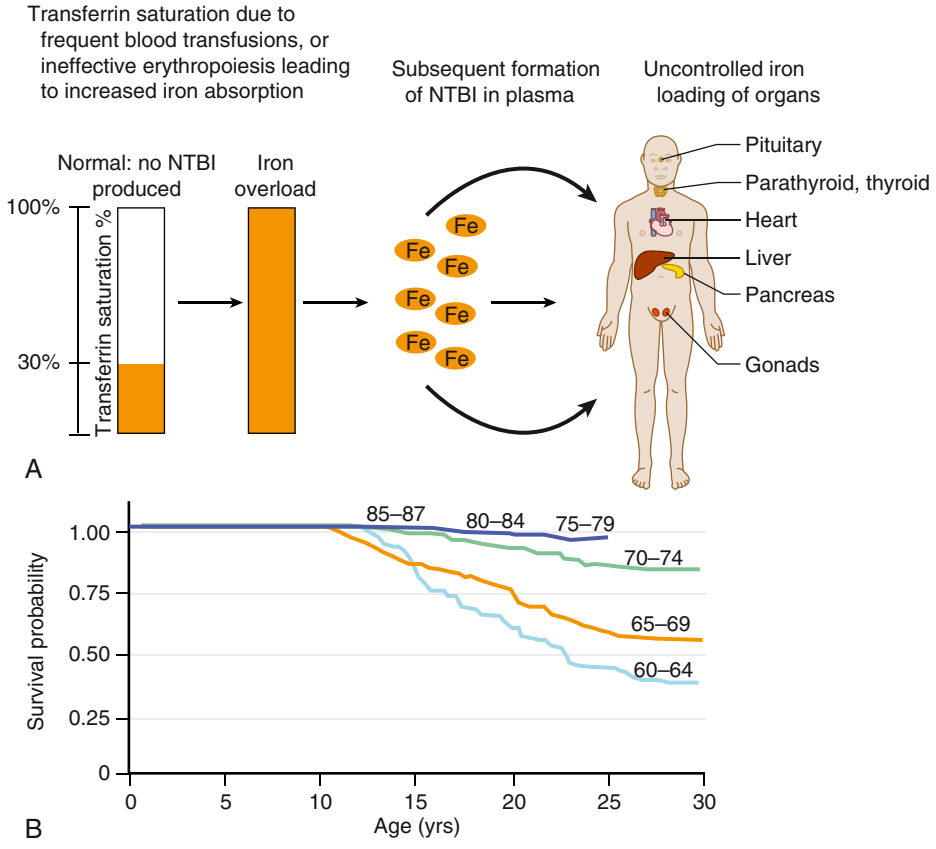

FIGURE 148-3. A, Transfusion iron overload and specific organ loading. B, Survival of Italian thalassemia major patients by cohort of birth. NTBI = non–transferrin-bound iron.

pancellular with the exception of heterocellular hereditary persistence of fetal hemoglobin) compared with δβ-thalassemia (uneven or heterocellular).

The definitive diagnosis of the thalassemia syndromes involves the identification of the underlying mutations by polymerase chain reaction (PCR) restriction enzyme analysis, PCR allele-specific oligonucleotides, gap PCR, and direct sequencing that at present is probably the easiest and most reliable method. For deletion forms of α-thalassemia, the multiplex ligation-dependent probe amplification is a recently introduced, useful method.

TREATMENT AND PROGNOSIS

Life expectancy is normal in patients with β-thalassemia minor. Other patients affected by different forms of thalassemia develop a variety of complications mainly due to iron overload, which requires monitoring to direct iron chelation therapy. The most notable are heart failure and iron overload in the liver.

Medical Treatment

Thalassemia Minor

No specific treatment is required for α- or β-thalassemia heterozygotes (carriers, thalassemia minor), but they should receive appropriate genetic counseling. During pregnancy, thalassemia-carrying women may become more anemic, so they should be observed carefully, mainly during the second and third trimesters, and supported with folic acid. When true iron deficiency is associated with thalassemia traits, iron supplementation should be provided, and levels of transferrin saturation and ferritin should be monitored.

Hemoglobin H Disease

HbH patients in general have higher hemoglobin levels (8 to 9 g/dL) and do not need regular blood transfusion. Supplementation with folic acid (2 to 5 mg/day) is generally recommended, especially in pediatric patients. The major complications in HbH disease are hemolytic crises that may occur during or after acute infections; in such cases, immediate intervention, including blood transfusions and treatment for infections, should be promptly administered. Prognosis generally depends on the degree of transfusion-dependency and iron overload.

Thalassemia Intermedia and Major

The clinical management of thalassemia intermedia and thalassemia major remains challenging. Prolongation of life, now well into the third or fourth decade, is accompanied by several complications, partly due to the underlying disorder and partly as a consequence of the treatment with blood transfusions and iron overload.

Patients with thalassemia intermedia generally experience puberty late, but they have normal sexual development and are usually fertile. Women with thalassemia intermedia may have successful pregnancies, although complications may occur during pregnancy. Overall prognosis generally depends on the degree of transfusion-dependency and iron overload.

In untreated β-thalassemia major, the mortality rate is high around puberty. However, children who are well transfused to maintain a hemoglobin level above 9 g/dL have relatively normal growth and development, and if they are adequately transfused and are fully adherent with iron chelation therapy (see Iron Overload) can enter puberty and become sexually mature. Unfortunately the current adult population of thalassemia major patients often suffers from now-avoidable side effects of long-term treatment, including transfusion-associated infections (particularly hepatitis B and hepatitis C infection [Chapters 134 and 135] and, in some populations, HIV infection [Chapter 355]), as well as end-organ damage (liver, heart, endocrine glands) due to unsatisfactory long-term iron chelation. The main causes of death in adult thalassemia major patients still remain cardiac complications, mainly in poorly chelated patients, although liver cirrhosis is also increasing because of the prolongation of life.

The supportive treatment of thalassemia major patients, best provided by a team of experts, includes regular transfusion therapy and iron chelation. The optimal transfusion regimen involves regular blood transfusions, usually administered every 2 to 5 weeks, to maintain the pretransfusion hemoglobin levels above 9 to 10.5 g/dL. The decision to initiate lifelong transfusion therapy should be based on a definitive diagnosis of severe thalassemia, taking into account the molecular defects, the severity of anemia on repeated measurement, the level of ineffective erythropoiesis, and the clinical criteria (such as failure to thrive or bone changes). It is advisable that thalassemia major patients receive leukoreduced packed red cells to minimize transfusion reactions and the transmission of pathogens. Adverse reactions to red blood cell transfusions may occur during or after transfusion and can be hemolytic and nonhemolytic. Transfusion-related acute lung injury is rare but severe and must be immediately managed (Chapter 162).

Many patients with thalassemia major commonly require splenectomy because of hypersplenism, but optimal management may delay or even obviate the need for splenectomy. Splenectomy should be considered only for patients whose annual blood consumption increases progressively and is responsible for significant increases in iron stores despite good chelation therapy or in the presence of symptoms due to splenic enlargement or hypersplenism. The major complication of splenectomy is severe and sometimes overwhelming infection (Chapter 154). Because removal of the spleen may reduce the primary immune response to encapsulated organisms, it is advisable to delay splenectomy until patients are at

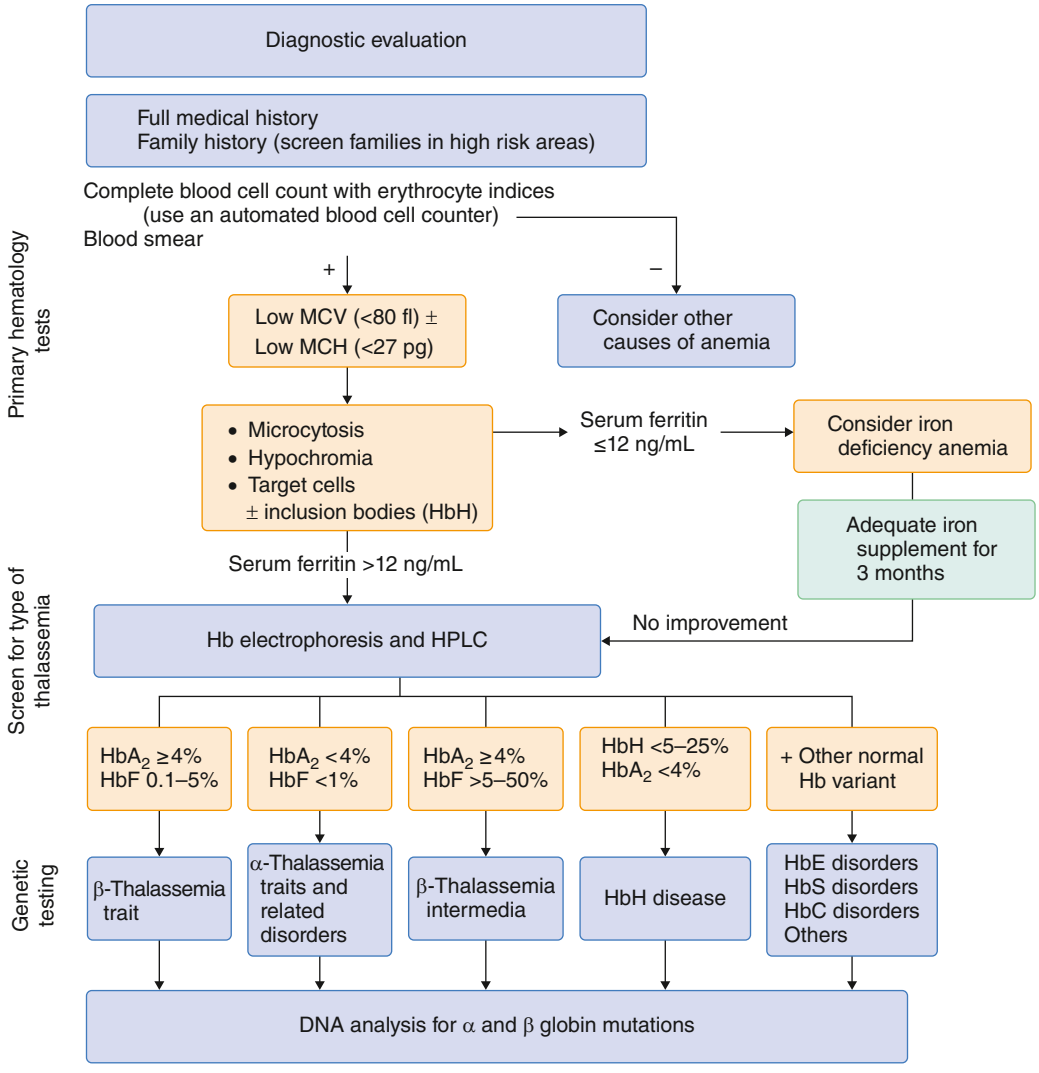

FIGURE 148-4. Diagnostic approach to suspected thalassemia. Hb = hemoglobin; HPLC = high-performance liquid chromatography; MCH = mean corpuscular hemoglobin; MCV = mean corpuscular volume.

least 5 years old. The mortality rate for overwhelming infection after splenectomy in patients with thalassemia is approximately 50% despite intensive supportive care. Therefore, it is mandatory to adopt preventive measures including immunoprophylaxis (vaccination against *Streptococcus pneumoniae*, pneumococcus, and meningococcus) (Chapter 154), chemoprophylaxis, and education of the parent and patient to recognize and to report febrile illnesses. After splenectomy, patients with thalassemia also have an increased risk of thrombosis.

The management of non–transfusion-dependent thalassemia intermedia is more complicated because of the wide heterogeneity of phenotypes. However, increasing evidence supports the benefit of preventive transfusion therapy to decrease the incidence of complications rather than reserving transfusion for when complications develop. The initiation of iron chelation therapy in patients with thalassemia intermedia depends not only on the amount of excess iron but also on the rate of iron accumulation, the duration of exposure to excess iron, and various other factors in individual patients.

Increasing Red Cell Release

Two new molecules, sotatercept[14] and luspatercept,[15] which are activin-type IIA and IIB receptor fusion proteins, can increase the release of mature erythrocytes into the circulation by acting mainly on late-stage erythropoiesis. Luspatercept (a recombinant fusion protein that binds to select transforming growth factor β superfamily ligands, given subcutaneously at a dose of 1.00 to 1.25 mg/kg every 3 weeks) is approved for adults with transfusion-dependent β-thalassemia, in whom it can reduce the transfusion burden by at least 33%, with analogous reductions in serum ferritin levels and no clinically meaningful changes in liver or myocardial iron concentrations.[A1]

Stimulation of Hemoglobin F Synthesis

An alternative treatment of β-thalassemia consists of the pharmacologic stimulation of HbF synthesis. In humans, hemoglobin switch from HbF to HbA occurs in the period around birth as a result of γ- to β-globin gene switching. A number of pharmacologic agents able to reactivate HbF synthesis have been identified, including hypomethylating agents, histone deacetylase inhibitors, and hydroxyurea. Whereas the effect of these pharmacologic treatments (particularly hydroxyurea) in sickle cell disease is clear (Chapter 149), their benefit on the clinical course of β-thalassemia is presently limited, perhaps because of the higher level of HbF required in β-thalassemia to achieve clinical results compared with those observed in sickle cell disease.

The reduction of α-globin expression may provide an equally plausible approach to ameliorating clinically severe forms of β-thalassemia, especially in patients with hemoglobin E β-thalassemia, who comprise about 50% of all patients born each year with severe β-thalassemia.

Experimental Therapies

Gene therapy (Chapter 34) using a lentivirus vector[16] or genome editing through CRISPR/Cas9 technology[17] is a potentially useful approach for increasing fetal hemoglobin production in patients who have thalassemia syndromes. Ongoing clinical trials are assessing efficacy in patients with transfusion-dependent β-thalassemia. New molecules with the potential ability to correct ineffective erythropoiesis or to generate iron-restricted erythropoiesis are in phase 2 clinical trials.

Iron Overload

Iron overload, which is an inevitable and serious complication of long-term blood transfusion therapy and hyperabsorption of dietary iron, requires adequate treatment to prevent early death, mainly from iron-induced cardiac disease.[18] The principal methods of determining body iron levels (Chapter 196) are measurements of the serum ferritin level and assessment of liver iron concentration from biopsy tissue or, as an alternative noninvasive method, by R2 MRI. High serum ferritin levels (>2500 μg/L) and high liver iron concentration (>15 g/dry weight) indicate high risk for significant morbidity and mortality. A cut-off of 800 μg/L ferritin and more than 7 g/dry weight liver iron concentration have been associated with high risk for morbidity in thalassemia intermedia and other forms of non–transfusion-dependent thalassemias.

Cardiac iron can be measured by a T2* MRI procedure that allows estimation of the cardiac iron load. MRI T2* values below 10 milliseconds are always associated with severe iron load and high risk for heart failure within 1 year. MRI T2* values above 20 milliseconds are considered normal, meaning no iron in the heart. Echocardiography also may be useful to evaluate functional changes.

For other organs, including liver disease, endocrinopathies, lung disease, thrombophilia, and bone disease, the diagnostic approaches are similar to those used in hemochromatosis (Chapter 196).

The oral iron chelator deferasirox is effective and safe in removing excess iron from different organs, including the heart[A2,A3] and is the first-line treatment in most countries.[19] The dose should be individualized according to age, history of adherence with previous chelation, and other factors. Monitoring and adjustment of iron chelation by repeated measurements of ferritin, calculation of iron intake by transfusions, and, whenever possible, measurement of cardiac and liver iron at least once by MRI are mandatory.

Prior to the availability of oral agents, the standard chelation therapy was deferoxamine, given for 10 to 24 hours daily as a slow, continuous, subcutaneous infusion 5 to 7 days per week. Unfortunately, adherence with the rigorous regimen of daily subcutaneous infusions is a serious limiting factor, and life expectancy in nonadherent patients is not different from that of untreated patients. The combination of deferasirox plus deferoxamine can further reduce iron overload compared with deferasirox alone.[A4]

Another oral iron chelator, deferiprone (75 to 100 mg/kg/day), may be more effective than deferoxamine in protecting the heart from the accumulation of iron.[A5] However, its use is restricted to U.S. patients who are unable to use deferoxamine or patients with an unsatisfactory response to deferoxamine, as judged by serum ferritin levels and by liver iron concentrations. A potential benefit of combined deferoxamine and deferiprone therapy has been observed, and this combination should be considered for patients with high levels of heart iron or cardiac dysfunction.

In patients with thalassemia major and cardiac siderosis, amlodipine added to chelation therapy reduces cardiac iron more effectively than chelation therapy alone,[A6,A7] but larger studies will be required to inform the evaluations. The use of proton pump inhibitors may further reduce serum ferritin levels.[A8]

Hydrops Fetalis

Infants with hydrops fetalis syndrome almost always die either in utero (30 to 40 weeks' gestation) or soon after birth, but some infants with hemoglobin Bart hydrops fetalis can survive with in utero blood transfusions and premature delivery by caesarean section. However, subsequent development is abnormal, and survivors require regular blood transfusions after birth.

Bone Marrow Transplantation

Allogeneic hematopoietic cell transplantation (Chapter 163) in thalassemia syndromes has been increasingly successful during the past two decades, mainly in β-thalassemia major.[20] Predictors of poor transplant outcome are hepatomegaly, history of irregular chelation, and hepatic fibrosis. Patients are categorized into three risk classes. Class 1 patients have none of these adverse risk factors, class 2 patients have one or two adverse risk factors, and class 3 patients have all three. The probabilities of thalassemia-free survival for patients younger than age 17 years at the time of hematopoietic cell transplantation from a human leukocyte antigen (HLA)-identical relative were 87% and 85%, respectively, in patients belonging to class 1 and class 2 and much lower in young patients in class 3. The progressive adjustment of conditioning regimens in class 3 patients and in adults (>17 years old) has significantly reduced the incidence of transplant-related mortality in patients in class 3. Only 25 to 30% of patients with diseases potentially curable by hematopoietic cell transplantation have a suitable HLA-compatible sibling. Bone marrow transplantation from unrelated donors increases significantly the incidence of acute and chronic graft-versus-host disease, particularly in thalassemia. A study from the Eurocord cooperative group reported the outcome of 33 patients with class 1 and class 2 thalassemia who received cord blood hematopoietic stem cells from an HLA-identical sibling; no patient died of transplant-related complications, suggesting that related cord blood hematopoietic cell transplantation is a safe procedure for thalassemia patients.

UNSTABLE HEMOGLOBINOPATHIES

More than 80 rare mutant hemoglobins have been reported to cause hemolytic anemia by either amino acid replacements or deletions that significantly lower the solubility of hemoglobin. These mutant hemoglobins thereby form intracellular precipitates that can be detected as so-called Heinz bodies when the blood smear is exposed to a supravital stain. Structural abnormalities include mutations that weaken the linkage between heme and globin, disrupt secondary (α-helical) structure, or introduce a charged or polar side group into the hydrophobic interior of the globin subunit.

This disorder, sometimes called congenital Heinz body hemolytic anemia, is inherited in an autosomal dominant manner. Severely affected individuals have jaundice, splenomegaly, and, on occasion, dark brown urine due to the release of heme and aberrant conversion to dipyroles. The instability of a few of these globin mutants is so extreme that they cannot be detected by routine laboratory methods. The result is a thalassemia phenotype with microcytosis and ineffective erythropoiesis. Like individuals with glucose-6-phosphate dehydrogenase deficiency (Chapter 147), patients with unstable hemoglobin mutants often lack clinical symptoms and signs of hemolysis until they develop an infection or are exposed to an oxidant drug.

The diagnosis can be established by a combination of a positive Heinz body preparation and either abnormal hemoglobin electrophoresis or demonstration of a precipitate after exposure of a hemolysate to heat or isopropanol. Some clinics have access to a reference laboratory that can identify the specific mutation by α- and β-globin DNA sequencing.

Most individuals with this disorder do not require treatment, but some are symptomatic from severe anemia. Splenectomy generally results in a significant increase in red cell mass. However, the fraction of Heinz body–positive red cells increases markedly after splenectomy, and these patients are at significant risk for development of pulmonary hypertension and cor pulmonale.

149 SICKLE CELL DISEASE AND OTHER HEMOGLOBINOPATHIES

JO HOWARD

SICKLE CELL DISEASE

DEFINITION

Sickle cell disease is caused by a mutation in the β-globin gene. The resulting clinical syndromes are characterized by chronic hemolytic anemias and can be complicated by vaso-occlusion and vasculopathy that can cause widespread acute and chronic organ damage as well as premature mortality.

EPIDEMIOLOGY

The sickle mutation became prominent several thousands of years ago in Sub-Saharan African and Arab-Indian populations. Its persistence was due to a selective advantage in areas where falciparum malaria was endemic, with sickle trait carriers estimated to have approximately 90% protection against severe malaria infection. The carrier frequency is now highest in West and Central Africa (up to 50%), in Arab populations in the Middle East, and in

Cardiac iron can be measured by a T2* MRI procedure that allows estimation of the cardiac iron load. MRI T2* values below 10 milliseconds are always associated with severe iron load and high risk for heart failure within 1 year. MRI T2* values above 20 milliseconds are considered normal, meaning no iron in the heart. Echocardiography also may be useful to evaluate functional changes.

For other organs, including liver disease, endocrinopathies, lung disease, thrombophilia, and bone disease, the diagnostic approaches are similar to those used in hemochromatosis (Chapter 196).

The oral iron chelator deferasirox is effective and safe in removing excess iron from different organs, including the heart[A2,A3] and is the first-line treatment in most countries.[19] The dose should be individualized according to age, history of adherence with previous chelation, and other factors. Monitoring and adjustment of iron chelation by repeated measurements of ferritin, calculation of iron intake by transfusions, and, whenever possible, measurement of cardiac and liver iron at least once by MRI are mandatory.

Prior to the availability of oral agents, the standard chelation therapy was deferoxamine, given for 10 to 24 hours daily as a slow, continuous, subcutaneous infusion 5 to 7 days per week. Unfortunately, adherence with the rigorous regimen of daily subcutaneous infusions is a serious limiting factor, and life expectancy in nonadherent patients is not different from that of untreated patients. The combination of deferasirox plus deferoxamine can further reduce iron overload compared with deferasirox alone.[A4]

Another oral iron chelator, deferiprone (75 to 100 mg/kg/day), may be more effective than deferoxamine in protecting the heart from the accumulation of iron.[A5] However, its use is restricted to U.S. patients who are unable to use deferoxamine or patients with an unsatisfactory response to deferoxamine, as judged by serum ferritin levels and by liver iron concentrations. A potential benefit of combined deferoxamine and deferiprone therapy has been observed, and this combination should be considered for patients with high levels of heart iron or cardiac dysfunction.

In patients with thalassemia major and cardiac siderosis, amlodipine added to chelation therapy reduces cardiac iron more effectively than chelation therapy alone,[A6,A7] but larger studies will be required to inform the evaluations. The use of proton pump inhibitors may further reduce serum ferritin levels.[A8]

Hydrops Fetalis

Infants with hydrops fetalis syndrome almost always die either in utero (30 to 40 weeks' gestation) or soon after birth, but some infants with hemoglobin Bart hydrops fetalis can survive with in utero blood transfusions and premature delivery by caesarean section. However, subsequent development is abnormal, and survivors require regular blood transfusions after birth.

Bone Marrow Transplantation

Allogeneic hematopoietic cell transplantation (Chapter 163) in thalassemia syndromes has been increasingly successful during the past two decades, mainly in β-thalassemia major.[20] Predictors of poor transplant outcome are hepatomegaly, history of irregular chelation, and hepatic fibrosis. Patients are categorized into three risk classes. Class 1 patients have none of these adverse risk factors, class 2 patients have one or two adverse risk factors, and class 3 patients have all three. The probabilities of thalassemia-free survival for patients younger than age 17 years at the time of hematopoietic cell transplantation from a human leukocyte antigen (HLA)-identical relative were 87% and 85%, respectively, in patients belonging to class 1 and class 2 and much lower in young patients in class 3. The progressive adjustment of conditioning regimens in class 3 patients and in adults (>17 years old) has significantly reduced the incidence of transplant-related mortality in patients in class 3. Only 25 to 30% of patients with diseases potentially curable by hematopoietic cell transplantation have a suitable HLA-compatible sibling. Bone marrow transplantation from unrelated donors increases significantly the incidence of acute and chronic graft-versus-host disease, particularly in thalassemia. A study from the Eurocord cooperative group reported the outcome of 33 patients with class 1 and class 2 thalassemia who received cord blood hematopoietic stem cells from an HLA-identical sibling; no patient died of transplant-related complications, suggesting that related cord blood hematopoietic cell transplantation is a safe procedure for thalassemia patients.

UNSTABLE HEMOGLOBINOPATHIES

More than 80 rare mutant hemoglobins have been reported to cause hemolytic anemia by either amino acid replacements or deletions that significantly lower the solubility of hemoglobin. These mutant hemoglobins thereby form intracellular precipitates that can be detected as so-called Heinz bodies when the blood smear is exposed to a supravital stain. Structural abnormalities include mutations that weaken the linkage between heme and globin, disrupt secondary (α-helical) structure, or introduce a charged or polar side group into the hydrophobic interior of the globin subunit.

This disorder, sometimes called congenital Heinz body hemolytic anemia, is inherited in an autosomal dominant manner. Severely affected individuals have jaundice, splenomegaly, and, on occasion, dark brown urine due to the release of heme and aberrant conversion to dipyroles. The instability of a few of these globin mutants is so extreme that they cannot be detected by routine laboratory methods. The result is a thalassemia phenotype with microcytosis and ineffective erythropoiesis. Like individuals with glucose-6-phosphate dehydrogenase deficiency (Chapter 147), patients with unstable hemoglobin mutants often lack clinical symptoms and signs of hemolysis until they develop an infection or are exposed to an oxidant drug.

The diagnosis can be established by a combination of a positive Heinz body preparation and either abnormal hemoglobin electrophoresis or demonstration of a precipitate after exposure of a hemolysate to heat or isopropanol. Some clinics have access to a reference laboratory that can identify the specific mutation by α- and β-globin DNA sequencing.

Most individuals with this disorder do not require treatment, but some are symptomatic from severe anemia. Splenectomy generally results in a significant increase in red cell mass. However, the fraction of Heinz body–positive red cells increases markedly after splenectomy, and these patients are at significant risk for development of pulmonary hypertension and cor pulmonale.

149 SICKLE CELL DISEASE AND OTHER HEMOGLOBINOPATHIES

JO HOWARD

SICKLE CELL DISEASE

DEFINITION

Sickle cell disease is caused by a mutation in the β-globin gene. The resulting clinical syndromes are characterized by chronic hemolytic anemias and can be complicated by vaso-occlusion and vasculopathy that can cause widespread acute and chronic organ damage as well as premature mortality.

EPIDEMIOLOGY

The sickle mutation became prominent several thousands of years ago in Sub-Saharan African and Arab-Indian populations. Its persistence was due to a selective advantage in areas where falciparum malaria was endemic, with sickle trait carriers estimated to have approximately 90% protection against severe malaria infection. The carrier frequency is now highest in West and Central Africa (up to 50%), in Arab populations in the Middle East, and in

ABSTRACT

Sickle cell disease is caused when a homozygous GAG-to-GTG mutation in codon 6 of the β-globin chain of human hemoglobin results in a single amino acid substitution, Glu6Val. This point mutation is sufficient to cause increased polymerization of hemoglobin in red blood cells that are deoxygenated during transit through the microcirculation of tissues and organs, thereby leading to distortion of red cell shape from round, pliable biconcave discs to rigid sickle cells that occlude the microvasculature. The clinical sequelae of this pathophysiology include episodic vaso-occlusive events that are associated with pain crises, hemolytic anemia, stroke, acute chest syndrome, pulmonary hypertension, urologic and renal complications that can lead to chronic kidney disease, and other ischemic organ involvement. Individuals who are heterozygous for the mutation have sickle trait that does not cause disease but can be infrequently associated with specific complications. Curative options include hematopoietic stem cell transplantation and gene therapy, but at present both are associated with significant morbidity and mortality. In addition to well-coordinated palliative care, the use of hydroxyurea and transfusion therapy, including exchange transfusions, can favorably affect the natural history of the disease in certain situations. Newer treatment options that can reduce symptoms and complications include crizanlizumab, voxelotor, and L-glutamine.

some populations in India (Fig. 149-1). Forced movement of African populations during the slave trade and, more recently, migration because of war and economic pressures have led to increasing numbers of carriers and affected individuals in the Americas, the Caribbean, Europe, and worldwide.

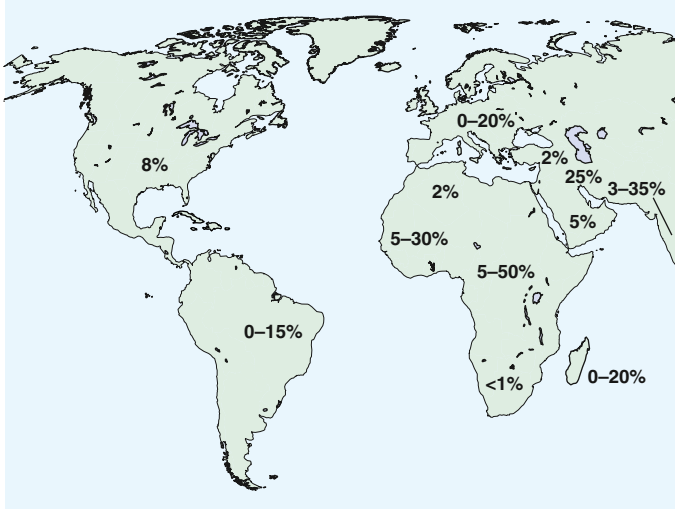

FIGURE 149-1. Worldwide prevalence of the sickle cell trait. Shown are the percentages of individuals with sickle cell trait in regions of the world where the hemoglobin S (HbS) gene is often present. In each geographic area, the prevalence of sickle cell trait can vary markedly according to racial or ethnic group, by historical migration patterns, and even from village to village. Not shown is the high concentration of the HbS gene in areas of Europe, such as London, Manchester, and Paris, where migrants from Africa or Afro-Caribbean populations have settled.

The prevalence of sickle cell disease and sickle trait varies across the world, but more than 75% of the estimated 300,000 to 400,000 births affected annually with sickle cell anemia (HbSS) occur in Sub-Saharan Africa, with these numbers predicted to increase.[1]

PATHOBIOLOGY

Globin, which is the protein portion of hemoglobin, has an iron-containing porphyrin heme ring that allows the molecule to transport oxygen efficiently. Mutations that cause changes in the amino acid sequence of the globin polypeptide can cause clinically significant diseases, including sickle cell disease, that collectively are termed hemoglobinopathies. Sickle hemoglobin (HbS:$\alpha_2\beta_2^s$), which is caused by an adenine (A) to thymidine (T) substitution (GAG to GTG) in codon 6 of the β-globin gene (HBB), results in a valine residue (Glu6Val) instead of the normal glutamic acid residue (Fig. 149-2). Homozygous sickle cell disease (HbSS) is an autosomal recessive condition, so each offspring of two sickle cell carrier parents has a 25% chance of being affected (Fig. 149-3AI).

HbS polymerizes when it becomes deoxygenated, and this polymerization distorts the shape of red cells into the characteristic sickle shape (Fig. 149-3Aii) and leads to red cell damage, hemolysis, and vaso-occlusion. The deoxygenation of red cells occurs in the circulation as they cross the capillary bed; but as they return to the lungs, oxygen uptake occurs, and the polymers deaggregate. This sickling–desickling cycle is repeated as the red cell recirculates, but if the passage of red cells is delayed, cell sickling, membrane damage, and vaso-occlusion occur before transit through the microvasculature is complete. The formation of polymers (and the severity of sickling) may be increased by a higher intracellular hemoglobin concentration, low pH, and raised temperature and can be decreased by the presence of other intracellular hemoglobins, such as fetal hemoglobin (HbF).

The polymerization of sickle hemoglobin leads to red cell damage by several mechanisms that result in red cell destruction (hemolysis) and vaso-occlusion.[2] Most hemolysis is extravascular because it occurs when macrophages

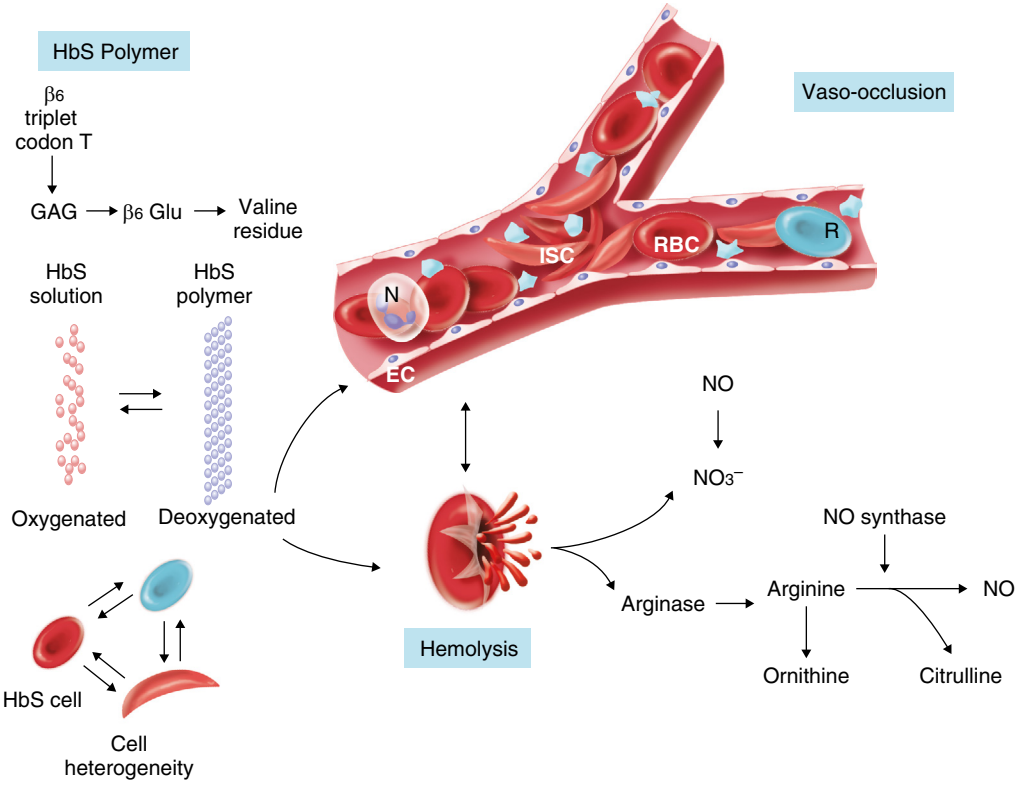

FIGURE 149-2. Pathophysiology of sickle cell disease. An adenine (A) to thymidine (T) transversion (A6T) at codon 6 in the β-hemoglobin gene on chromosome 11 (*HBB*) leads to the substitution of a glutamic acid codon by a valine codon. β6 valine allows the hemoglobin S (HbS) molecule ($\alpha_2\beta_2^5$) to polymerize when it is deoxygenated. DeoxyHbS polymer injures the erythrocyte and leads to a heterogeneous population of sickle cells with damaged membrane cytoskeleton, reduced cation and water content, and altered distribution of membrane lipids. In the vasculature, sickle cells interact with endothelium and other blood cells to cause vaso-occlusion. Some damaged erythrocytes hemolyze intravascularly, thereby releasing heme into the plasma to scavenge nitric oxide (NO) and to reduce hemoglobin to methemoglobin and nitrate. NO, by binding soluble guanylate cyclase, converts cyclic guanosine triphosphate to guanosine monophosphate, thereby relaxing vascular smooth muscle and causing vasodilation. A state of reduced endothelial NO bioavailability in sickle cell disease impairs the homeostatic vascular functions of NO, such as inhibition of platelet activation and aggregation and transcriptional repression of genes transcribing cell adhesion molecules. Hemoglobin, heme, and heme iron catalyze the production of oxygen radicals and protein nitration, potentially further limiting NO bioavailability and activating endothelium. Lysed erythrocytes also liberate arginase, which destroys L-arginine, the substrate for NO production, providing another mechanism for endothelial NO deficiency. The normal balance of vasoconstriction versus vasodilation is therefore skewed toward vasoconstriction as well as endothelial activation and proliferation. EC = epithelial cell; ISC = irreversibly sickled cell; N = neutrophil; R = reticulocyte; RBC = red blood cell.

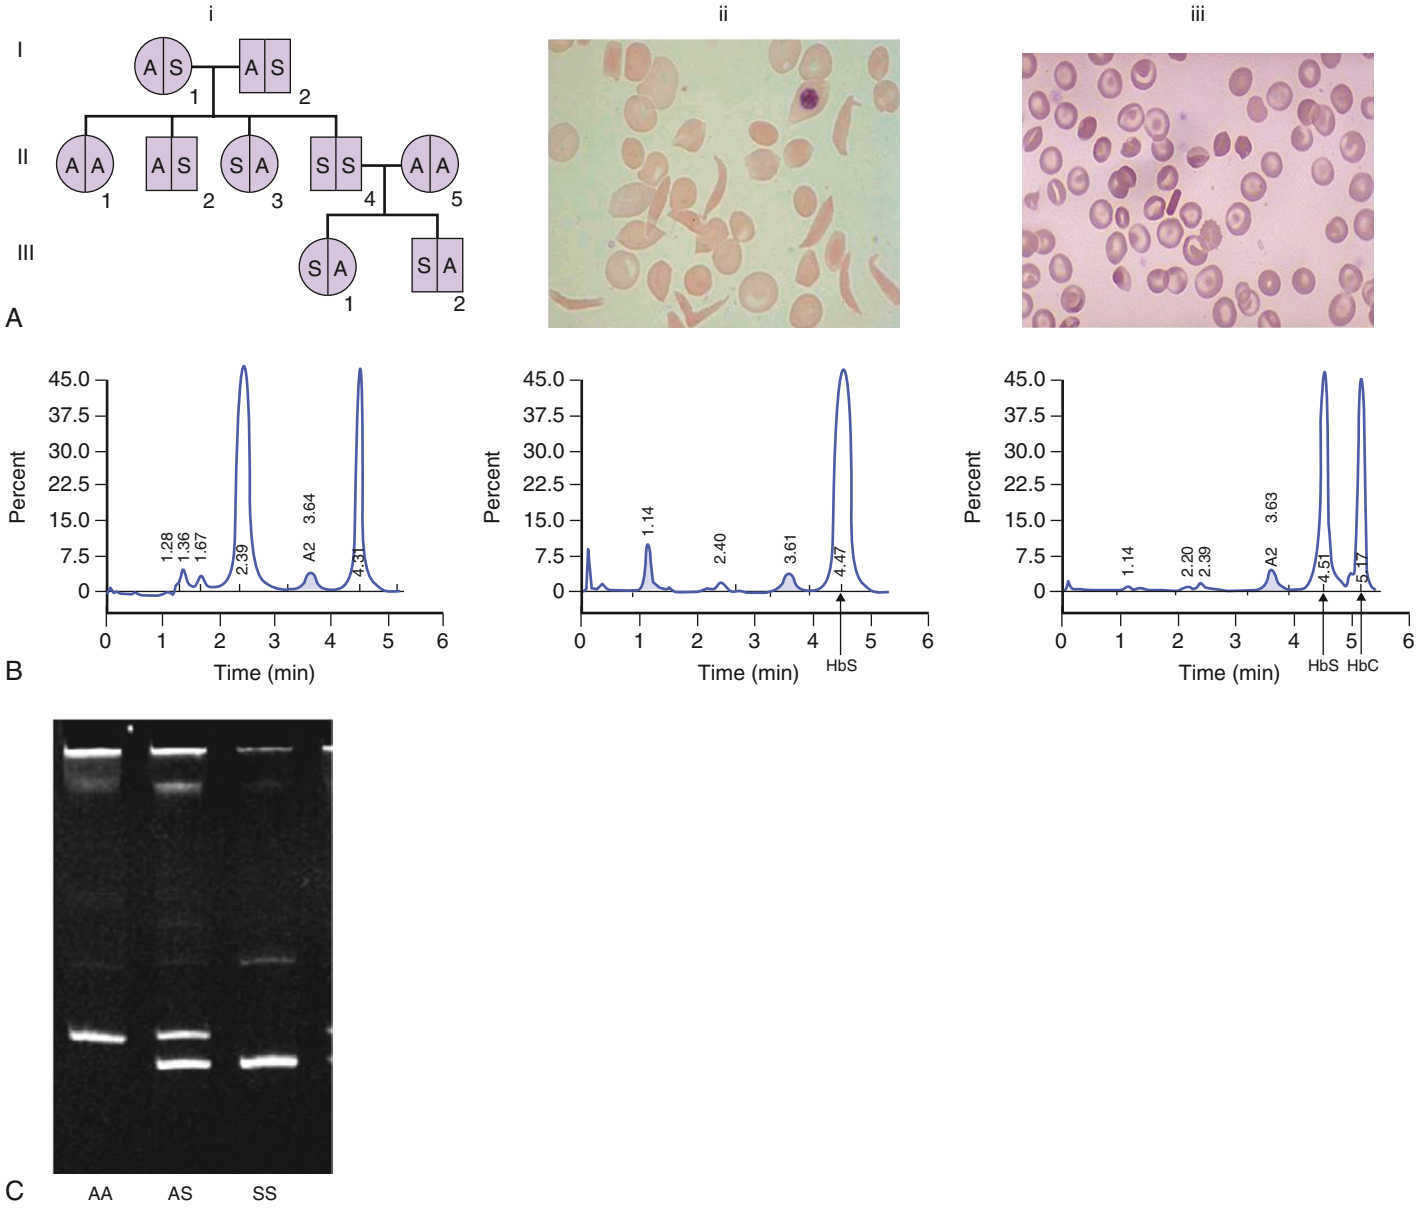

FIGURE 149-3. Diagnosis of sickle cell disease. A, A prototypical family structure in which both parents (I) have sickle cell trait and each offspring (II) has a 25% chance of having sickle cell anemia (SS). Each child of an affected parent (III) will have sickle cell trait (SA) if the other parent has a normal hemoglobin (AA) genotype. The blood films (*center* and *right*) are from patients with sickle cell anemia and hemoglobin SC (HbSC) disease, respectively. Note the irreversibly sickled cells in the former and the hemoglobin C (HbC) crystal and target cells in the latter. **B**, High-performance liquid chromatography profiles from patients with sickle cell trait *(left)*, sickle cell anemia *(center)*, and HbSC disease *(right)*. **C**, Amplification-refractory mutation system–based separation of the β-globin genes from a normal subject (AA), a carrier of sickle cell trait (AS), and a patient with sickle cell anemia (SS).

recognize damaged sickle erythrocytes, thereby resulting in erythrophagocytosis. Intravascular hemolysis liberates hemoglobin into the circulation, where it binds to, and thereby depletes, free plasma haptoglobin and scavenges nitric oxide (NO). In addition, these sickled red cells adhere to activated vascular endothelial cells, thereby promoting inflammation as well as leukocyte and platelet adherence to endothelium. These interactions with endothelium lead to vascular obstruction, tissue ischemia, and then vaso-occlusion. Endothelial cells respond to biologic modifiers that are generated during these vaso-occlusive episodes and the resulting inflammation. The initiation of vaso-occlusion is complex, and mechanisms include the following:

- Cellular damage from adhesive interactions among sickle cells, leucocytes, endothelial cells, and platelets and involving cell adherence molecules such as P selectin, which is expressed on endothelial cells and platelets when they are activated. Leukocytes are then captured on the endothelium.
- Adherent sickle cells and shear stresses that release reactive oxidant species express endothelin and disturb NO balance.
- Reperfusion injury, which can activate endothelial cells and stimulate inflammation.
- Reticulocytes, which are prematurely released from the bone marrow and have adhesive ligands that augment interactions between erythrocytes and endothelial cells.

Hemoglobin variants that have the β-globin gene Glu6Val substitution (HbS) are prone to polymerization. Accumulation of these HbS polymers within sickled erythrocytes causes cellular injury, thereby leading to the clinical syndrome of sickle cell disease. In homozygous sickle cell disease (HbSS) or coinheritance of HbS and β^0-thalassemia (HbSβ^0-thalassemia), the cells contain HbS and no HbA and have the greatest clinical severity (sickle cell anemia). The coinheritance of HbS with other hemoglobin variants (e.g., HbC, HbE, HbSβ^+-thalassemia, HbSD^{Punjab}, HbSO^{Arab}) are also associated with sickling disorders of varying severity (Table 149-1). Although most of the more than 1000 hemoglobin mutations are clinically insignificant, others can occasionally affect the stability and function of hemoglobin and cause hemolytic anemia, disordered oxygen transport, or methemoglobinemia (Chapter 144).

CLINICAL MANIFESTATIONS

Sickle Cell Trait (Sickle Cell Carrier; HbAS)

Approximately 18 to 25% of the population of Sub-Saharan Africa are sickle cell carriers and have what is termed sickle cell trait. Carriers are protected against intracellular sickling because the red cells contain a predominance of HbA compared with HbS (usually 35 to 40% HbS) and because the HbA inhibits hemoglobin polymerization, except under extreme conditions (prolonged

TABLE 149-1 GENETIC AND LABORATORY FEATURES OF COMMON SICKLE HEMOGLOBINOPATHIES*

GENOTYPE	GENETICS	PREVALENCE AMONG AFRICAN AMERICANS†	HEMATOCRIT (%)	MCV (fL)	HbS (%)	HbA_2 (%)	HbF (%)	SEVERITY‡

Normal (HbAA)	Homozygous HbA	—	38-50	80-90	0	2-3	<1	—

*Many other abnormal globin genes can be found as compound heterozygotes with the HbS gene. The most common of these are α-thalassemia, HbD, HbO (Arabia), HbG (Philadelphia), HPFH, Hb Hope, and Hb Lepore. Average ranges of laboratory values are shown, but these can vary according to the patient's age.

†These figures differ by the prevalence of the involved genes in the population studied. In West and Central Africa, where the disease is most common, approximately 2% of all newborns have sickle cell disease. The prevalence of the HbC trait in African Americans is 3%, and that of the β-thalassemia trait is 1%. About 30% of African Americans carry an α-thalassemia gene, which can alter the phenotype of sickle cell disease by causing microcytosis, reduced cell density, and less hemolysis.

‡Severity of disease compared with sickle cell anemia, clinically the most severe genotype. This is a qualitative ranking of the clinical severity of each genotype; within each genotype, there is great clinical heterogeneity.

§Although this combination is still a rare genotype, the rising Asian population in the United States (HbE is a Southeastern Asian gene) will make it more frequent with time. With few cases reported compared with the other genotypes, the phenotype of HbSE disease is not totally defined. It may resemble HbS-β^+-thalassemia, with symptoms appearing mainly in adults.

¶Sickle cell trait should not be classified as a form of sickle cell disease. About 8% of African Americans are carriers of HbS. Carriers are hematologically normal with a normal life expectancy. The few abnormalities traceable to the presence of HbS, besides the renal lesions, include a four-fold increased risk for pulmonary embolism, an increased risk for splenic infarction at high altitude, and a higher risk for dying during the course of exertional heat illness.

Hb = hemoglobin; HbF = fetal hemoglobin; HPFH = hereditary persistence of HbF; MCV = mean corpuscular volume.

hypoxia, acidosis, or dehydration). The carrier state is not generally regarded as harmful; carriers have a normal life expectancy but may experience clinical complications.[3]

Limited epidemiologic studies of individuals with sickle cell trait suggest an increased risk for extreme exercise- and physical exertion–related injury, broadly including exertional rhabdomyolysis, heat-associated collapse, and unexplained sudden death.[4,5] Sickle cell trait can likewise be a cause of death during training and competition in athletes.

Renal abnormalities are among the most common manifestations of sickle cell trait, including hematuria and impaired urinary concentrating ability, and can lead to albuminuria and chronic kidney disease. Individuals with sickle cell trait are at increased risk for venous thromboembolism, specifically pulmonary embolism.[6]

Sickle Cell Disease

Sickle cell disease has remarkably variable clinical manifestations. An individual patient can have almost all known complications, whereas others may have virtually no complications but nevertheless die suddenly. Some individuals have severe complications but do not demonstrate other manifestations. Thus, the phenotypic variability of sickle cell disease is striking despite being a prototypical "single-gene" mendelian disorder. Specific sickle cell genotypes have differing severity, with HbSS and HbSβ^0-thalassemia following a similarly severe disease course, whereas HbSC, HBSβ^+-thalassemia (and the other genotypes) tend to have a milder disease phenotype. However, some patients with HbSS may have infrequent pain episodes and few complications, whereas some patients with HbSC may experience frequent severe pain crises. Factors causing this phenotypic variability include coinheritance of disease-modifying genes, including HbF and α-thalassemia, as well as variations in genes that affect inflammation, nitric oxide biology, oxidant injury, cell-cell interactions, vasoregulation, coagulation, and hemostasis.

Multiorgan Disease and Variation with Age

Although sickle cell disease is most commonly associated with anemia and repeated pain episodes, the pathophysiologic process can affect all organs in the body (Table 149-2). Acute complications include an increased risk for infection, stroke, and chest complications. Chronic complications include chronic lung disease, chronic renal failure, pulmonary hypertension, and ophthalmologic complications.

TABLE 149-2 ACUTE AND CHRONIC COMPLICATIONS OF SICKLE CELL DISEASE

SYSTEM	ACUTE COMPLICATIONS	CHRONIC COMPLICATIONS
Neurologic	Acute ischemic stroke Acute hemorrhagic stroke Venous sinus thrombosis	Silent cerebral ischemia Vasculopathy (moyamoya disease) Headache Cognitive dysfunction
Cardiorespiratory	Acute chest syndrome	Pulmonary hypertension Asthma Chronic sickle lung disease Sleep-disordered breathing Myocardial impairment
Renal	Acute renal failure Hematuria Urinary tract infection	Enuresis Proteinuria Chronic renal failure
Urologic	Priapism	Erectile dysfunction
Orthopedic	Osteomyelitis	Avascular necrosis
Ophthalmologic	Vitreous hemorrhage Retinal detachment Retinal artery occlusion	Retinopathy
Others	Acute splenic sequestration Acute hepatic sequestration Gallstone disease (biliary colic, cholecystitis)	Chronic splenomegaly Splenic dysfunction Sickle hepatopathy Leg ulceration

Complications typically vary with age. Dactylitis (pain crisis affecting hands and feet) is often the first symptom seen in young children when the levels of

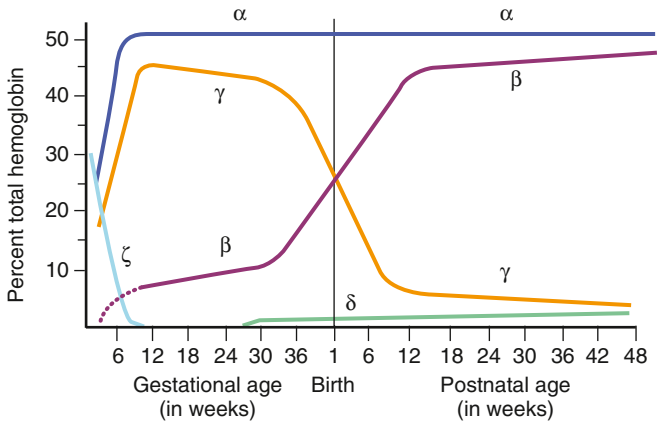

FIGURE 149-4. Human globin genes. Expression of globin genes during development. The α chains are expressed throughout gestation and adult life, the fetal γ-globin chains are expressed predominantly in utero, and the β-globin and δ-globin genes are expressed mainly postnatally. This switching of gene expression patterns accounts for the different hemoglobins present in the embryo, fetus, and adult. This phenomenon also accounts for the observation that disorders of α-globin can affect both fetus and adult, whereas β-globin chain diseases usually are not clinically apparent in the first months of life, when fetal hemoglobin levels are still high.

HbS increase between 6 and 12 months of age as hemoglobin switches from HbF to HbS (Fig. 149-4). Splenic dysfunction, which occurs early in life, increases susceptibility to infection and results in high rates of infective deaths in the absence of antibiotic prophylaxis and vaccination. Splenic sequestration is most common in affected individuals who are younger than age 5 years before the development of splenic infarction, although it may occur later in persons with milder disease phenotypes. Before the introduction of transcranial Doppler screening and primary stroke prevention (see later), stroke was most common in young children and in older adults; the risk is now markedly less in children but not in adults.

Most chronic organ damage does not become clinically significant until adulthood, but invariably organ damage will begin in early childhood. For example, although evidence of renal dysfunction (e.g., hyposthenuria and microalbuminuria) occurs in early childhood, end-stage renal failure is uncommon before late adulthood. Similarly, acute chest syndrome, asthma, and sleep-disordered breathing are all common in children, but severe chronic lung disease becomes apparent in adulthood. Pulmonary hypertension, retinopathy, leg ulcers, and avascular necrosis are all uncommon in childhood but much more common in adults. With an increasing life expectancy, sickle cell disease has now evolved into a debilitating disorder with substantial morbidity resulting from ongoing sickle cell vasculopathy and multiorgan damage.[7] Patients should be offered the option of curative therapies as their best option for improved long-term survival and quality of life.

Pain

Acute Pain

Acute pain episodes (vaso-occlusive crises) are the hallmark of sickle cell disease, occur with unpredictable frequency, may be triggered by infection, dehydration, or stress, or may occur with no precipitant. Pain crises are the most common reason for hospital admission in patients with sickle cell disease, but pain is also experienced frequently in the community and can have a significant impact on quality of life. Almost 30% of adults with sickle cell disease have pain on more than 95% of days, and only about 15% have pain on fewer than 5% of days. Overall, patients experience pain on about 50% of days but use health care on fewer than 5% of days.

Young children typically experience pain in the fingers and toes (dactylitis), but older children and adults tend to experience pain in the arms, legs, and trunk. Examination of the affected area is usually normal, but swelling and acute tenderness may be evident. No diagnostic tests exist for sickle crisis, so diagnosis is usually based on the patient's history. An individual patient will usually describe the pain as typical for sickle cell disease, and atypical pain requires further investigation to look for alternative causes.

Chronic Pain

Chronic pain refers to pain that persists for more than 3 months. In patients with sickle cell disease, chronic pain may be due to an identifiable underlying cause, most commonly avascular necrosis. However, some patients experience severe daily pain with no clear stimulus, perhaps because of central sensitivity syndromes that are associated with an increased sensitivity to painful and nonpainful stimuli and are precipitated and reinforced by repeated painful and stressful stimuli.

Anemia

Patients with HbSS/HbSβ^0-thalassemia usually have a baseline hemoglobin of 6 to 9 g/dL, whereas patients with HbSC and HbSβ$^+$-thalassemia will have a higher baseline hemoglobin of 8 to 12 g/dL. Patients usually tolerate this degree of anemia, although some patients experience significant fatigue. Anemia, sometimes associated with renal dysfunction, often worsens in older adulthood.

Acute anemia (a decrease in hemoglobin of >2 g/dL) may be associated with worsening symptoms of fatigue and breathlessness, and intervention with transfusion may be required. Causes of acute anemia include worsening hemolysis, parvovirus (erythrovirus) B19 infection (potentially causing pure red cell aplasia or hypoplasia), splenic sequestration, folate deficiency, and any cause of anemia seen in non–sickle cell disease patients. Parvovirus B19 (Chapter 342), which causes slapped-cheek syndrome in children, usually manifests as an acute viral illness with profound anemia and reticulocytopenia. Splenic sequestration is most common in young children before splenic infarction and is characterized by anemia and splenic enlargement.

Neurologic Complications

Acute Ischemic Stroke

In untreated children and adults with sickle cell disease, strokes occur in approximately 10% of patients by age 20 years and 25% by age 40 years. Cerebral vasculopathy is the most common cause in children, but adults also have comorbid conditions such as diabetes, hypertension, and atrial fibrillation. Acute ischemic stroke can also occur in the context of acute pain crisis or acute anemia. The typical features of acute ischemic stroke (Chapter 376) include hemiparesis, facial droop, or dysphasia, but patients may present with loss of consciousness or behavioral change.

Acute Hemorrhagic Stroke

Patients with sickle cell disease also are at increased risk for intracerebral, intraventricular, subdural, and subarachnoid hemorrhage (Chapter 377), often related to the underlying cerebral vasculopathy. The prevalence of both moyamoya (a rare, chronic occlusive cerebrovascular disease characterized by progressive stenosis of the intracranial terminal carotid arteries with an abnormal vascular network at the base of the brain) and cerebral aneurysms are increased in this group of patients. Presentation with headache and decreased consciousness is more common than with focal neurologic signs.

Silent Cerebral Infarction and Other Neurologic Complications

MRI of patients with sickle cell disease frequently shows small ischemic lesions that are not associated with neurologic deficits. These silent cerebral infarcts increase with increasing age and are associated with cognitive impairment, including a reduction in IQ. MRI screening of children may identify affected individuals at an early age. Venous sinus thrombosis, posterior reversible encephalopathy syndrome, and headaches are also more common in patients with sickle cell disease.

Cardiorespiratory Complications

Acute Chest Syndrome

Acute chest syndrome is an acute illness characterized by fever and/or respiratory symptoms accompanied by a new pulmonary infiltrate on chest radiograph. Patients may present to the hospital with acute chest syndrome, or it may develop 1 to 3 days after admission for an acute pain crisis. Etiologies include infection (bacterial or viral), fat embolism, and pulmonary infarction (Chapter 68). Severity is variable, but it may result in severe hypoxia, respiratory failure, and death.

Pulmonary Hypertension

Pulmonary hypertension, with a mean pulmonary artery pressure of 25 mm Hg or greater, is reported in 6 to 11% of adults with sickle cell disease and is associated with increased mortality. Pathogenesis is multifactorial and includes left-sided heart disease, chronic lung disease, chronic thromboembolic disease, and intravascular hemolysis. *N*-terminal pro–brain natriuretic peptide (BNP) levels are typically elevated, and echocardiography is the best noninvasive test.

Chronic Lung Disease and Sleep-Disordered Breathing

About 20% of children with sickle cell disease have asthma, which may be caused by increased pulmonary capillary blood flow or by the chronic inflammation

of the lungs. The prevalence of asthma is not increased in adults with sickle cell disease, but about 70% of adults with sickle cell disease develop restrictive lung defects, which can be associated with daytime hypoxia, chest pain, and progressive restrictive lung defects and fibrosis on high-resolution CT scanning. Sleep-disordered breathing (Chapter 374), with nocturnal hypoxia and obstructive sleep apnea, is seen in up to 40% of children and 60% of adults with sickle cell disease.

Renal and Urologic Complications

Renal complications are seen in up to 60% of patients with sickle cell disease, commencing in early childhood and progressing with increasing age. A distal renal tubule–concentrating defect, which is an early manifestation of renal damage, results in hyposthenuria (an inability to concentrate urine), nocturnal enuresis, and a predisposition to dehydration. An increased glomerular filtration rate (GFR), owing to anemia and high cardiac output, leads to glomerular hypertrophy and damage and then to microalbuminuria, which is seen in 20% of children and 60% of adults with sickle cell disease and can progress to unselective proteinuria and even nephrotic syndrome (Chapter 107).

Hematuria, which is also common in sickle cell disease as well as in sickle cell trait (see earlier), can be due to renal papillary necrosis. This syndrome can be painful and profuse. Renal medullary carcinoma is a highly aggressive malignancy that predominantly afflicts young adults and adolescents with sickle cell hemoglobinopathies.

Acute kidney injury (Chapter 106) occurs in 2 to 10% of patients who are admitted with acute painful crisis and can be precipitated by dehydration, sepsis, and drugs. Cortical ischemia, perhaps due to sickling in the low-flow low-oxygen cortical areas of the kidney, also can contribute to tubular interstitial disease (Chapter 108). Progressive renal dysfunction can result in end-stage kidney disease, with a requirement for dialysis or renal transplantation.

Priapism

Priapism is a persistent, prolonged, and painful penile erection unrelated to sexual stimulation. Priapism is common in men and boys with sickle cell disease and may occur as short, intermittent, self-limited episodes (stuttering priapism) or as severe acute episodes lasting for more than an hour (fulminant priapism). Acute priapism may be preceded by stuttering priapism and can result in long-term erectile dysfunction.

Infection

Sickle cell patients experience increased morbidity and mortality from infection, in part due to functional asplenia or hyposplenia (Chapter 154), and also due to increased rates of gram-negative sepsis. Hyposplenia develops from infancy and leads to a deficiency in response to encapsulated bacteria and hence increased risk for invasive infection with organisms such as *Streptococcus pneumoniae* (Chapter 268), *Neisseria meningitides* (Chapter 274), and *Haemophilus influenzae* type b (Chapter 277). Patients with sickle cell disease are more likely to have adverse outcomes from coronavirus disease 2019 (COVID-19) infection (Chapter 336).[8]

DIAGNOSIS

Routine Blood Tests

The usual steady-state hemoglobin level is 5 to 10 g/dL in HbSS and is higher in the milder phenotypes. The anemia in HbSS is typically normochromic and normocytic, but microcytosis is often seen in HbSC disease, and marked microcytosis and hypochromia are seen in HbSβ-thalassemia. Most affected individuals have reticulocytosis and evidence of hemolysis with a raised bilirubin and lactate dehydrogenase (LDH). The blood film in HbSS will show numerous sickle cells, polychromasia, and features of hyposplenism (in adults). In addition, hypochromia is also prominent in HbSβ-thalassemia. In HbSC disease, target cells, densely staining contracted boat-shaped red cells, and HbC crystals may be seen with less sickled cells and polychromasia than in HbSS (see Figs. 149-3Aii and 149-3Aiii).

Analysis of Hemoglobin Type

High-pressure liquid chromatography (HPLC) is now the most common method of hemoglobin analysis. Variant hemoglobins are identified by their elution time from an ion exchange column and can be quantified. HPLC is quick, is reliable, and allows high throughput of samples (see Fig. 149-3B). Confirmatory testing should be performed with alternative techniques. These include the following:

- The sickle solubility test will detect sickling of hemoglobin in solution by treatment with a reducing agent. It is specific for sickle hemoglobin but does not differentiate among HbAS, HbSS, and other compound heterozygotes of sickle cell hemoglobin.
- Hemoglobin electrophoresis was the first method used to demonstrate hemoglobin variants but is time-consuming and labor-intensive.
- DNA sequence analysis identifies the specific globin gene mutation (see Fig. 149-3C).
- Tandem mass spectrometry identifies the specific amino acid change in the globin chain.

Screening

Screening for sickle cell trait is currently required in some branches of the U.S. Armed Forces because of an increased risk from complications of extreme exercise. Antenatal screening aims to identify couples at high risk for an affected pregnancy to enable counseling and prenatal diagnosis (via chorionic villus sampling or amniocentesis) early enough to allow reproductive choice. Preconceptual screening provides couples with information about the risks of an affected birth before conception and allows them to consider the option of preimplantation diagnosis.

TREATMENT AND PREVENTION

General Measures

Sickle cell disease is a chronic disease for which good nutrition and a high fluid intake should be encouraged. Patients and their families should be educated about acute complications and should be taught how to palpate the spleen, how to manage simple pain crises, and when to go to the emergency department. Regular outpatient clinic visits will ensure appropriate screening for chronic disease complications (including screening for stroke risk) and early intervention.[9] The increased production of red blood cells, combined with inadequate nutrition, leads to accelerated consumption of folic acid; supplementary folic acid is typically recommended, although patients with a good dietary intake may not require it. There are significant psychosocial implications of chronic illness, and patients and their families should be offered psychological and social support if needed. The transition from pediatric to adult care is a time of heightened vulnerability and should be managed in a structured way.

Management of Complications

Pain

Mild acute pain episodes can be managed at home with simple analgesia (acetaminophen, nonsteroidal anti-inflammatory drugs; Table 26-4), fluids, and rest, but more severe pain crises may need hospital admission for strong opiate analgesia (Table 26-6). Patients and their families should be made aware of situations when they should be seen in the hospital (Table 149-3).

Inpatients typically require parenteral analgesic. Patients often find patient-controlled analgesic devices beneficial, and the use of patient-controlled analgesic may reduce total opiate intake. Patients being treated with opiates should be monitored for respiratory depression and excessive sedation and should be offered adjuvant therapy to manage opiate side effects (emesis [Table 118-5], constipation [Table 122-3], and pruritus [Table 403-10]). Doses of opiate pain relief should be titrated down as soon as pain settles.

Patients with acute pain episodes should be monitored for the development of other complications, particularly acute chest syndrome, which typically begins 24 to 72 hours after the onset of an acute pain crisis and is more common in patients who have chest and back pain. Early incentive spirometry may reduce the subsequent incidence of acute chest syndrome, and regular monitoring of oxygen saturations will allow early identification of those with worsening hypoxia, which can be a precursor to acute chest syndrome. Patients with recurrent acute pain crisis should be offered hydroxyurea therapy.

TABLE 149-3 SYMPTOMS THAT SHOULD PROMPT HOSPITAL ADMISSION: "RED FLAG" EVENTS

- Severe pain not settling with usual analgesia
- Atypical pain
- Temperature >38° C
- Chest pain
- Shortness of breath
- Neurologic symptoms (e.g., weakness of a limb or facial droop, diminished level of consciousness)
- Pain associated with unusually severe headaches
- Severe lethargy
- Priapism
- Severe jaundice

Chronic pain can be difficult to treat and worsened by opiate therapy. Referral to chronic pain services is often helpful (Chapter 26).

Infection and Infection Prophylaxis

Vaccination for pneumococcus, meningococcus, and *Haemophilus* (Chapter 15) decreases the risk for early mortality and morbidity from invasive bacterial disease, but vaccine-resistant serotypes can still cause serious infections. Infections, especially with encapsulated organisms, require prompt antibiotic treatment.

Stroke

For patients with suspected strokes, urgent magnetic resonance imaging (MRI) or MR angiography can confirm and localize the stroke, although computed tomography (CT) may be used in emergency situations to exclude acute hemorrhagic stroke. Xanthochromia in cerebrospinal fluid can confirm a subarachnoid hemorrhage.

After initial management with hydration and oxygenation, urgent exchange transfusion should be performed to minimize ischemic damage and improve perfusion of the brain. If there is marked anemia (hemoglobin <6 g/dL), simple transfusions may be given to achieve a post-transfusion hemoglobin concentration of about 10 g/dL and HbS percentage of less than 30%, but initial exchange transfusion may prevent recurrent stroke more effectively than initial simple transfusion.[10] In adults with sickle cell disease, thrombolysis appears to be safe in the absence of hemorrhagic transformation.[11]

For an acute hemorrhagic stroke, treatment should be on a specialized neurosurgery unit and should generally be similar to treatment of patients without sickle cell disease. However, exchange transfusion therapy should be considered before neurosurgical intervention.

The risk for recurrent stroke is high, and transfusion therapy seems to be more effective than hydroxyurea in preventing recurrent stroke. Patients should be offered long-term blood transfusion to maintain HbS percentage of less than 30%, most effectively by repeated automated or manual exchange transfusions, although the optimal duration of such therapy is uncertain.[A1] Surgical revascularization may be indicated for patients with recurrent acute ischemic stroke or progressive vasculopathy.

Children who have silent cerebral infarction may benefit from educational or medical intervention. Chronic transfusion therapy may be of benefit, particularly in patients who have abnormal transcranial Doppler studies.

On transcranial Doppler screening in children, a raised time-averaged mean of maximal velocity is associated with an increased risk of stroke. In such children, a blood transfusion strategy to maintain HbS% at less than 30% can reduce the risk of stroke by 90%. As a result, transcranial Doppler scanning is now routine in children ages 2 to 16 years. Stopping transfusions after 3 years leads to an increased risk of recurrent stroke, whereas changing to hydroxyurea therapy after 1 year of transfusions is as effective as continuing with transfusion.[A2]

Cardiorespiratory

Initial treatment of the acute chest syndrome is supportive with pain relief, antibiotics, and oxygen therapy, but more severe presentations may require treatment with simple or exchange transfusion and/or noninvasive or invasive respiratory support.[12] Patients with severe or recurrent acute chest syndrome should be offered treatment with hydroxyurea.

Patients with catheterization-proved pulmonary hypertension should be offered sickle cell disease–modifying therapy or specific therapy for pulmonary hypertension (see Fig. 69-6) under the guidance of an expert. For sleep-disordered breathing (Chapter 374), treatment with nocturnal oxygen or noninvasive respiratory support may be required.

Renal and Urologic Disease

Hematuria may require blood transfusion and occasionally interventional radiology or surgery. Hematuria in patients older than age 40 years, particularly if painless, always should be evaluated by a urologist.

Proteinuria is associated with progression of chronic kidney disease, so patients should be offered screening for proteinuria (with albumin-creatinine or protein-creatinine ratio). Early intervention with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers is indicated in patients who have significant proteinuria (protein-creatinine ratio >50 mg/mmol). Renal function should be monitored regularly to allow optimization of the treatment of hypertension and proteinuria and thereby slow progression.

Priapism

Young men with sickle cell disease should be educated about priapism and encouraged to come to the emergency department for episodes that persist for more than 1 hour. Initial conservative management includes pain relief, fluids, gentle exercise and urination, and oral α-adrenergic agents (etilefrine). If the priapism fails to resolve, a urologist should be contacted to perform penile aspiration, which can be combined with the injection of α-adrenergic agents into the corpus cavernosa. The procedure will often cause detumescence; if not, further surgical intervention will be needed. Transfusion therapy may be helpful to support surgery and possibly to relieve persistent priapism. Treatment of stuttering priapism should be considered for symptomatic relief and with the aim of preventing future episodes of fulminant priapism. Oral α-adrenergic agents and antiandrogens should be considered under guidance of an expert urologist, and phosphodiesterase type 5 (PDE5) inhibitors also may be considered.

Management of Pregnancy

Although most women with sickle cell disease should expect to have successful pregnancies and healthy babies, these pregnancies are associated with an increased rate of maternal and fetal morbidity and mortality. Complications include increased sickle complications (pain, chest complications), pregnancy complications (infection, raised blood pressure), and high rates of premature birth and fetal growth restriction. Women should be counseled about the risks of pregnancy during their routine outpatient appointments, and preconceptual care should include partner screening, review of medications, and evaluation of chronic complications that may affect the pregnancy. When pregnant, women should be enrolled into multidisciplinary antenatal care with an obstetrician who has experience in sickle cell disease and a hematologist. Caregivers should consider prescribing daily low-dose aspirin (e.g., 81 mg daily) for prevention of preeclampsia (Chapter 221). Patients should be followed regularly throughout pregnancy with blood pressure, urinalysis, and ultrasound monitoring. Prophylactic transfusion is not recommended for all pregnancies but may reduce the risk for pain crisis, chest complications, and fetal complications. If there are no obstetric complications, the pregnancy should be allowed to continue to term, anticipating spontaneous labor and normal delivery. Women with sickle cell disease are at increased risk for venous thrombosis (Chapter 68), and their risk should be assessed using appropriate tools and the need for thromboprophylaxis considered (Chapter 221).[13]

Management of Surgery

General anesthesia is associated with increased risk for complications, in particular, increased pain crises and acute chest crises. These complications can be reduced with careful preoperative care (hydration, oxygenation) and consideration of preoperative blood transfusion. In low- to moderate-risk surgery in patients with non-HbSS genotypes, transfusion may not be needed. Simple transfusion aiming for a hemoglobin concentration of more than 9 g/dL is as effective as exchange transfusion for low- and moderate-risk surgery, but high-risk surgery (cardiac or neurosurgery) requires preoperative exchange transfusion.[14]

Disease-Modifying Therapies

Hydroxyurea

Hydroxyurea increases HbF levels and reduces cellular adhesion and hemolysis. Randomized controlled trials in various settings have shown that hydroxyurea reduces acute pain episodes, chest crises, and rates of hospitalization in adults and children with sickle cell anemia with few side effects regardless of the severity of symptoms.[A3] Dose-escalation protocols (up to 30 mg/kg/day) are superior to fixed-dose protocols (at 20 mg/kg/day).[A4] In addition, hydroxyurea reduces the risk of stroke in patients who have elevated transcranial Doppler studies. Adherence to hydroxyurea clearly reduces emergency visits and hospitalizations.[15] Hydroxyurea should be offered to all infants, children, and adolescents with sickle cell anemia, irrespective of severity, and to adults with recurrent pain episodes, severe or recurrent acute chest syndrome, and symptomatic anemia.

Hydroxyurea is well tolerated. Its main side effect is myelosuppression, and regular blood monitoring is required while on the drug. Because of suggestive evidence regarding teratogenicity and effects on spermatogenesis, hydroxyurea should be avoided in patients who are trying to conceive.

Anemia and Blood Transfusion

Red cell transfusion is used both to treat the acute complications of sickle cell disease and as long-term disease-modifying therapy. Patients who have chronic anemia may need intervention with hydroxyurea, transfusions, or erythropoiesis-stimulating agents. Acute anemia typically requires blood transfusion, aiming for a return to the patients' baseline hemoglobin concentration.

Acute indications for transfusion include acute anemia, acute chest syndrome, stroke, and multiorgan failure. Transfusion is not indicated for the treatment of simple acute pain crises. Long-term transfusion is indicated for primary and secondary stroke prevention and for the prevention of recurrent pain episodes or recurrent acute chest syndrome if there has not been a response to hydroxyurea therapy.

Blood can be administered as a simple or "top-up" transfusion to increase hemoglobin levels and improve oxygen-carrying capacity or as an exchange transfusion (manual or automated). Exchange transfusion allows a more marked reduction of HbS compared with HbA and is more likely to reduce vaso-occlusion.[16] In view of the increased risk for alloimmunization and delayed hemolytic transfusion reactions in patients with sickle cell disease, blood should be ABO Rh (CcDEe) and Kell compatible, and blood should be antigen-negative for clinically significant antibodies that are currently or have previously been detected (Chapter 162).

Long-term or frequent intermittent transfusion can result in iron overload and iron deposition in the liver and other organs. The patient should be monitored with ferritin and liver iron quantification by MRI, and iron chelation therapy should be instigated if the patient is iron-loaded (see Chapter 196). Both deferasirox and desferrioxamine are effective and licensed for use in sickle cell disease. Deferiprone is not currently licensed for use in sickle cell disease but is also effective.

TABLE 149-4 NEW MEDICATIONS FOR TREATMENT OF SICKLE CELL DISEASE

DRUG NAME	MODE OF ACTION	DOSE	LICENSED INDICATIONS (UNITED STATES)
L-Glutamine	Antioxidant	5 g-15 g orally, twice daily based on body weight	Reduction of acute complications in sickle cell disease in adults and pediatric patients 5 years and older
Crizanlizumab	Anti-P selectin	5 mg/kg IV infusion over 30 min on Week 0, 2, and every 4 weeks thereafter	Reduction in the frequency of vaso-occlusive crises in adults and pediatric patients 16 years and older with sickle cell disease
Voxelotor	HbS polymerization inhibitor	1500 mg orally, daily	The treatment of sickle cell disease in adults and pediatric patients 12 years and older

HbS = hemoglobin S; IV = intravenous.

Other Disease Modifying Therapies (Table 149-4)

L-Glutamine, an antioxidant, can reduce the rate of vaso-occlusive pain crises and hospital admissions.[A5] Crizanlizumab, an anti-P selectin agent, reduces the frequency of vaso-occlusive cries and increases the median time to first and second crisis.[A6] Both drugs are useful to reduce the frequency of vaso-occlusive pain events in patients who have frequent pain crises. Voxelotor, which is a hemoglobin modifier that inhibits the polymerization of hemoglobin and reduces hemolysis, raises hemoglobin by 1.0 g/dL in over 50% of recipients without adverse events.[A7]

Other promising agents currently in development for the acute or long-term treatment of sickle cell disease act through different mechanisms. Examples include drugs targeting HbS polymerization (e.g., pyruvate kinase activators),[17] histone deacetylase inhibitors, and drugs targeting inflammation (e.g., interleukin 1-beta [IL-1b] blockade). A randomized trial of canakinumab, which is an IL-1b blocker, did not show a pre-specified reduction in pain but did show reduction in markers of inflammation, sickle cell disease–related adverse events, and hospitalization rates.[A8]

Curative Therapies

Stem Cell Therapy

Successful hematopoietic stem cell transplantation (Chapter 163) is a potentially curative option for sickle cell disease. When performed in young patients, hematopoietic stem cell transplantation from human leukocyte antigen (HLA)–matched siblings results in excellent overall survival and event-free survival.[18] The utility of this approach is limited because only about 10 to 20% of sickle cell disease patients will have HLA-identical siblings available as donors. Hematopoietic stem cell transplantation from alternative donors (particularly haplo-identical transplants) have shown good outcomes in small studies but are associated with increased morbidity and mortality. There is increasing evidence of the efficacy of reduced-intensity conditioning approaches in adults, associated with reduced adverse effects.[19]

Gene Therapy

Gene therapy (Chapter 34), which is another potentially curative option for sickle cell disease, involves manipulation of hematopoietic stem cells to correct or circumvent the sickle mutation followed by autologous transplantation of the manipulated cells. Clinical trials using lentiviral vectors to add modified antisickling β-globin variants have showed sustained production of the modified β-globin with reduced hemolysis and resolution of severe vaso-occlusive events.[20] Gene-editing techniques using CRISPR/Cas9 technology to encourage production of fetal hemoglobin (HbF) also can be effective, with persistence of high levels of HbF and elimination of vaso-occlusive pain crises for at least 1 year.[21]

PROGNOSIS

In resource-rich countries with universal neonatal screening, antibiotic prophylaxis, improved supportive care, and successful research trials, most children with sickle cell disease reach adulthood. In the United States, nearly 95% of persons with sickle cell disease reach age 18 years. Nevertheless, adults with sickle cell disease still have a high burden of pain and comorbidity, and the median age of death is 43 years.[22] The extent to which newer drugs will impact chronic organ damage, quality of life, and longevity is unclear. In Sub-Saharan Africa, by contrast, where almost 80% of the projected 306,000 newborns worldwide with sickle cell disease are born, mortality remains 50 to 90% before age 5 years.

OTHER HEMOGLOBINOPATHIES

Hemoglobin C trait is a benign condition in which lysine replaces glutamic acid at the same sixth position on the hemoglobin beta chain where valine causes the sickle cell mutation. Homozygous HbC disease is associated with a mild hemolytic anemia and splenomegaly. HbC disease is characterized by a peripheral smear with a large population of target cells (see Fig. 149-3Aiii), with some red cells containing crystals. Individuals with HbC disease generally do not have clinical sickle crises or other complications. HbS/HbC disease occurs in about 1 per 1100 Black Americans. Patients who have HbS/HbC disease tend to have a clinical syndrome intermediate in severity between homozygous hemoglobin C disease and homozygous sickle cell anemia. Treatments, when needed, are similar to those for sickle cell anemia.

Hemoglobin E and the HbE thalassemias are discussed in Chapter 143.

Other than HbS, HbC, and HbE, most hemoglobinopathies do not cause clinical abnormalities. Among those that may have some clinical complications are some of the unstable hemoglobin variants, in which the mutant hemoglobin tends to precipitate intracellularly and causes a so-called Heinz body hemolytic anemia. These conditions are covered in the section on "Unstable Hemoglobinopathies" in Chapter 143. Another group of hemoglobinopathies are globin chain mutations that cause increased binding of oxygen by the abnormal hemoglobin, that is, the high-oxygen-affinity hemoglobin variants. These individuals generally have a secondary erythrocytosis as a compensatory response to their relative ineffectiveness in releasing O_2 to tissues. High-oxygen-affinity hemoglobinopathies are best diagnosed by formal study of the patient's oxyhemoglobin dissociation curve and P-50 values, which can be obtained with a commercially available instrument such as the Hemox-Analyzer, which measures in vitro deoxygenation of the sample using nitrogen gas and simultaneously determines oxygen tension with a Clarke electrode. Estimations of the P-50 by blood gas analyzers on venous blood are more convenient but have not been well validated in the screening of hemoglobin variants with high oxygen affinity. Despite their polycythemia, these patients do not have the other diagnostic characteristics of polycythemia vera (Chapter 152).

150 MEGALOBLASTIC ANEMIAS

SALLY P. STABLER

DEFINITION

Megaloblastic anemia is defined as an anemia or pancytopenia resulting from failure of DNA synthesis and imbalance of maturation between the nucleus and the cellular cytoplasm resulting in large cells subject to maturation arrest and early destruction. Large, macrocytic, red blood cells are also seen in conditions other than megaloblastic anemia (Table 150-1). In practical terms, however, many of the causes of macrocytic red blood cells overlap with those of full-blown megaloblastic anemias. The most frequent causes of severe megaloblastic anemia are deficiencies of cobalamin (vitamin B_{12}) and folate, two vitamins with interrelated roles in the synthesis of thymidine and purines for DNA synthesis[1,2] (Table 150-2).

EPIDEMIOLOGY

Cobalamin Deficiency

Cobalamin is synthesized only by microorganisms, and humans obtain the vitamin through ingestion of animal-source foods because plants do not utilize cobalamin.[3] There are many populations in the world that do not consume adequate cobalamin-containing food due to scarcity and expense of animal-source food or belief systems against the use of such foods. Recommended daily allowances in the United States have been set at 2.4 μg/day, which is readily achieved with an omnivorous diet containing meat, dairy, eggs, fish, or shellfish. Lactovegetarians are at high risk for dietary deficiency,[4] and foods targeted to vegetarian populations in high-resource countries can be supplemented with cobalamin.[5] The fetus and breast-feeding infant obtain cobalamin from the mother, and thus requirements are increased to 2.6 μg for pregnancy and 2.8 μg for lactating women. The breast milk of cobalamin-deficient women has low concentrations of the vitamin and their infants can have severe developmental and growth impairment. An efficient enterohepatic circulation of cobalamin prevents loss of the vitamin so that individuals on deficient or marginal diets will take years to become deficient if the gastrointestinal tract is functioning.[6]

Cobalamin is a trace component of food-bound proteins in the diet, and most causes of severe deficiency relate to the inability to absorb the vitamin. The failure of secretion of gastric intrinsic factor due to an autoimmune disease of the gastric mucosa is known as pernicious anemia and results in life-threatening anemia, pancytopenia, or myeloneuropathy unless treated.[7] Surgery or disease of the stomach, pancreas, or ileum also will cause deficiency.[8] The normal processes of cobalamin absorption are shown in Fig. 150-1.

The incidence of pernicious anemia is reported to range from 1 to 50 per 100,000 persons per year, depending on the criteria used for diagnosis. The prevalence has been described as 50 to 4000 cases per 100,000 persons, again depending on diagnostic criteria. Pernicious anemia becomes more common with age, and the highest prevalence occurs in persons of African or European ancestry with lower incidence and prevalence in East Asians.[9] Mild atrophic gastritis with protein-bound cobalamin malabsorption occurs in up to 20% of older adults, particularly Whites. Dietary cobalamin deficiency is population dependent, but can range from 30 to 50% in areas of South America, Africa, and India.

Folate Deficiency

In contrast to cobalamin, folates are abundant in foods of plant origin and are also found in dairy and organ meats. Folates are susceptible to loss in cooking, particularly if the cooking water is discarded and not incorporated into the dish. Populations with limited access to or distaste for vegetables, legumes, or fruits may have folate deficiency. Alcohol and some other drugs interfere with folate absorption or promote excretion and are major causes of folate deficiency seen clinically. Folates are absorbed mainly in the upper small

Other megaloblastic anemias

TABLE 150-2 CAUSES OF MEGALOBLASTIC ANEMIA

COBALAMIN (VITAMIN B_{12}) DEFICIENCY
Lack of intrinsic factor
Pernicious anemia (type A gastritis)
Gastrectomy, gastric bypass
Congenital defect in gastric intrinsic factor
Food cobalamin malabsorption
Atrophic gastritis (type B gastritis)
Gastric or achlorhydria
Exocrine pancreatic dysfunction
Disorders of the distal ileum
Surgical resection of distal 1-2 ft.
Inflammatory bowel disease
Surgical reconstruction—ileal conduit or cystoplasty
Congenital defects of cubam receptor (Imerslund-Gräsbeck syndrome)
Usurpation of intestinal cobalamin
Tropical sprue, bacterial overgrowth, blind loops
Parasitic infection—*Diphyllobothrium latum* and *Giardia lamblia*
Nutritional cobalamin deficiency
Breast-fed infant of a deficient mother
Diet lacking animal source food, such as vegan, lacto-ovo vegetarian, or impoverished low-meat diet
Drug-induced cobalamin deficiency
Nitrous oxide abuse or anesthesia in a cobalamin-deficient patient
Metformin, histamine blocking or proton pump inhibitor drugs
Inborn errors of cobalamin metabolism
Transport—transcobalamin deficiency
Cellular metabolism—mutations that cause combined methylmalonic acidemia and homocystinuria (CblC-J)
FOLATE DEFICIENCY
Nutritional folate deficiency
Lack of fresh fruit, green leafy vegetables, legumes, organ meats
Anorexia nervosa and other eating disorders
Alcohol abuse combined with poor nutrition
Folate malabsorption
Celiac or tropical sprue
Crohn disease and other small intestinal diseases
Increased demand or loss
Pregnancy
Hemolytic anemias
Proliferative skin diseases
Leukemias
Hemodialysis
Drug-caused folate deficiency
Antifolates—methotrexate, pemetrexed, pralatrexate, pyrimethamine, sulfasalazine, trimethoprim
Anticonvulsants—phenytoin, carbamazepine, valproic acid
Methylation-requiring drugs—L-Dopa, high-dose niacin, α-lipoic acid
Inborn errors of folate metabolism
MTHFD1 deficiency
PCFT (*SLC46A1*) mutation
MEGALOBLASTIC ANEMIA NOT DUE TO COBALAMIN OR FOLATE DEFICIENCY
Inborn errors
Thiamine responsive megaloblastic anemia (*SLC19A2* mutation)
Hereditary orotic aciduria
Lesch-Nyhan syndrome
Drugs affecting DNA synthesis
Cancer chemotherapy—hydroxyurea, azathioprine, others
Antiretrovirals—zidovudine, stavudine
Tyrosine kinase inhibitors—imatinib, sunitinib, others

CblC-J = cobalamin C, D, E, F, G, and J (defects); MTHFD1 = methylenetetrahydrofolate dehydrogenase 1; PCFT = proton-coupled folate transporter.

ABSTRACT

The most common causes of megaloblastic anemia are cobalamin (B_{12}) or folate deficiencies. Methylmalonic acid is the most sensitive and specific marker of cobalamin deficiency. Folate deficiency is rare in countries with folate-fortified food sources and is usually associated with alcohol abuse. Cobalamin deficiency can be treated with injections or high-dose oral preparations. The severity of myeloneuropathy due to cobalamin deficiency is inversely related to the severity of megaloblastic anemia, but the myelopathy is reversible if treated early.

intestine; thus, diseases such as celiac or tropical sprue, bacterial overgrowth, or inflammatory bowel diseases are complicated by clinical folate deficiency. Many countries including the United States, Canada, Chile, Costa Rica, and South Africa have fortified grain products with folic acid. This has virtually eliminated folate deficiency except in those persons with impaired absorption or high alcohol intake. Countries without fortification may have a significant folate-deficient population depending on customary dietary food patterns which in resource-poor countries provide less than 50% of recommended folate intake.[10,11]

A recommended daily allowance for folate in the United States is 400 µg for adult men and nonpregnant women. The requirement has been increased to 600 µg for pregnant women and 500 µg for lactating women. Food folates are polyglutamated and are less bioavailable than the synthetic folic acid used to fortify food and supplements, which has made estimation of total folate intake more difficult in fortified populations.

PATHOBIOLOGY

Cobalamin

Cobalamin is necessary for only two enzymatic reactions in higher animals. In one reaction methyl-cobalamin is a cofactor for the enzyme methionine synthase, which uses methyl-tetrahydrofolate (methyl-THF) to methylate homocysteine to form methionine. Methionine can be activated to S-adenosylmethionine, which is the methyl donor for many reactions including the important synthesis of creatine, lipids, neurotransmitters, DNA methylation, and many other compounds. The demethylated folate product, THF, is the precursor for the other folate coenzymes. One coenzyme, 5, 10-methyleneTHF, participates in the formation of thymidine from dUMP by thymidylate synthase. Thymidine is critical for DNA synthesis and the accumulation of uracil is harmful; if incorporated into DNA it can cause prolongation of the cell cycle, chromosomal damage, and maturation arrest. Apoptosis may occur due to the impaired DNA repair with cell fragmentation and resulting cell death.

The buildup of methyl-THF, which cannot be converted to THF due to the decrease in methionine synthase activity, is referred to as the "methylfolate trap." This build-up causes a secondary state of folate deficiency in the cobalamin-deficient patient. Methyl-THF is not a good substrate for polyglutamation and therefore it diffuses out of cells and will be lost in the urine. The impairment in methionine synthase activity is the primary cause for the indistinguishable megaloblastic anemia seen with either cobalamin or folate deficiency. When methionine synthase activity is impaired, serum homocysteine levels increase (Chapter 193).

The second cobalamin-dependent reaction uses adenosyl-cobalamin to convert a product of propionic acid metabolism, L-methylmalonyl-CoA, to succinyl-CoA by the enzyme L-methylmalonyl-CoA mutase. When the mutase is blocked by deficiency of adenosyl-cobalamin, the methylmalonyl-CoA is hydrolyzed to methylmalonic acid, a compound with unknown metabolic fate. Elevated methylmalonic acid has been shown to be a sensitive indicator of impaired mutase activity and thus of cobalamin deficiency in many experimental cellular or animal models as well as in human patients.[12] There are no roles for folate metabolism in this pathway.

Cobalamin Absorption

The cobalamin in unfortified food consists of the coenzyme forms bound to the two enzymes. Because there are only trace amounts of cobalamin (average 4 to 6 µg in omnivorous diets) there is a multistep process involving binding proteins and receptors to provide for absorption of the vitamin. The normal processes of absorption are shown in Fig. 150-1 and reviewed elsewhere in detail. Food is mixed with saliva and digested in the stomach where pepsin and gastric acid release cobalamin from the food protein allowing it to bind to haptocorrin (HC), also called R-protein or R-factor, a glycoprotein present in saliva. The HC-cobalamin complex moves to the duodenum where it is joined by HC-cobalamin recycled from bile. Pancreatic proteases with bicarbonate digest the HC releasing cobalamin to be bound by intrinsic factor (IF), which had been secreted by the gastric parietal cells. IF binding is specific for true cobalamin and does not bind the cobalamin analogues found widely in the

environment. The IF-cobalamin complex travels to the distal ileum where it is bound by the cubam receptor, a complex of cubilin and amnionless. The IF-cobalamin complex is internalized in lysosomes and two specific exporters (products of the LMBD1 and ABCD4 genes) are required to export it into the cytoplasm. Eventually cobalamin is bound to transcobalamin (TC), which is the physiologic delivery protein. A specific transcobalamin receptor (CD 320) facilitates cellular uptake wherein the TC is degraded by lysosomes and the cobalamin becomes available for intracellular processes. There are many intracellular transporters and enzymes responsible for the eventual appearance of the coenzyme forms of methyl-cobalamin on methionine synthase and adenosyl-cobalamin on L-methylmalonyl-Co-A mutase. The study of congenital defects in these enzymes, which are designated Cbl A-Cbl J, has elucidated much of this complicated metabolism. Some of these disorders are included in Table 150-2.

Cobalamin Transport

About 80% of total cobalamin in blood is bound to HC and only 10 to 20% to the delivery protein, TC. TC is known to be the most important carrier because inborn errors in TC lead to infantile megaloblastic anemia and severe disability. In contrast, deficiencies of HC are moderately common and do not appear to result in disease. HC binds analogues of cobalamin that are abundant in the human colon, foods, and the environment and may have a role in sequestering the analogues to facilitate their excretion. HC is present in white blood cells such as granulocytes. HC-cobalamin is taken up by the asialoglycoprotein receptors in the liver, which may facilitate the removal of analogues by secretion into the bile. There are problems in interpreting total cobalamin values because the cobalamin bound to TC is a small part of the circulating total, as discussed in the section on Diagnosis.

Malabsorption of Cobalamin as a Cause of Deficiency

Pernicious Anemia

Pernicious anemia was recognized many decades before cobalamin was identified because of the histamine-fast achlorhydria found in some patients with fatal progressive macrocytic pancytopenia. It is misnamed because it is a gastric disease, and many patients may not even have anemia. Pernicious anemia is due to a chronic inflammatory attack on the mucosa of the fundus and body of the stomach in which there are inflammatory infiltrates and an immune response to gastric H/K ATPase in the parietal cells. With atrophy of the gastric mucosa there is loss of the gastric parietal cells which produce IF in addition to stomach acid. This type A gastritis takes many years to develop and initially may cause iron deficiency anemia before the lesion is severe enough to result in the loss of IF.

Patients may produce anti-intrinsic factor antibodies, which can also block absorption of cobalamin. The cobalamin secreted into bile is lost in pernicious anemia because there is no IF in the duodenum to bind the cobalamin. Thus, instead of the usual normal loss of about 1 μg of cobalamin per day there may be 5 to 9 μg lost, greatly shortening the time to develop deficiency.

Helicobacter pylori is another cause of chronic gastritis, although it mostly affects the antrum of the stomach (Type B gastritis). Whether *H. pylori* plays a role in the progression of pernicious anemia and cobalamin deficiency is still undefined.

Pernicious anemia is found in association with other autoimmune disorders such as endocrinopathies like autoimmune thyroid disease, type I diabetes mellitus, and vitiligo. Relatives of patients with pernicious anemia may have the full spectrum of autoimmune diseases. The relationship between Graves disease and pernicious anemia is especially strong with about a quarter of the patients having both illnesses. It is important that women with autoimmune thyroid disease have adequate cobalamin status prior to pregnancy and throughout lactation.

Protein-Bound Cobalamin Malabsorption

Less severe forms of gastric atrophy appear in older adults, most frequently in those of European ancestry, wherein a loss of pepsin and gastric acid prevents the total release of cobalamin[13] from protein binding in food. Stomach acid–blocking medications may also impair the absorption of protein-bound cobalamin. The actual risk is uncertain because these medications are used frequently in an aging population that also has age-related gastric atrophy. Patients with gastric atrophy may be identified by serum markers as discussed in the Diagnosis section.

Cobalamin Malabsorption Due to Surgery

Total gastrectomy invariably results in severe cobalamin deficiency due to the loss of IF after 1 to 5 years depending on the underlying status of cobalamin stores. Bariatric surgery such as the Roux-en-Y gastric bypass and sleeve gastrectomy cause the food-cobalamin stream to be separated from the cells secreting IF because the stomach is bypassed. The cubam receptor is present in the distal 1 to 2 feet of ileum, so its loss due to inflammatory bowel disease or the surgical use of distal ileum to create an ileal conduit diversion or ileal cystoplasty causes cobalamin deficiency.

Other Causes of Malabsorption

Exocrine pancreatic dysfunction may cause failure of digestion of HC and release of cobalamin for binding by IF. Bacterial overgrowth as seen in tropical sprue has been shown to cause both cobalamin and folate deficiency. Infestation with a freshwater fish tapeworm, *Diphyllobothrium latum*, is an uncommon cause of usurpation of cobalamin in the duodenum. *Giardia lamblia* is a more common protozoal intestinal infection that may cause decreased cobalamin absorption.

Congenital Malabsorption of Cobalamin

Abnormal gastric IF (GIF) manifests as megaloblastic anemia in infancy or childhood, depending on the underlying cobalamin status at birth. Much more common disorders include mutations in the cubam receptor which have been found in either the cubilin or amnionless protein. This was initially described in Scandinavia and was given the name Imerslund-Gräsbeck disease, but it is particularly common in the Middle East. It is not known whether heterozygotes for these mutations might be more predisposed to nutritionally or atrophic gastritis-induced cobalamin deficiency.

Cobalamin Deficiency Due to Drugs

Many studies have reported on the effects of metformin on cobalamin status. Although it does appear to decrease serum cobalamin levels and may cause malabsorption in the ileum, it is not known whether it can induce full-blown megaloblastic anemia. The anesthetic agent nitrous oxide is a definite cause of cobalamin deficiency, usually manifesting as myeloneuropathy. The gas inactivates methionine-synthase and increases excretion of cobalamin, therefore repeated use induces a severe deficiency. Prolonged continuous use will cause bone marrow aplasia in about 10 days. Persons at risk are often employed in dental or medical offices where nitrous oxide is available or abuse nitrous oxide–containing whipping cream dispensers. There are also reports of a subacute neurologic progression of cobalamin deficiency occurring in patients with unrecognized pernicious anemia after only one episode of nitrous oxide anesthesia, symptoms occurring over days to weeks.[14] Often neurologic damage is permanent despite adequate replacement with cobalamin.

Folate

Folate Metabolism

The role of methyl-THF as a cofactor for methionine synthase was described above. However, there are other folate coenzymes that function as cofactors for many enzymes involved in amino acid metabolism, purine synthesis, methylation reactions, one carbon metabolism, and regulatory functions. Inhibition of these reactions due to folate deficiency can cause decreased cellular growth and proliferation, which is exploited in the use of antifolates for cancer chemotherapy. One cellular form, 5,10-methyleneTHF, is at a branch point to be used by thymidylate synthase to produce the thymidine necessary for DNA synthesis, or is reduced irreversibly by 5,10-methylenetetrahydrofolate reductase (MTHFR) to methyl-THF. As discussed above, methyl-THF must be converted by cobalamin-dependent methionine synthase before the folate can be used in other reactions. A common polymorphism in MTHFR (C677T), known as the thermolabile mutation, renders the enzyme somewhat less efficient and results in higher homocysteine and lower folate levels when folate intake is low. The prevalence of the polymorphism is quite variable, ranging from less than 1% in Africans to 30% in Mediterranean, Mexican, and northern Chinese populations. Its association with risk for various human disorders has been extensively studied but not clearly defined. The polymorphism changes the proportions of folate coenzyme forms, decreasing methyl-THF, and thus circulating folate levels. The increase in homocysteine levels and decrease in folate levels is most apparent in populations on low or marginal folate intakes.

Folate Absorption and Transport

Natural food folates are polyglutamated and must be hydrolyzed by an upper small intestinal brush border enzyme, folylpolyglutamate hydrolase. Folate monoglutamate is transported into the cells by a surface protein–coupled folate transporter (PCFT). Folic acid (nonreduced folate), a stable form, is used in supplements and fortified grains and has a bioavailability of about 90%. Folic

acid is reduced to THF and then methylated and released into the plasma. The reduced folate carrier (RFC, solute carrier family, SLC19A1) transports folates into and out of the cell. Absorbed folates in the portal circulation are taken up in the liver, polyglutamated, and retained or released into the circulation or bile. Circulating folates are bound to proteins, particularly albumin. Red blood cells accumulate folates during erythropoiesis, and thus the red cell folate level may more constantly reflect long-term folate status than serum folate. Concentrations of folates in CSF are three-fold higher than in blood, and the choroid plexus has abundant receptors for uptake and transport.

Causes of Nutritional Folate Deficiency

Nutritional folate deficiency occurs in the areas of the world that do not currently have folate food fortification. The foods containing the highest amount of naturally occurring folate are dark green leafy vegetables, beans and other legumes, nuts, orange juice, and liver or other organ meats. Potatoes, many fruits, and eggs have moderate amounts of folate but dairy items and muscle meat are much lower in folate. In high-resource countries, cereals, snack bars, sport drinks, and other foods promoted for health and exercise are often fortified with folic acid. Natural food folate intake has been estimated to be roughly 200 μg/day with an extra 200 μg in nonsupplement users from the added folic acid in fortified grains in persons in the United States. Total folate in supplement users was much higher, between 700 to 1000 μg per day. Low serum folate was found in approximately 15% in surveys of the U.S. population prior to the food folate fortification program. Nutritional folate deficiency is common in areas of the world with limited opportunity for consumption of fresh vegetable foods and is particularly a problem for women of childbearing age who require increased quantities to prevent folate deficiency–associated pregnancy complications. Folate-deficient diets are often deficient in other nutrients such as vitamin C, iron, and other vitamins and minerals.

Malabsorption of Folate

The serum folate level decreases within 3 weeks of severe folate malnutrition or malabsorption and megaloblastic bone marrow changes occur after 15 to 20 weeks. Folate malabsorption occurs in diseases of the upper small intestine and is rarely seen after gastrectomy or with Roux-en-Y gastric bypass. Celiac disease, which causes villous atrophy of the small intestine, causes folate deficiency in up to half of the patients. Tropical sprue, a cause of chronic diarrhea and progressive small intestinal villous atrophy, also causes folate deficiency with or without cobalamin deficiency. Inflammatory bowel disease, particularly Crohn disease, causes folate deficiency in addition to iron and vitamin B_{12} deficiency.

Conditions with Increased Folate Requirements

Diseases in which there is increased cellular proliferation may result in folate depletion. This includes skin diseases such as psoriasis and chronic hemolytic anemias, particularly sickle cell disease. Folates and other water-soluble vitamins are lost during renal hemodialysis.

Alcohol and Folate Deficiency

Alcohol abuse is the most common cause of folate deficiency manifesting megaloblastic anemia. Even well-nourished alcoholics may have macrocytosis and elevated homocysteine values, often when serum folate and hemoglobin are still normal. Alcohol-induced impairment of folate metabolism is exacerbated by poor nutrition. Megaloblastic anemia due to alcohol-associated folate deficiency still occurs despite the food folate fortification program in the United States. Folate-deficient alcoholics have been shown to have impaired intestinal absorption of folate, oxidative destruction of folates, impaired hepatic uptake, reduced storage, and enhanced renal excretion. Effects on the enzymes of methionine metabolism, particularly methionine synthase, are likely due to the toxic metabolites of ethanol. It may be difficult to recognize megaloblastic anemia in alcoholics because their frequently coexisting iron deficiency due to gastrointestinal bleeding may mask macrocytosis. In addition, alcohol induces sideroblastic anemia, an iron utilization defect, which can also mask macrocytosis. Nonalcohol related causes of cirrhosis can cause macrocytosis due to membrane abnormalities in the red cells, even with adequate folates.

Drugs That Cause Folate Deficiency

There are many drugs that interfere with folate metabolism (Table 150-2). The anticonvulsants, particularly carbamazepine, phenytoin, valproate, and phenobarbital have all been shown to cause macrocytosis, folate depletion, and hyperhomocysteinemia. Folic acid supplements improve folate status without preventing the antiseizure efficacy. There are many antifolates in common use, being exploited for their inhibitory effect on cellular proliferation such as methotrexate, pemetrexed, and pralatrexate used in cancer chemotherapy and in rheumatic diseases. It is interesting that the beneficial effect of methotrexate in rheumatoid arthritis is not counteracted by providing supplemental folic acid. Some antibiotics such as trimethoprim, pyrimethamine, and some sulfa derivatives are antifolates. Sulfasalazine used for inflammatory bowel disease will also cause folate depletion. Functional folate deficiency can be induced by drugs that require methylation for metabolism by depleting the normal stores of methyl groups. Drugs such as L-dopa, high-dose niacin, and an over-the-counter agent, α-lipoic acid, all raise homocysteine.

Inborn Errors of Folate Metabolism

There are two inborn errors of folate that present as megaloblastic anemia: methylenetetrahydrofolate dehydrogenase deficiency (MTHFD1) and hereditary folate malabsorption due to mutations in the protein-coupled folate transporter (PCFT). MTHFD1 deficiency has been found in six infants and children with megaloblastic anemia, immunodeficiency, or inflammatory conditions and hyperhomocysteinemia. Treatment with high doses of folic acid or folinic acid were beneficial in several of the patients. It is not yet known whether this disorder will be found in adult medicine.

Severe deficiencies of MTHFR (not the common thermolabile polymorphism) cause hyperhomocysteinemia with low methionine, but **not** megaloblastic anemia. These patients may present with thrombotic complications of hyperhomocysteinemia (Chapter 67) and neurologic deficits (Chapter 384). Treatment with betaine and folic acid greatly improves the prognosis.

CLINICAL MANIFESTATIONS

Definition of Macrocytosis

The best definition of macrocytosis is red blood cell mean cell volume (MCV) that is higher than the expected value for any individual patient. Clinicians who rely on laboratory reported ranges such as 80 to 100 fL will make errors in diagnosis because the MCV is affected by ethnicity and age. For instance, 30% of persons with African ancestry in the United States have one deleted α hemoglobin subunit and their median MCV is about 84 fL. It would take much longer for these individuals to increase the MCV to greater than 100 fL than someone whose normal MCV was 92 fL. Persons with β-thalassemia trait, hemoglobin E, and iron deficiency will also not usually have an increase in MCV to more than 100 fL despite the coexistence of severe megaloblastic anemia. Individuals with a combination of microcytic red cell indices and megaloblastosis may have oval macrocytes visible on the peripheral blood smear and a high red cell distribution width (RDW).

The causes of macrocytosis are shown in Table 150-1. As indicated, macrocytosis is not equivalent to megaloblastosis: there are many causes of macrocytic peripheral red blood cell indices that are not associated with a megaloblastic state. Reticulocytes, newly released red cells that are less than 24 hours old, are at their largest size and decrease as they age over 120 days in the circulation. Thus, reticulocytosis will increase the MCV, in many cases to over 100 fL. A rise in MCV may be the first sign of autoimmune hemolytic anemia and is also commonly found in patients with fragmentation anemia, sickle cell anemia, or with hemolysis due to infectious agents. Macrocytosis can be seen in patients who are post-splenectomy or have liver disease of any type, especially with associated alcoholism. Severe portal hypertension causes macrocytosis with thrombocytopenia and leukopenia mimicking a true megaloblastic anemia when examining only the peripheral blood smear. Chronic lung disease, particularly with associated hypoxia-induced polycythemia, is frequently macrocytic. Hypothyroidism and severe hyperglycemia also cause macrocytosis. The primary bone marrow disorders such as aplastic anemia, pure red cell aplasia, myelodysplastic syndrome, idiopathic myelofibrosis, and multiple myeloma may cause striking macrocytosis, with or without associated cytopenias. Cold agglutinins and paraproteinemias cause red cell clumping, which may lead to rouleau formation that can cause an erroneously high MCV. Drugs with effects on DNA synthesis, such as antiretrovirals, chemotherapy agents, and antifolates, cause macrocytosis.

Complications of Megaloblastic Anemias

Examples of peripheral blood smears and bone marrow aspirate and biopsy in megaloblastic anemia are shown in Fig. 150-2A-D (also see Chapter 143). The hallmark of megaloblastic pathology in the marrow is that cells are large ("megalo") and their nuclei have not matured ("blastic"); thus there are oval macrocytes and occasionally even a megaloblastic nucleated red blood cell detected on the peripheral blood smear. Other red blood cells are misshapen and fragmented and can be mistaken for schistocytes as seen in fragmentation anemias. There may be thrombocytopenia and leukopenia when

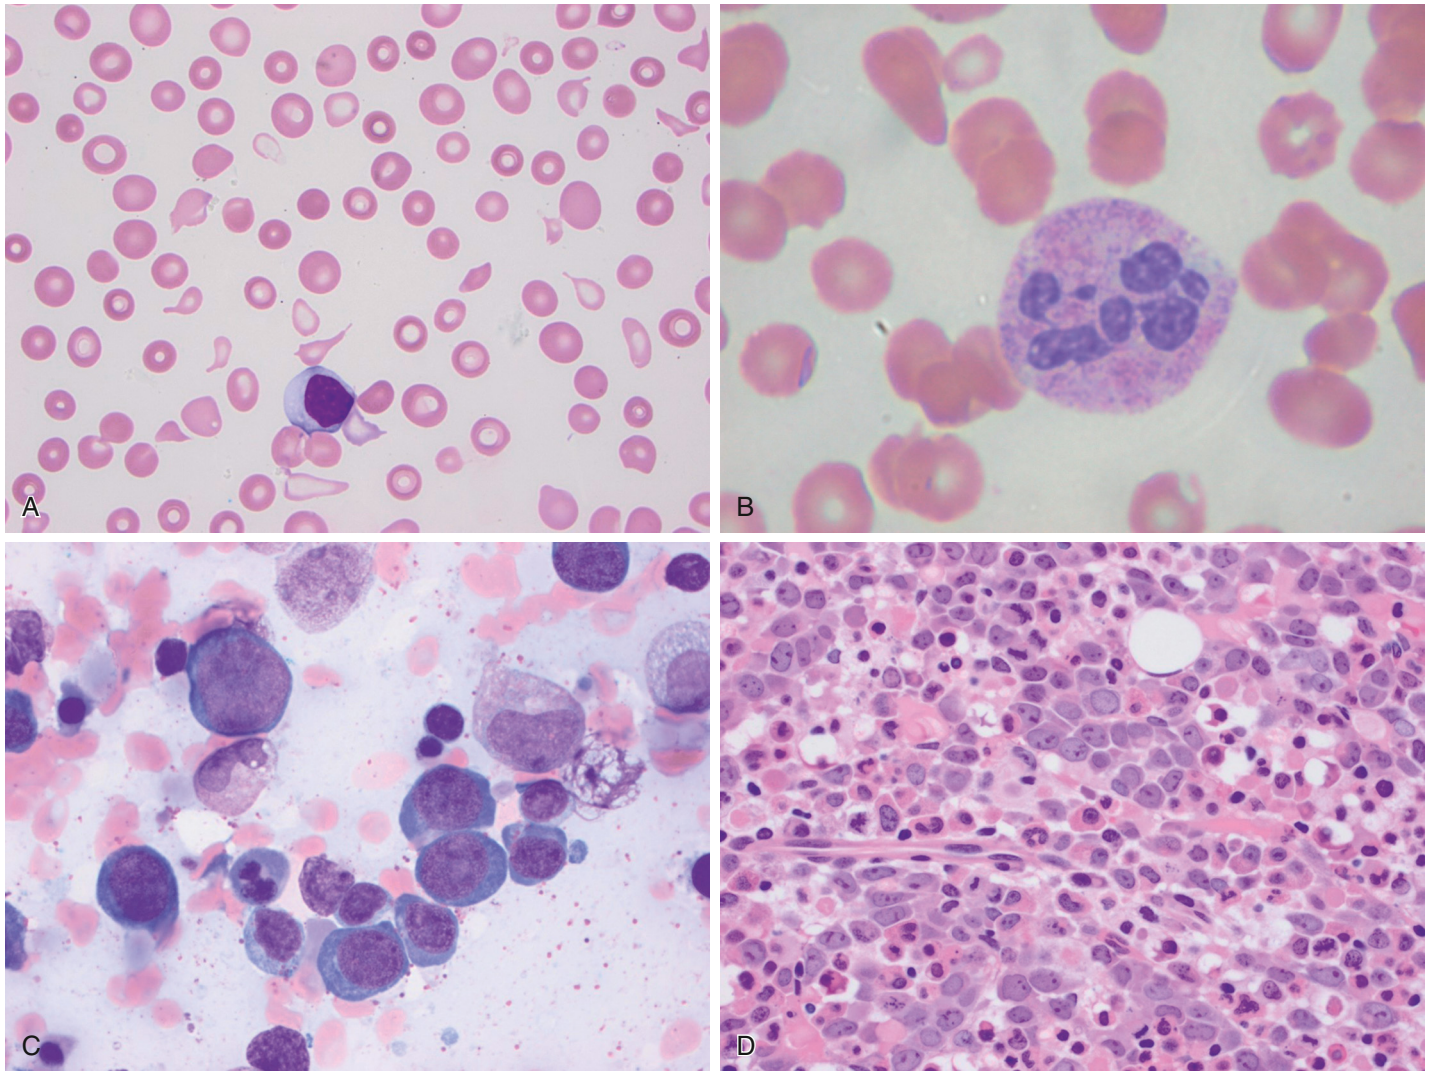

FIGURE 150-2. **Photomicrographs of peripheral smear, bone marrow aspirate, and biopsy are shown. A**, Oval macrocytes and fragmented red blood cells are present in a smear from a patient with severe cobalamin deficiency and thalassemia trait, demonstrating an extreme range in size and shape of the red blood cells. **B**, Hypersegmented neutrophil. **C**, A group of megaloblastic red cell precursors all with an open lacy chromatin pattern is shown from a bone marrow aspirate. Red cell dysplasia and giant metamyelocytes are also present. **D**, The bone marrow biopsy shows hypercellularity with a predominance of large erythroblasts and many mitotic figures, all potentially confused with acute leukemia. The erythroid hyperplasia in the bone marrow of a patient with megaloblastic anemia is due to "ineffective erythropoiesis." (Photomicrographs: 2B courtesy of John W. Ryder, MD, Department of Pathology, University of Colorado School of Medicine; 2 A, C, and D courtesy of Zenggang Pan, MD, PhD, Department of Pathology, University of Colorado School of Medicine.)

anemia becomes severe. Hypersegmented granulocytes are present. The presence of one 6-lobed or five 5-lobed granulocytes per 100 cells is considered abnormal. Some red blood cells may show basophilic stippling. A megaloblastic blood smear with oval macrocytes and fragmented red blood cells with thrombocytopenia has frequently been mistaken for microangiopathic hemolytic anemia such as thrombotic thrombocytopenia, as documented by case reports. Reticulocytopenia in megaloblastic anemias differentiates these microangiopathic-appearing red cells in the peripheral smear from hemolytic anemias. The bone marrow biopsy and aspirate smear is hypercellular with a decreased myeloid : erythroid ratio. There is delayed maturation of erythroblasts, which to the inexperienced observer may even suggest a diagnosis of acute leukemia because they are large cells with open chromatin and blue cytoplasm. The normal process of shrinking and condensing of the nucleus during erythropoiesis is impaired so that the chromatin pattern remains open and lacy (i.e., "megaloblastic"). Although nuclear maturation is delayed, cytoplasmic maturation (e.g., hemoglobinization of the cytoplasm) proceeds unimpaired, leading to the morphologic phenomenon of "nuclear cytoplasmic dissociation." These red cell precursors have poor survival within the bone marrow and pathologic abnormalities suggestive of cellular dysplasia with nuclear fragments in the red cells are present. The cellular apoptosis causes intramedullary hemolysis or "ineffective erythropoiesis." Maturation of white cell precursors is delayed, producing giant metamyelocytes and bands. Flow cytometry of the bone marrow demonstrates left shifts in erythroblasts and white cell precursors which again could lead the unwary to diagnose acute leukemia. Cytogenetic studies may show chromosomal fragmentation and in some cases even clonal abnormalities which correct with vitamin replacement and resolution of megaloblastic anemia.

Intramedullary hemolysis causes indirect hyperbilirubinemia, low serum haptoglobin, and sometimes extreme values for lactate dehydrogenase. The presence of markers of hemolysis and fragmented cells on a peripheral blood smear accompanied by a normal instead of low reticulocyte count can mimic hemolytic anemia. Furthermore, defects of cobalamin metabolism, such as a cobalamin-C mutation, can present with the hemolytic-uremic syndrome.

Other tissues that have rapid cellular turnover may become likewise megaloblastic. This abnormality is particularly common in the gastrointestinal tract, where it sometimes causes malabsorption. Cells of the uterine cervix can become megaloblastic and appear dysplastic. Impairment of spermatogenesis can cause infertility. Atrophy and glossitis of the tongue mucosa may occur. Some individuals may have areas of skin hyperpigmentation.

Neurologic Abnormalities Due to Cobalamin Deficiency

Cobalamin is necessary for the development and initial myelination and maintenance of the spinal cord and brain. Demyelination can be demonstrated on imaging in both brain and spinal cord as depicted schematically in Fig. 150-3. Cobalamin-deficient infants may have delay or failure in normal myelination which occurs during the first year of life. The demyelinating lesion, often termed "subacute combined degeneration," begins with symptoms of symmetric paresthesia, usually in the lower extremities but sometimes involving

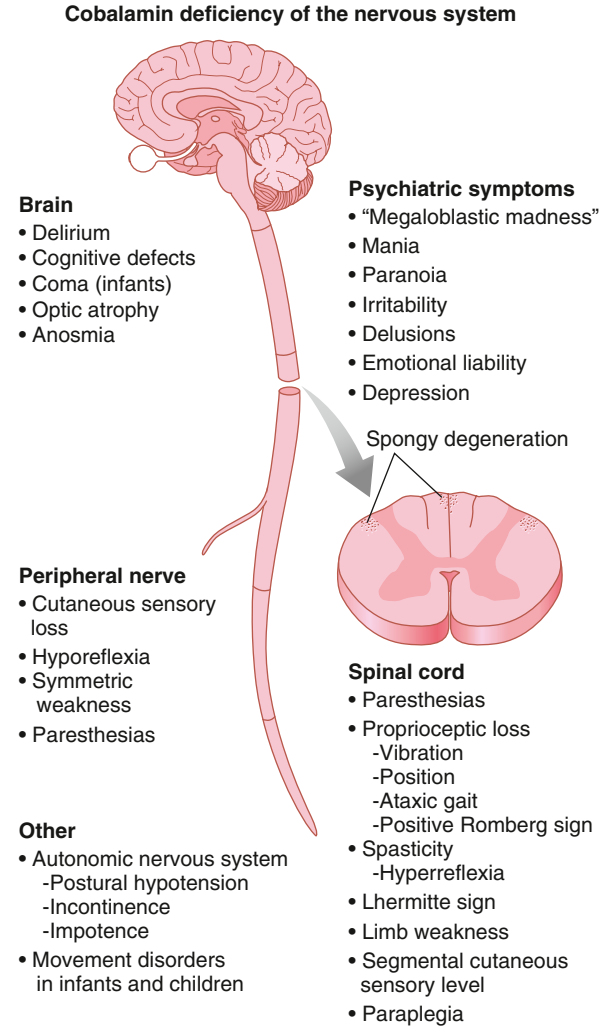

FIGURE 150-3. The myriad symptoms and signs of cobalamin deficiency of the nervous system are shown. These range from paresthesias without objective signs to severe motor loss, even quadriplegia. The spongy degeneration shown in the cross-section depiction of the spinal cord may be seen on magnetic resonance imaging as increased signal intensity on T2 weighted images often described as an inverted "V" sign. Also see Chapter 388. (Adapted from Stabler SP. Megaloblastic anemias: pernicious anemia and folate deficiency. In: Young NS, Green SL, High KA, eds. *Clinical Hematology*, Philadelphia: Mosby Elsevier; 2006:242-251.)

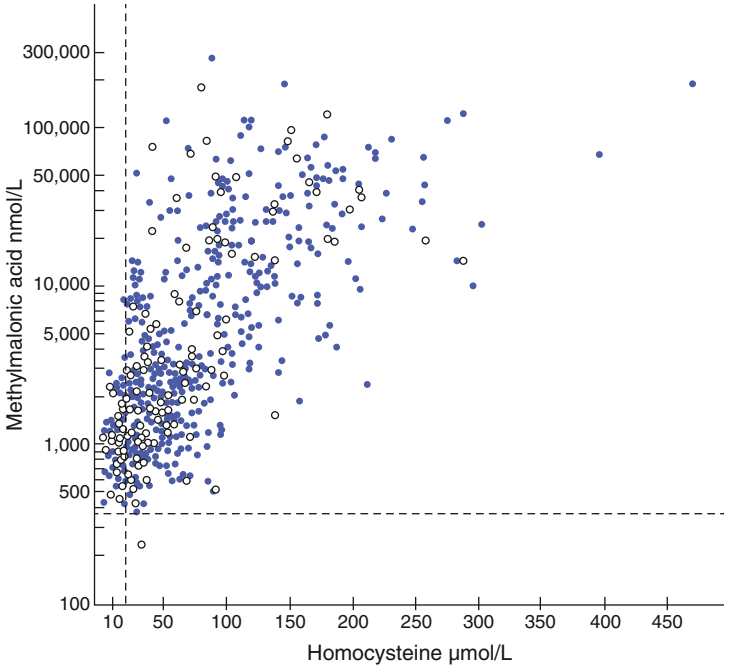

FIGURE 150-4. Serum methylmalonic acid plotted against serum homocysteine in patients with clinically ascertained and documented cobalamin deficiency. The serum methylmalonic acid plotted against homocysteine in about 500 patients with clinically ascertained cobalamin deficiency. Patients had either megaloblastic anemia (closed circles), which in most cases was proven to respond to cobalamin treatment, or a neurologic syndrome compatible with that found in cobalamin deficiency. Those shown as open circles had hematocrit values over 38%. Values were equal for methylmalonic acid and homocysteine whether the patients had anemia or mainly neurologic abnormalities. Methylmalonic acid was greater than 1000 nmol/L in 90% of these clinically proven patients. Hatched lines represent methylmalonic acid 376 nmol/L and homocysteine 21.3 μmol/L. (Previously published in Stabler S. Vitamin B12. In: Erdman, Jr. JW, McDonald IA, Zeisel SH, eds. *Present Knowledge in Nutrition*. 10th ed. Ames, IA: Wiley-Blackwell; 2012.)

the hands first. There is early impairment of proprioception ending with loss of vibration and position sense manifesting as ataxic gait. Other common signs and symptoms are shown in Fig. 150-3. As the severity of the spinal lesions increases weakness develops, with spasticity and hyperreflexia, and eventually patients may develop a segmental cutaneous sensory level and even paraplegia. Altered mental status occasionally occurs particularly with irritability, delusions, paranoia, lability, even mania called "megaloblastic madness" in the past.

The underlying biochemical lesions causing the neurologic disease are still unknown, although changes in lipids, growth factors, cytokines, or methylation status of proteins have all been studied. There is a strong inverse relationship between the severity of the neurologic abnormalities and the hematologic abnormalities. Therefore, the coexistence of anemia is helpful in a patient with a compatible neurologic disorder in suggesting cobalamin deficiency but is not required. Patients with a normal hemoglobin level and a neurologic presentation have similar metabolic abnormalities as do patients with anemia (Fig. 150-4). There is also an inverse relationship between the duration of neurologic abnormalities prior to diagnosis and the completeness of correction after adequate cobalamin replacement, so early diagnosis is imperative (see Chapter 384).

DIAGNOSIS

Cobalamin and Folate Biochemical Assays

Measurement of the serum cobalamin or folate level has been a time-honored method of screening. Original tests have been replaced today with automated assays of cobalamin levels performed on instruments with platforms for multiple analytes. These methods rely on purified intrinsic factor (IF) as the cobalamin binder, often using chemiluminescent microparticle immunoassays for detection. It has been reported that denaturation of anti-IF antibodies present in samples from patients with pernicious anemia can be incomplete, and thus normal to even high values of cobalamin are reported falsely. In general, the values reported from these automated methods are higher than with the historical assays, which complicates comparison of reference ranges. Extremely low values of serum cobalamin (<70 pg/mL) usually reflect deficiency associated with clinical abnormalities that will improve with treatment, but such patients are rare. There is a large equivocal range (100 to 300 pg/mL) in which further testing with metabolites is needed to distinguish between false-positive low and true-positive low or low normal values.

A low serum folate (<3 ng/mL) is clinically significant when found in food folate fortified countries such as the United States. Most authorities have, however, raised the lower limit of the reference range to 5 to 6 ng/mL, values that overlap with the median in populations without fortification. Red blood cell folate should be a good marker of longer-term folate status but the methodology of measuring folate in the presence of the red cell protein matrix has led to poor reproducibility, and the assay cannot be recommended for routine clinical use outside of research investigations.

An assay of the amount of cobalamin bound to transcobalamin, holo-transcobalamin (Holo-TC or "active B_{12}"), is available in Europe and Canada but not yet FDA-approved in the United States. Anti-intrinsic factor antibodies, which are present in pernicious anemia, do not affect this assay, but a polymorphism in the TC gene prevents measurement using this method. Holo-TC increases after oral intake of a large amount of cobalamin and thus is being developed as a test for absorption.

Methylmalonic Acid and Homocysteine Markers of Deficiency

Excess methylmalonic acid is produced when L-methylmalonyl-Co-A mutase is blocked by cobalamin deficiency. Therefore, elevated serum or urine methylmalonic acid has been proven to be a very sensitive indicator of cobalamin status. Patients who have low cobalamin values but normal serum methylmalonic

acid do not respond to treatment and have false-positive low cobalamin levels. The methylmalonic acid value is the first test to become abnormal in infrequently treated patients with proven pernicious anemia. The methylmalonic value decreases immediately after treatment, normalizing within days to weeks. Thus, methylmalonic acid must be assayed prior to treatment. A common clinical error is to treat a patient who likely has a false-positive low cobalamin level and when anemia or the clinical symptoms do not respond, to proceed with assaying methylmalonic acid. After treatment, serum methylmalonic acid normalizes or decreases into the high normal range in seniors (<400 nmol/L) and others with mild renal insufficiency.

Methylmalonic acid values increase above the reference range in renal insufficiency but are usually less than 1000 nmol/L even in patients on renal dialysis. A related metabolite, 2-methylcitric acid, is measured with methylmalonic acid by some commercial testing laboratories and, if higher than the simultaneous methylmalonic acid value, will diagnose renal insufficiency rather than vitamin deficiency. Methylmalonic acid is a product of propionic acid metabolism; thus gut bacterial overgrowth can cause higher values sometimes responsive to antibiotics. A polymorphism in HIBCH, an enzyme in valine catabolism, may cause a mild increase in methylmalonic acid.

Patients with severe inborn errors of cobalamin metabolism rarely normalize methylmalonic acid, even with very intensive parenteral treatment. Such individuals are occasionally detected in adult medicine practices and should be referred to a metabolic center.

Homocysteine

Homocysteine levels increase when either cobalamin or folate deficiency impairs the activity of methionine synthase and cannot be used to distinguish between cobalamin or folate deficiency, because serum homocysteine levels are elevated in 95% of clinically proven folate-deficient individuals. When patients with elevated serum homocysteine levels are treated with the wrong vitamin, the homocysteine level does not decrease. Elevated homocysteine responds to treatment with the correct vitamin very rapidly, often within hours; thus, as in the case of methylmalonic acid, it must be measured prior to any treatment. Even nutritious hospital food may correct elevated homocysteine. Adding vitamins to intravenous fluids for suspected alcoholic patients in the emergency department will correct serum folate levels, and if homocysteine is not assayed rapidly it too will have fallen, yet the patient will still have unexplained megaloblastic anemia. There is a strong relationship between folate intake and homocysteine values in populations that are cobalamin replete. U.S. population serum homocysteine values fell by several μmol/L after folate food fortification. Renal failure increases homocysteine by unclear mechanisms because homocysteine is not dependent on urinary clearance, although the kidney is rich in homocysteine-metabolizing enzymes. Homocysteine can be elevated in hypothyroidism, severe pyridoxine deficiency, and in the presence of antifolate drugs.

If cobalamin is measured because of vague complaints of fatigue and nonspecific neurologic or psychiatric symptoms, most values lower than 200 pg/mL will be false-positive low. The sensitivity of a low cobalamin value (<200 pg/mL) is about 60%.

The sensitivity of a serum methylmalonic acid value higher than 400 nmol/L is about 98% for clinical deficiency, but its specificity for clinical abnormalities is much less because serum methylmalonic acid rises quickly in response to cobalamin depletion. It may be mildly abnormal in patients with other causes of anemia or neurologic syndromes, as seen frequently in seniors or vegetarians. Patients with modest elevations of methylmalonic acid (<700 nmol/L) may not have any clinical syndrome attributable to cobalamin deficiency.

Diagnosis of Pernicious Anemia

Blocking anti-intrinsic factor antibodies are found in 50 to 70% of patients. Anti–parietal cell antibodies are found in a higher percentage (90%) but are less specific because they are found in other autoimmune diseases and forms of gastritis. Demonstration of histamine-fast achlorhydria is rarely performed but is very specific for pernicious anemia. The gastric antrum is spared in pernicious anemia, and the gastrin-producing cells may become hyperplastic. Elevated fasting serum gastrin is suggestive of pernicious anemia. Another marker of the gastric mucosa is pepsinogen-1, which is low in pernicious anemia. These markers, however, are affected by the widespread use of proton pump inhibitor medications. At least a week after a cobalamin injection should elapse before testing for anti-intrinsic factor antibodies.

Endoscopy with gastric biopsy is the best method of diagnosing atrophic gastritis, and some experts recommend that patients with pernicious anemia have at least one screening endoscopy because they are at greater risk for carcinoid tumors and adenocarcinoma of the stomach. This approach would be mandatory for patients who have symptoms consistent with gastric neoplasm or coexisting iron deficiency.

A radio-labeled cobalamin absorption test known as the Schilling test is no longer available. A test using the increase in holo-TC values after three doses of unlabeled oral cobalamin is being investigated and may prove to be a good substitute.

Folate Malabsorption

There are no specific tests for folate malabsorption. The presence of a disease of the upper small intestine such as celiac disease, tropical sprue, or Crohn disease will point to folate malabsorption. Folate deficiency is often associated with iron and multiple other nutrient deficiencies in contrast to cobalamin deficiency due to pernicious anemia.

TREATMENT

Cobalamin Deficiency

The primary goals of treatment of cobalamin deficiency are to restore the normal tissue content of cobalamin (between 2 to 5 mg in an adult human) and prevent relapse. Parenteral administration of either cyano- or hydroxy-cobalamin is rapidly effective. Common treatment regimens in severely symptomatic patients would be daily intramuscular or subcutaneous injection of 1 mg (1000 μg) for 7 days or every other day for 2 weeks, followed by weekly injections for 8 weeks, then monthly. Less symptomatic patients could be loaded with biweekly or weekly doses for 8 weeks followed by monthly administration. Hydroxycobalamin is retained better than cyano-cobalamin and after loading can be given at 2- to 4-month intervals instead of monthly. About 150 μg is retained after an injection of 1 mg, which is why it is necessary to provide multiple injections during the loading treatment phase to achieve the replacement of 2 to 5 mg. However, a single 10,000 μg dose can correct pernicious anemia for at least 3 months.[15] Methylmalonic acid remains elevated in about 20% of pernicious anemia patients injected monthly with cyano-cobalamin, which will normalize with a shorter time interval between injections. There is no toxicity upper limit for cobalamin, and patients may claim that their well-being is enhanced by injections as frequent as every 2 to 3 weeks.

A small percentage (0.5 to 2%) of a high dose of oral cobalamin is absorbed by mass action in the upper intestinal tract without IF or an intact ileum. Randomized trials comparing parenteral and high oral doses (1000 to 2000 μg/day) have shown equivalent clinical correction, rise in serum cobalamin, and normalization of elevated methylmalonic[A1,A2] acid and homocysteine levels.[16] Patients with severe abnormalities should receive at least 2000 μg/day initially, so they absorb 20 to 40 μg/day. High-dose cobalamin tablets containing 500 μg to 2.5 mg dosages are available without prescription in the United States. Physician error is one of the leading causes of discontinuation of treatment in pernicious anemia. Patients should be taught to start self-directed treatment with high-dose oral tablets if denied medical follow-up for cobalamin deficiency. High-dose preparations may be less available in other parts of the world. There are also preparations designed for intranasal or sublingual use, which have been less studied in patients with true pernicious anemia. Patients and providers may have preferences as to cost, convenience, compliance, and comfort relating to injected versus oral treatment.[17]

The alternative cobalamin forms methyl- and adenosyl-cobalamin are also available for replacement but are unstable, converting to the aquo(hydroxy) form on exposure to light. There is no advantage in using these expensive alternatives because they will undergo the same metabolic conversions as does cyano- or hydroxyl-cobalamin. Treatment of neuropathic pain with methylcobalamin may be an exception.[18]

Treatment of Dietary Deficiency

Patients with dietary deficiency should be loaded with high-dose oral or parenteral cobalamin to replete tissue stores (2 to 5 mg). This is crucial for vegetarian women contemplating pregnancy, especially from countries with high prevalence of cobalamin deficiency. The amount of cobalamin in maternal vitamins is too low to replete stores quickly; IF-mediated absorption is limited to 2 to 5 μg per day, so it would take an entire pregnancy to replace 1 to 2 mg, and the infant could be born deficient. The breast-feeding mother should also be loaded to normal stores because her breast milk will be deficient if only small supplements are used. The cobalamin-replete vegetarian can supplement smaller quantities such as in multivitamin tablets (i.e., 3 to 9 μg/day). Persons who avoid animal-source foods are often also deficient in iron and many other vitamins. There is a large literature on methods to improve growth and development of children in resource-poor countries with combinations of protein, iron, folic acid, cobalamin, and other nutrients.

Recommendations for Treatment of Seniors

The incidence of both true pernicious anemia and atrophic gastritis increase with age. The high usage of metformin and stomach acid–blocking drugs is also more prevalent with age, which compounds the potential malabsorption of

cobalamin. Elevated methylmalonic acid, which corrects with cobalamin treatment, is very prevalent (up to 40%) in studies of the oldest old. Theoretically, smaller doses of cobalamin should be effective in patients who still have some residual IF, but studies in seniors have shown that at least 500 μg/day is necessary to correct most individuals with elevated methylmalonic acid. The Food and Nutrition Board recommended that seniors take an unspecified dose of cobalamin daily. It seems prudent to recommend a supplement of at least 1000 μg/day for individuals at risk for malabsorption. Many clinical trials of cobalamin and folate replacement in correcting diseases of aging such as cognitive impairment[A3,19,20] or osteoporosis have been disappointing. A possible exception is a trial of cobalamin in improving nerve conduction in seniors.

Treatment of Folate Deficiency

Because either cobalamin or folate deficiency causes megaloblastic anemia and elevated homocysteine levels, it is important to distinguish which vitamin is deficient or to treat potential deficiency of both. If serum methylmalonic acid is elevated then there is at least cobalamin deficiency (Table 150-3). This consideration is particularly important in countries with food folate fortification where almost all elevated homocysteine is due to cobalamin deficiency and not folate deficiency. Pharmacologic doses of folic acid (i.e., 1 mg daily) can partially correct megaloblastic anemia in cobalamin-deficient anemia, which has been termed "masking of pernicious anemia." Unfortunately, if neurologic lesions are present they will continue to progress and may become irreversible if a cobalamin-deficient patient is treated with only folate. Over-the-counter folic acid supplements are topped at 800 μg in the United States to prevent inadvertent use by patients with pernicious anemia. Prescription doses of 1 to 5 mg daily of oral folic acid are acceptable treatments for replacement. Patients who have ongoing alcoholism, gut malabsorption, hemolytic anemia, or other unknown pathology should remain on replacement indefinitely. Folic acid 1 mg daily can also be given to patients taking methotrexate for rheumatologic disease, or to patients taking niacin or L-dopa to prevent hyperhomocysteinemia. Pretreatment with folic acid and cobalamin is used with the multitargeted antifolate chemotherapy agents. There is no advantage to treating with methyl-THF over folic acid.

Treatment of Hyperhomocysteinemia

Severe hyperhomocysteinemia (homocysteine >50 μmol/L) is a prothrombotic condition whether due to classical homocystinuria, other inborn errors of metabolism, or vitamin deficiency (Chapter 193). There are many case reports of thrombosis as the presenting complaint in pernicious anemia. The association of hyperhomocysteinemia with vascular disease and thrombosis prompted many large trials of folic acid or combination B vitamin (high-dose cobalamin, vitamin B_6, plus folate) therapy in vascular disease, but the trials have not been successful or have been even harmful,[A4] except for a decrease the incidence of stroke in folate-deficient populations.[21] For example, a randomized trial of antihypertensive medication with or without folic acid, 800 μg daily, in China demonstrated a hazard ratio of 0.79 for decreased risk of stroke,[A5] and a trial of high-dose combination cobalamin, folic acid, and vitamin B_6 in high-altitude soldiers in India decreased thrombotic events by 54%.[A6] Beneficial effects of folic acid or combination B vitamin treatment are easier to prove in populations that are not already eating folate fortified food. Trials in patients with renal failure, especially on dialysis, have not shown benefit in homocysteine lowering and perhaps harm in diabetic kidney disease.

Any patient with extreme hyperhomocysteinemia (>100 μmol/L) should be investigated thoroughly with assay of methylmalonic acid and methionine and a documented response to treatment after replacement. Patients with milder types of pyridoxine-responsive classic homocystinuria may present in adulthood with thrombotic disease, although not with megaloblastic anemia. All patients with nonresponsive hyperhomocysteinemia should be referred to a metabolic center.

TABLE 150-3 USING METABOLITES TO DIAGNOSE COBALAMIN AND FOLATE DEFICIENCY

If methylmalonic acid is elevated >400 nmol/L, consider cobalamin deficiency
If homocysteine is elevated >14 μmol/L, then consider either cobalamin or folate or both deficiencies
Pretreatment metabolite testing will distinguish between true-positive and false-positive low cobalamin values
Metabolite testing is prudent in severe anemia/pancytopenia or demyelinating central nervous system disease regardless of vitamin levels

PREVENTION

Severe consequences of cobalamin deficiency can be prevented by investigating those patients at highest risk, which includes patients with autoimmune thyroid disease, vitiligo, history of gastrointestinal surgery, and family histories of pernicious anemia and autoimmunity. The tragedy of the cobalamin-deficient breast-fed infant should be completely avoidable if attention is paid to the prepregnancy cobalamin status of women who are at risk for deficiency especially with Graves or other autoimmune thyroid disease, vitiligo, status post bariatric or other gastrointestinal surgery, inflammatory bowel disease, and those who avoid animal-source foods. Women who limit animal-source food and immigrants from countries with known cobalamin deficiency should be proven to be cobalamin replete prior to pregnancy. Newborn screening programs using tandem mass spectrometry have revealed that there are as many infants with nutritional cobalamin deficiency as with the inborn errors of cobalamin metabolism. It is possible that prompt treatment of these infants will prevent the worst of the growth failure and neurodevelopmental abnormalities seen when they are discovered later.[22]

The widespread cobalamin and other micronutrient deficiencies in resource-poor areas of the world and in populations who shun animal-source foods is a difficult problem. Increasing meat, dairy, and other animal foods is an expensive approach for populations eating mostly plant-based proteins. Some fermented plant foods such as enset, tempeh, and algae derivatives do contain cobalamin although the concentrations are likely variable. Innovative approaches such as supplementing toothpaste have been tested and could potentially be useful.[A7] Another approach such as fortifying tea bags in India with both cobalamin and folic acid might be useful.

Prevention of Folate Deficiency

Folate food fortification, which has been adopted by many countries, can effectively raise folate levels.[A8] The programs were designed to increase folate status in women to prevent neural tube defects. Neural tube defects have decreased by 25 to 50% depending on the preexisting folate status of the population. Despite food fortification, women of childbearing age in the United States are recommended to take supplements of 400 μg of folic acid daily. Prenatal vitamins are fortified with folic acid at 1 mg/day and are recommended prior to conception and throughout gestation and breastfeeding. Folic acid supplements of 1 mg daily should be given to patients with inflammatory bowel disease, celiac disease, on methotrexate or older anticonvulsants, and to those with chronic hemolytic anemias. Dietary folate deficiency can be corrected by adding green leafy vegetables, legumes, fruits, and organ meats to the diet.

PROGNOSIS

Megaloblastic Anemia

Megaloblastic anemia due to cobalamin or folate deficiency should correct completely with the appropriate vitamin so long as there are no comorbidities. There is an increase in reticulocyte count within 5 days, and the hemoglobin normalizes by 1 to 2 months. Some patients can produce a unit of blood per week with replacement. Thrombocytopenia and leukopenia also correct within the first 2 weeks. Iron deficiency will manifest as a blunting of the hemoglobin response, a fall in MCV into the microcytic range, and a decrease in serum ferritin and iron saturation. The anemia of chronic renal failure may coexist in seniors with cobalamin deficiency and could be treated if appropriate with erythropoiesis-stimulating agents (Chapter 116). Patients with intestinal diseases may need combination cobalamin and folic acid treatment.

The most likely diagnosis in a failure of vitamin treatment is that of an incorrect diagnosis due to a false-positive low vitamin level. There may be cobalamin deficiency with coexisting myelodysplastic syndrome or other bone marrow disease. Folate-deficient alcoholics often have multifactorial anemia and a prolonged period of abstinence with folic acid treatment may be required, especially if the bone marrow is sideroblastic.

Correction of glossitis and other megaloblastic abnormalities in the intestinal tract may manifest as positive weight gain in malnourished patients.

Recurrent macrocytosis or anemia during adequate cobalamin replacement may suggest associated autoimmune disease, particularly thyroid disorders or autoimmune hemolytic anemia. Recurrent iron deficiency due to malabsorption from achlorhydria could be a continuing problem, especially pertinent in patients who have undergone bariatric surgery.

Cobalamin Deficiency of the Central Nervous System

The demyelinating nervous system pathology is not always reversible with cobalamin treatment (Chapter 384). The duration of and severity of symptoms before treatment is inversely correlated with the extent of correction of the abnormalities. Paresthesias and behavioral changes are the quickest and most likely to correct. Spinal cord lesions that have progressed to

severe sensory loss and motor weakness usually do not correct fully. The cobalamin-deficient infant often has residual impairments and permanent disability. There is an occasional patient who develops paresthesias in the first few days after cobalamin replacement, which will resolve with further treatment.

It is important to document elevated methylmalonic acid or homocysteine in a patient who presents without megaloblastic anemia because there is a significant probability of a false-positive low cobalamin level in such patients. Lack of improvement or progression of neurologic symptoms and signs when cobalamin has been adequately replaced is proof that there is another cause for the symptoms. Diseases such as spinal stenosis or multiple sclerosis will not respond to cobalamin replacement, and delay in diagnosis during futile cobalamin therapy may harm the patient.

151 APLASTIC ANEMIA AND RELATED BONE MARROW FAILURE STATES

AMY E. DEZERN AND ROBERT A. BRODSKY

IDIOPATHIC APLASTIC ANEMIA

DEFINITION

Idiopathic aplastic anemia is a hematopoietic stem cell disorder associated with markedly reduced marrow cellularity and markedly decreased hematopoiesis. The decreased hematopoiesis may disproportionately affect fewer lineages in early stages, but aplastic anemia is ultimately associated with trilineage hypoplasia.

EPIDEMIOLOGY

Aplastic anemia can be inherited or acquired. The majority of cases of acquired aplastic anemia are idiopathic, but causative conditions include viral infections and medications (Table 151-1).

Aplastic anemia is chiefly a disease of children and younger adults, with a second peak in incidence observed in patients age 60 years and older. Aplastic anemia is rare in Western Europe and the United States (fewer than two cases per million population per year). The incidence of aplastic anemia is higher in Asia at five to six cases per million population per year. The higher incidence in Asian countries has been linked to environmental factors such as chemicals or infections more than genetic factors. Both males and females are equally affected.

TABLE 151-1 PRIMARY AND SECONDARY CAUSES OF ACQUIRED APLASTIC ANEMIA

PRIMARY
Idiopathic aplastic anemia
Pregnancy-associated aplastic anemia
Classical paroxysmal nocturnal hemoglobinuria syndrome (Chapter 146)
SECONDARY
Drug associated (see E-Table 151-1)
Iatrogenic/cytotoxic
Radiation-associated
Viruses (Epstein-Barr virus, cytomegalovirus, hepatitis A, B, or C))
Autoimmune (autoimmune hepatitis and pancytopenia of autoimmune disease)

PATHOBIOLOGY

Acquired aplastic anemia is believed to be the result of an autoimmune attack directed at hematopoietic progenitor cells (Chapter 142). The immune attack is primarily directed by cytotoxic T cells that target hematopoietic stem cells and cause apoptosis, thereby leading to hematopoietic failure.[1,2]

Aplastic anemia is most often associated with normal cytogenetics. An abnormal karyotype in a patient with a hypocellular marrow is more consistent with a diagnosis of myelodysplastic syndrome (Chapter 167), although chromosomal abnormalities such as trisomy 8 or deletion 13q may still be consistent with an aplastic anemia diagnosis.

Acquired aplastic anemia generally lacks germline mutations, whereas inherited forms are driven by a germline mutation.[3] About 60 to 70% of idiopathic aplastic anemia patients demonstrate acquired clonality at the time of diagnosis on sensitive next-generation sequencing and array-based karyotyping using comparative genomic hybridization. The clones often remain despite therapies other than hematopoietic stem cell transplant and are frequently the source of relapse and/or progression.

CLINICAL MANIFESTATIONS

At initial presentation, many patients with aplastic anemia manifest symptoms of anemia, including fatigue, weakness, pallor, and headaches. Severe thrombocytopenia (Chapter 158) causes petechiae of the skin and mucous membranes, epistaxis, and/or gum bleeding. Fever and infections can also be seen in the presence of neutropenia (Chapter 153). However, some patients are identified earlier in the course of disease because of cytopenias found on routine laboratory testing before they have any symptoms or signs of the disease.

DIAGNOSIS

The diagnosis of aplastic anemia requires either a bone marrow with <25% of the normal cellularity or bone marrow with <50% normal cellularity in which less than 30% of the cells are hematopoietic. Cellularity is often profoundly decreased (<10%; Fig. 151-1), but small islands of hematopoiesis can be seen. The marrow aspirates in aplastic anemia do not show overt dysplastic changes, and blastic forms are not increased. The peripheral blood in aplastic anemia shows pancytopenia with a relative lymphocytosis, but is otherwise unremarkable.

Idiopathic aplastic anemia is a diagnosis of exclusion, and no single test can consistently distinguish aplastic anemia from other causes of bone marrow failure. However, extensive historical questions, findings on the physical examination, and laboratory diagnostics can help determine the cause of bone marrow failure (Table 151-2). Congenital forms must be excluded, especially in younger patients, prior to making a diagnosis of acquired aplastic anemia.[4] Aplastic anemia must be differentiated from hypoplastic myelodysplastic syndrome (Chapter 167), in which the mutational spectrum overlaps with aplastic anemia, as well as from inherited bone marrow failure disorders for which the phenotypic presentations might be indiscernible.

Aplastic anemia is further classified by the severity of the depression of peripheral blood counts. *Severe aplastic anemia* is defined by depression of blood counts involving at least two hematopoietic lineages (i.e., absolute reticulocyte count <60,000/μL, absolute neutrophil count <500/μL, or a platelet count <2000/μL) and bone marrow hypocellularity (<30%, excluding lymphocytes). *Very severe aplastic anemia* has an absolute neutrophil count of <200/μL, whereas *moderate aplastic anemia* is characterized by depression of blood counts not fulfilling the definition of severe disease (Table 151-3).

151 APLASTIC ANEMIA AND RELATED BONE MARROW FAILURE STATES

AMY E. DEZERN AND ROBERT A. BRODSKY

IDIOPATHIC APLASTIC ANEMIA

DEFINITION

Idiopathic aplastic anemia is a hematopoietic stem cell disorder associated with markedly reduced marrow cellularity and markedly decreased hematopoiesis. The decreased hematopoiesis may disproportionately affect fewer lineages in early stages, but aplastic anemia is ultimately associated with trilineage hypoplasia.

EPIDEMIOLOGY

Aplastic anemia can be inherited or acquired. The majority of cases of acquired aplastic anemia are idiopathic, but causative conditions include viral infections and medications (Table 151-1).

Aplastic anemia is chiefly a disease of children and younger adults, with a second peak in incidence observed in patients age 60 years and older. Aplastic anemia is rare in Western Europe and the United States (fewer than two cases per million population per year). The incidence of aplastic anemia is higher in Asia at five to six cases per million population per year. The higher incidence in Asian countries has been linked to environmental factors such as chemicals or infections more than genetic factors. Both males and females are equally affected.

TABLE 151-1 PRIMARY AND SECONDARY CAUSES OF ACQUIRED APLASTIC ANEMIA

PRIMARY
Idiopathic aplastic anemia
Pregnancy-associated aplastic anemia
Classical paroxysmal nocturnal hemoglobinuria syndrome (Chapter 146)
SECONDARY
Drug associated (see E-Table 151-1)
Iatrogenic/cytotoxic
Radiation-associated
Viruses (Epstein-Barr virus, cytomegalovirus, hepatitis A, B, or C))
Autoimmune (autoimmune hepatitis and pancytopenia of autoimmune disease)

PATHOBIOLOGY

Acquired aplastic anemia is believed to be the result of an autoimmune attack directed at hematopoietic progenitor cells (Chapter 142). The immune attack is primarily directed by cytotoxic T cells that target hematopoietic stem cells and cause apoptosis, thereby leading to hematopoietic failure.[1,2]

Aplastic anemia is most often associated with normal cytogenetics. An abnormal karyotype in a patient with a hypocellular marrow is more consistent with a diagnosis of myelodysplastic syndrome (Chapter 167), although chromosomal abnormalities such as trisomy 8 or deletion 13q may still be consistent with an aplastic anemia diagnosis.

Acquired aplastic anemia generally lacks germline mutations, whereas inherited forms are driven by a germline mutation.[3] About 60 to 70% of idiopathic aplastic anemia patients demonstrate acquired clonality at the time of diagnosis on sensitive next-generation sequencing and array-based karyotyping using comparative genomic hybridization. The clones often remain despite therapies other than hematopoietic stem cell transplant and are frequently the source of relapse and/or progression.

CLINICAL MANIFESTATIONS

At initial presentation, many patients with aplastic anemia manifest symptoms of anemia, including fatigue, weakness, pallor, and headaches. Severe thrombocytopenia (Chapter 158) causes petechiae of the skin and mucous membranes, epistaxis, and/or gum bleeding. Fever and infections can also be seen in the presence of neutropenia (Chapter 153). However, some patients are identified earlier in the course of disease because of cytopenias found on routine laboratory testing before they have any symptoms or signs of the disease.

DIAGNOSIS

The diagnosis of aplastic anemia requires either a bone marrow with <25% of the normal cellularity or bone marrow with <50% normal cellularity in which less than 30% of the cells are hematopoietic. Cellularity is often profoundly decreased (<10%; Fig. 151-1), but small islands of hematopoiesis can be seen. The marrow aspirates in aplastic anemia do not show overt dysplastic changes, and blastic forms are not increased. The peripheral blood in aplastic anemia shows pancytopenia with a relative lymphocytosis, but is otherwise unremarkable.

Idiopathic aplastic anemia is a diagnosis of exclusion, and no single test can consistently distinguish aplastic anemia from other causes of bone marrow failure. However, extensive historical questions, findings on the physical examination, and laboratory diagnostics can help determine the cause of bone marrow failure (Table 151-2). Congenital forms must be excluded, especially in younger patients, prior to making a diagnosis of acquired aplastic anemia.[4] Aplastic anemia must be differentiated from hypoplastic myelodysplastic syndrome (Chapter 167), in which the mutational spectrum overlaps with aplastic anemia, as well as from inherited bone marrow failure disorders for which the phenotypic presentations might be indiscernible.

Aplastic anemia is further classified by the severity of the depression of peripheral blood counts. *Severe aplastic anemia* is defined by depression of blood counts involving at least two hematopoietic lineages (i.e., absolute reticulocyte count <60,000/μL, absolute neutrophil count <500/μL, or a platelet count <2000/μL) and bone marrow hypocellularity (<30%, excluding lymphocytes). *Very severe aplastic anemia* has an absolute neutrophil count of <200/μL, whereas *moderate aplastic anemia* is characterized by depression of blood counts not fulfilling the definition of severe disease (Table 151-3).

ABSTRACT

Bone marrow failure syndromes are a heterogeneous group of clinically and pathologically distinct disorders associated with cytopenias and a lack of normal hematopoiesis. The clinical and biologic complexity, as well as their overlapping features, can pose a diagnostic and therapeutic challenge. Aplastic anemia is the prototypical disorder of bone marrow failure. Symptoms related to anemia, thrombocytopenia, and neutropenia can result in considerable clinical consequences to patients. Though aplastic and other bone marrow failure conditions are not considered overtly malignant, they confer a significant risk of morbidity and even mortality. Improvement in diagnostic tests, molecular screening, and novel treatments are advancing the care for patients with bone marrow failure syndromes.

KEYWORDS

bone marrow failure
aplastic anemia
paroxysmal nocturnal hemoglobinuria
large granular lymphocytosis
anemia
pure red cell aplasia
Fanconi anemia

E-TABLE 151-1 DRUGS AND TOXINS ASSOCIATED WITH APLASTIC ANEMIA

DOSE DEPENDENT

Antineoplastic Agents
Antimetabolites
Alkylating and cross-linking agents
Cytotoxic antibiotics
Plant alkaloids
Topoisomerase inhibitors

Antimicrobial Agents
Chloramphenicol, dapsone, fluorocytosine

Anti-Inflammatory and Antirheumatic Agents
Colchicine, allopurinol

Insecticides
Chlordane, chlorophenothane (DDT), lindane, parathion

Other Chemicals
Benzene
Benzene-containing chemicals: kerosene, chlorophenols, carbon tetrachloride

DOSE INDEPENDENT
Idiosyncratic, likely immune mediated

Antimicrobial Agents
Chloramphenicol, dapsone, sulfonamides, tetracycline, methicillin, amphotericin, quinacrine, chloroquine, pyrimethamine

Anticonvulsants
Hydantoins, carbamazepine, phenacemide, primidone, ethosuximide

Anti-Inflammatory Agents
Phenylbutazone, indomethacin, ibuprofen, oxyphenbutazone, sulindac, naproxen, dipyrone, piroxicam

Antiarrhythmic Drugs
Quinidine, tocainide, procainamide

Metals
Gold, arsenic, mercury, bismuth

Antihistamines
Cimetidine, ranitidine, chlorpheniramine, pyrilamine, tripelennamine

Diuretics
Acetazolamide, furosemide, chlorothiazide, methazolamide

Hypoglycemic Agents
Chlorpropamide, tolbutamide

Antithyroid Drugs
Propylthiouracil, potassium perchlorate, methylthiouracil, methimazole, carbimazole

Antihypertensive Agents
Methyldopa, enalapril, captopril

Sedatives
Chlordiazepoxide, chlorpromazine, meprobamate, prochlorperazine

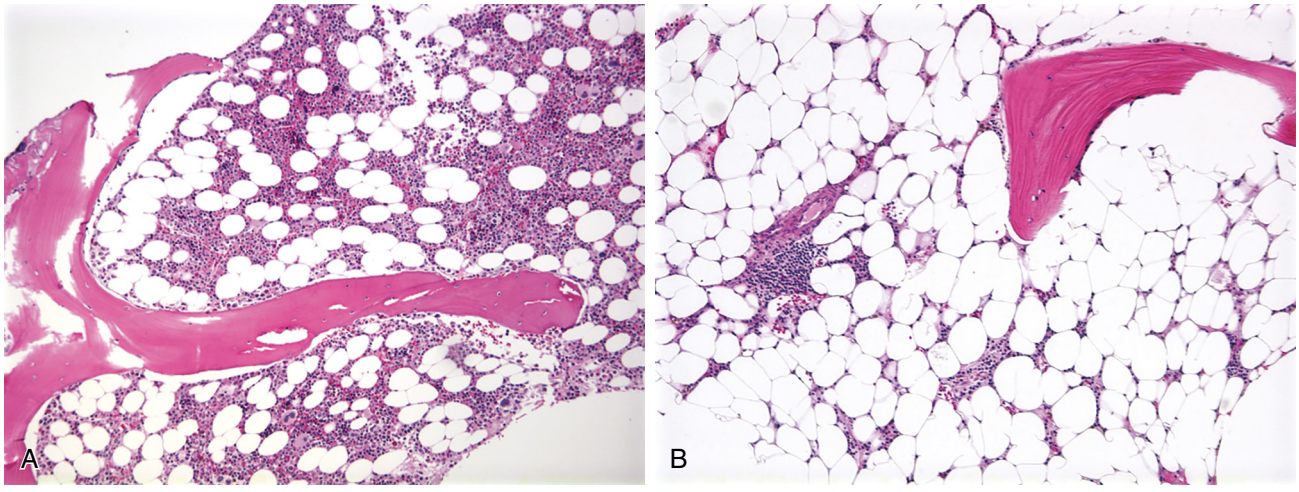

FIGURE 151-1. Two bone marrow biopsy samples from different patients. A, This specimen, from a normal individual, shows an abundance of hematopoietic cells, including myeloid and erythroid precursors and normal-appearing megakaryocytes. **B,** A specimen from a patient with severe aplastic anemia shows few detectable hematopoietic cells, and those that can be seen (one small nest) are lymphocytes. Some lymphoid cells are usually detectable and probably play an important pathophysiologic role in many cases of acquired idiopathic aplastic anemia, a disorder that is most often immunologically mediated. (Courtesy Dr. Ken Gatter, Oregon Health and Science University.)

TREATMENT

Definitive treatment with either immunosuppressive therapy or allogeneic hematopoietic stem cell transplantation (Chapter 163) is necessary for patients with severe or very severe aplastic anemia, but no standard of care exists for moderate aplastic anemia. Younger age (typically age <40 years) and the presence of a matched sibling donor favor the use of allogeneic hematopoietic stem cell transplantation, whereas older age (age >40 years) and absence of a matched sibling donor typically favor the use of immunosuppressive therapy. However, hematopoietic stem cell transplantation from haploidentical or unrelated donors is increasingly being used as front-line therapy for children and younger adults.

Hematopoietic Stem Cell Transplantation (HSCT)

Adolescents and young adults who meet criteria for severe disease and who have an HLA-matched sibling donor should proceed directly to hematopoietic stem cell transplantation (Chapter 163).[5] Predictors of survival following hematopoietic stem cell transplantation include matched sibling donor, recipient age <16 years, early transplant within 12 weeks of diagnosis, and a non-radiation conditioning regimen. Compared with standard immunosuppressive therapy, hematopoietic stem cell transplantation markedly reduces the risk of relapse and mitigates the risk for the later development of sequelae such as myelodysplasia, acute myeloid leukemia, or classical paroxysmal nocturnal hemoglobinuria. With increasingly good results with haploidentical[6] as well as unrelated donor hematopoietic stem cell transplantation, more patients are receiving hematopoietic stem cell transplantation for aplastic anemia (Fig. 151-2).

Immunosuppressive Therapy

Immunosuppressive therapy is often first-line therapy for adolescents and young adults who have severe aplastic anemia and who lack matched sibling donors as well as for medically fit adults (over age 40 years). Immunosuppressive therapy typically uses a combination of anti-thymocyte globulin (ATG), cyclosporine (12 to 15 mg/kg in divided doses twice daily), and eltrombopag[7] (a thrombopoetin-receptor agonist at 150 mg daily) in adults. Of the two ATG preparations commonly used in clinical practice, horse ATG (40 mg/kg/day for 4 days) appears to be superior in the front-line treatment of severe aplastic anemia.[A1] Eltrombopag increases response rates by about 20% compared with ATG and cyclosporine alone.[A2] Corticosteroids are also administered during the first 2 weeks under expert oversight to prevent serum sickness.

General Care

Supportive long-term care is imperative for patients who have aplastic anemia. Placement of a central venous catheter should be strongly considered for all patients given the frequency of phlebotomy, transfusions, and administration of therapeutic medications. Patients who have severe cytopenias require frequent and sometimes urgent blood product support. Blood products should be irradiated (to prevent transfusion-associated graft-versus-host disease) and leukocyte-reduced (to prevent alloimmunization and reduce the incidence of cytomegalovirus infections; see Chapter 162).

Fungal and bacterial infections are a major cause of death in patients with severe aplastic anemia, but an active fungal infection should not delay more definitive therapy such as immunosuppressive therapy or hematopoietic stem cell transplantation. Approaches to prophylactic antibiotic therapy vary among institutions, but adding prophylactic granulocyte colony stimulating factor to immunosuppressive therapy is not of incremental value.[A3]

Aplastic Anemia During Pregnancy

Aplastic anemia can rarely present during pregnancy. Spontaneous remission can occur in 25 to 30% of patients, often upon birth or termination of the pregnancy. Pregnant patients can be followed with stringent supportive care, or cyclosporine may be considered. Complications appear to be more likely in pregnant patients who have low platelet counts and associated paroxysmal nocturnal hemoglobinuria (Chapter 146).

PROGNOSIS

The hematopoietic response rate after immunosuppressive therapy is about 70 to 80%, and the probability of survival at 5 years ranges from 60 to 85%. Patients who are treated with horse ATG plus cyclosporine can have about a 60% overall survival at 15 years, but failure-free survival (survival without relapse or secondary clonal disease beyond 10 years) after immunosuppressive therapy is less than 50%. Survival outcomes continue to improve for alternative donor hematopoietic stem cell transplantation, and haploidentical transplantation with post-transplant cyclophosphamide represents a potential cure in patients who have severe aplastic anemia.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria is a rare clonal disorder in which the activation of complement causes hemolytic anemia and sometimes bone marrow failure. A clone of paroxysmal nocturnal hemoglobinuria cells is seen in at least 50% of patients who have true aplastic anemia. Classical paroxysmal nocturnal hemoglobinuria is discussed in Chapter 146.

LARGE GRANULAR LYMPHOCYTE LEUKEMIA

DEFINITION AND EPIDEMIOLOGY

Large granular lymphocyte leukemia is a clonal lymphoid disorder characterized by a peripheral lymphocytosis of cytotoxic T-lymphocytes with concomitant cytopenias. Although an increase in the number of large granular lymphocytes can be associated with other entities, such as aplastic anemia or myelodysplastic syndrome, large granular lymphocyte leukemia is a distinct clinical entity.

Males and females are equally affected. The median age at diagnosis is 60 years, with very rare occurrence in younger children. The estimated incidence of large granular lymphocyte leukemia in the United States is 1 in 10,000,000 individuals. Large granular lymphocyte leukemia is associated with myelodysplastic syndrome (Chapter 167) in about 10% of cases.

PATHOBIOLOGY

The exact mechanism underlying the development of large granular lymphocyte leukemia is not fully understood. The leading hypothesis is the acquisition

TABLE 151-2 STANDARD EVALUATION OF A PATIENT WITH SUSPECTED APLASTIC ANEMIA TO ENCOMPASS RISK OF INHERITED DISORDERS

EVALUATION	PURPOSE
HISTORY AND PHYSICAL EXAMINATION	
Hematologic: Long-standing cytopenia(s) or macrocytosis Unexplained cytopenia(s) or macrocytosis, aplastic anemia, myelodysplastic syndrome, acute myeloid leukemia in one or more close relative(s)	Could suggest inherited bone marrow failure disorder due to identification of cytopenias at early age
Developmental: Short stature, physical anomalies (especially thumb or radial ray, cardiac, or renal)	Fanconi anemia or dyskeratosis congenita or thrombocytopenia-absent radius syndrome
Immunologic/Infectious Disease: Severe, recurrent, or atypical infections (e.g., mycobacterial, viral, fungal)	Could suggest GATA2 deficiency
Dermatologic: Gray hair prior to 25 Leukoplakia or nail dysplasia Reticulated skin pigmentation, café au lait macules	Could suggest dyskeratosis congenita or another short telomere syndrome
Pulmonary: Pulmonary fibrosis and/or early onset emphysema, pulmonary alveolar proteinosis, fungal or mycobacterial infection	Could suggest dyskeratosis congenita, another short telomere syndrome, or GATA2 deficiency
Abdominal: Pancreatic insufficiency, liver fibrosis, renal anomaly or malplacement	Could suggest dyskeratosis congenita, another short telomere syndrome, or Diamond Blackfan anemia
Oncologic: Head, neck, or anogenital squamous cell carcinoma, or early onset gastrointestinal cancer or multiple cancers in patient or close relatives	Could suggest short telomere syndrome
LABORATORY TESTING	
Complete blood count with differential and blood smear review	Assess severity of cytopenias and consider alternative etiologies
Reticulocyte count	Assess marrow response to anemia and use to assess the severity of aplastic anemia
Hemoglobin F%	Elevated levels may indicate an inherited bone marrow failure disorder
Levels of vitamin B_{12}, folate, copper, zinc, ferritin	Exclude vitamin or mineral deficiencies as cause or contributor to cytopenias
Serologies for hepatitis A/B/C, Epstein-Barr virus, parvovirus, and cytomegalovirus	Rule out infectious disease contributors to cytopenias and identify co-management needs during treatment and transplant
LDH, haptoglobin	Exclude a hemolytic component to anemia
Paroxysmal nocturnal hemoglobin clone	Assess presence or absence of GPI-anchored protein expression; presence suggests acquired rather than inherited disease
Antinuclear antibodies (plus anti-double-stranded DNA if positive)	Assess for systemic lupus erythematosus
Quantification of immunoglobulins A, G, M	Assess for additional immune deficits
Flow cytometry to assess numbers of B lymphocytes, T lymphocytes, and natural killer cells	Assess for additional immune deficits
Telomere length measurement of peripheral blood lymphocytes by fluorescence in situ hybridization	If telomere length <1st percentile, patient may have a short telomere syndrome and be at risk of increased transplant-related toxicity with standard preparative regimens
Chromosome breakage analysis on peripheral blood	If test is positive and consistent with a diagnosis of Fanconi anemia, Fanconi anemia–specific regimen should be utilized and patient is at increased risk of transplant-related toxicity.
Bone marrow aspirate and biopsy	Assess cellularity, iron stores, and reticulin fibrosis; exclude other marrow pathologies
Conventional karyotyping	Examine chromosomes in a sample of cells to identify genetic (acquired or inherited) problems as the cause of cytopenias
HLA typing	Determine HLA profile for stem cell donor search
Myeloid malignancy gene sequencing from peripheral blood or bone marrow	Evaluate for mutations in genes recurrently mutated in aplastic anemia (e.g., *PIGA*, *BCOR*, *BCORL1*) and/or myelodysplastic syndrome (e.g., epigenetic mutations, *TP53*).
Inherited bone marrow failure gene panel sequencing	Evaluate for multiple inherited bone marrow failure disorders (see E-Table 151-2) at once. Universal testing of young patients is also warranted.
Erythrocyte adenosine deaminase	Screen for Diamond Blackfan anemia

GPI = glycosylphosphatidylinositol; HIV = human immunodeficiency virus; HLA = human leukocyte antigen; LDH = lactase dehydrogenase.
Modified from DeZern AE, Churpek JE. Approach to the diagnosis of aplastic anemia. *Blood Adv*. 2021;5:2660-2671.

abnormalities in pathways that enhance survival, since normal large granulocytic lymphocytes undergo faster apoptosis whereas neoplastic lymphocytes appear to undergo reduced apoptosis. Mutations in *STAT3* are increased in patients with large granular lymphocyte leukemia, but these mutations are also detected when aplastic anemia, myelodysplastic syndrome, or pure red cell aplasia is associated with large granular lymphocytes.

CLINICAL MANIFESTATIONS

Patients most commonly present with asymptomatic neutropenia (Chapter 153) with or without concomitant anemia on routine laboratory evaluation, but some patients present with symptoms related to cytopenias. Large granular lymphocyte leukemia is also the most common cause of pure red cell aplasia in adults. Splenomegaly (Chapter 154), which is a common finding on physical

E-TABLE 151-2 DISTINGUISHING CLINICAL FEATURES OF THE INHERITED BONE MARROW FAILURE SYNDROMES THAT MAY BE INITIALLY DIAGNOSED IN ADULTHOOD

DISTINGUISHING FEATURES	FANCONI ANEMIA	SHORT TELOMERE SYNDROMES (DYSKERATOSIS CONGENITA)	DIAMOND-BLACKFAN ANEMIA
History	Skeletal and renal malformations, low birthweight, pancytopenia, family member with bone marrow failure, myelodysplasia, acute myelogenous leukemia, or squamous cell carcinoma at an early age Family member with Fanconi anemia	Intrauterine growth retardation, developmental delay, and short stature Family history of myelodysplasia, acute myelogenous leukemia, marrow failure, abnormal fingernails or toenails, leukoplakia, head and neck cancer, or pulmonary fibrosis	Low birthweight, arm and thumb deformities at birth
Physical findings	Thumb and radial malformations, hyperpigmented skin lesions (café au lait spots), short stature, myelodysplasia, acute myelogenous leukemia, squamous cell carcinoma at young age, renal and cardiac malformations, microcephaly, hypogonadism If physical manifestations are mild, this syndrome may not be recognized until adulthood	Lacy reticular pigmentation of skin, dystrophic fingernails and toenails, premature graying of hair, hair loss, short stature, oral leukoplakia, squamous cell cancer of head and neck, pulmonary fibrosis, osteopenia, hypogonadism	Triphalangeal thumbs, short stature, arm anomalies
Genes inactivated and (synonyms)	*FANCA,* FANCC,* FANCG,* FANCB, FANCD1 (BRCA2), FANCD2, FANCE, FANCF, FANCI, FANCJ (BRIP1), FANCL, FANCM, FANCN (PALB2), FANCO (RAD51C), FANCP (SLX4), FANCQ (ERCC4), FANCR (RAD51), FANCS (BRCA1), FANCT (UBE2T), FANCU (XRCC2), FANCV (REV7)* These genes encode proteins known to protect the genome from excessive damage induced by chemical cross-linking agents	*DKC1,† TERC,† TERT,† TINF2,† NOLA2 (NHP2), NOLA3 (NOP10) WRAPS3, STN1, NAF1, PARN, CTC1, ACD, RTEL1, POT1* These genes encode proteins known to participate in maintenance of telomeres	Ribosomal Genes *RPS19,‡ RPL11,‡ RPS26,† RPS10,‡ RPS35a,‡ RPS24,‡ RPS7, RPS17, RPL5, RPS20, RPS27, RPS28, RPS29, RPL15, RPL17, RPL26, RPL27, RPL31* Non-Ribosomal Gene Mutations *GATA1, TSR2*
Screening and diagnostic tests	1. Mitomycin C or diepoxybutane induced chromosomal breakage test using skin fibroblasts or peripheral blood lymphocytes 2. Gene sequencing	1. Quantitative analysis of telomere length (flow-FISH) in lymphocytes 2. Gene sequencing	*Note:* Isolated erythroid failure is more common than pancytopenic aplastic anemia. 1. No screening tests, although serum ADA is often elevated 2. Gene sequencing

*Mutations of these account for 85% of cases.
†Mutations of these genes account for 40-45% of cases. The 14 genes identified to date account for 70% of patients with clinically diagnosed dyskeratosis congenita.
‡Mutations of these genes account for 40-45% of cases.
ADA = adenosine deaminase; FISH = fluorescence in situ hybridization.

TABLE 151-3 CAMITTA CRITERIA FOR CLASSIFICATION OF APLASTIC ANEMIA

PERIPHERAL BLOOD CYTOPENIAS	NON-SEVERE (MODERATE) APLASTIC ANEMIA*	SEVERE APLASTIC ANEMIA†	VERY SEVERE APLASTIC ANEMIA‡
Bone marrow cellularity	<25%	<25%	<25%
Absolute neutrophil count		<500/μL	<200/μL
Platelet count		<20,000/μL	
Reticulocyte count		<1.0% corrected or <60,000/μL	

*Not meeting criteria for severe disease.
†Any 2 of 3.
‡Meets criteria for severe disease plus a lower absolute neutrophil count (<200/μL).

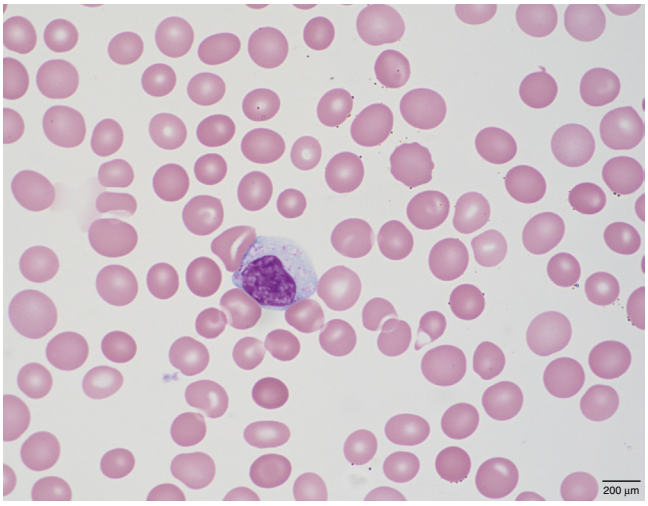

FIGURE 151-3. Large granular lymphocyte. (Courtesy of Rena Xian, MD, PhD.)

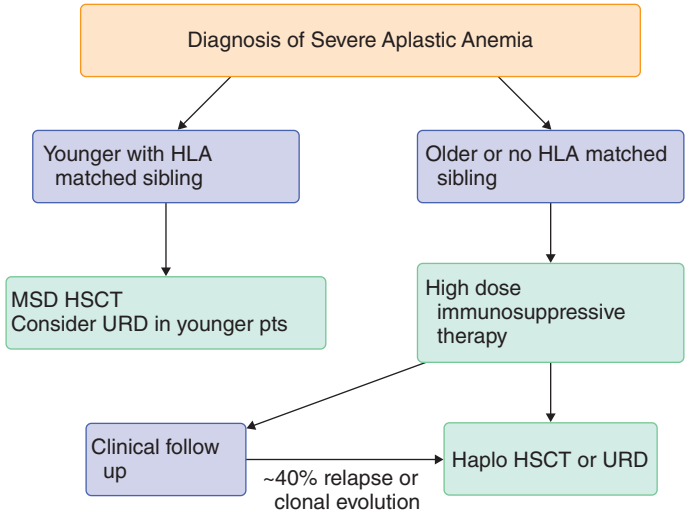

FIGURE 151-2. Therapeutic considerations for severe aplastic anemia. Haplo = haploidentical; HLA = human leukocyte antigen; HSCT = hematopoietic stem cell transplantation; MSD = matched sibling donor; URD = unrelated living donor.

examination, is seen in 25 to 50% of cases and is classically associated with rheumatoid arthritis (Chapter 243) in males.

DIAGNOSIS

No single laboratory test is diagnostic of large granular lymphocyte leukemia. In the appropriate clinical context, however, a combination of histomorphology and flow cytometry with molecular diagnostic studies are sufficient for diagnosis.[8]

The peripheral blood often shows neutropenia with a relative lymphocytosis. Large granulocytic lymphocytes with relatively abundant pale cytoplasm, scattered eosinophilic granules, mature chromatin, and smooth nuclear borders (Fig. 151-3) are best seen in the peripheral blood rather than in a bone marrow sample.

However, large granulocytic lymphocytes can be increased not only in true large granular lymphocyte leukemia but also in reactive conditions, other non-neoplastic bone marrow failure conditions, and neoplastic hematologic malignancies. Distinguishing true large granular lymphocyte leukemia from these conditions can be challenging. Large granulocytic lymphocytes also are often transiently increased in patients with viral infections and can even be increased in individuals with normal white blood cell counts. By comparison, cytotoxic T-lymphocytes are elevated for more than 6 months in the peripheral blood, and the increase is not attributable to any other cause. As a result, flow cytometry is critical for diagnosis and will reveal an immunophenotypic profile that is indicative of an activated cytotoxic T cell (e.g., $CD3^+$, T cell receptor [TCR]-$\alpha\beta^+$, $CD57^+$, $CD4^-$, $CD5^{dim}$, $CD8^+$, $CD16^+$, $CD27^-$, $CD28^-$). Demonstration of clonal T-cell gene rearrangements is also an important part of the diagnostic evaluation.

TREATMENT

Asymptomatic patients are best observed with routine blood counts and clinical follow-up, but treatment is indicated if patients are symptomatic because of severe cytopenias, recurrent infections, constitutional symptoms, or problematic splenomegaly (Chapter 154). Therapies commonly used under expert supervision include methotrexate, cyclophosphamide, cyclosporine, and alemtuzumab.[9] Patients often receive multiple sequential therapies because the disease often relapses.

When large granular lymphocyte leukemia is associated with the myelodysplastic syndrome (Chapter 167), it should be considered a paraneoplastic phenomenon; treatment should focus on the underlying myelodysplastic syndrome. The opposite is true with large granular lymphocyte leukemia–associated pure red cell aplasia, which often is more immune-responsive than pure red cell aplasia from other causes.

PROGNOSIS

Most cases of large granular lymphocyte leukemia follow a chronic course. Prognosis varies depending on the response to immunosuppressive therapy, as well as any underlying conditions, such as the myelodysplastic syndrome.

PURE RED CELL APLASIA

Pure red cell aplasia is a syndrome characterized by a severe normochromic, normocytic anemia (Chapter 144); reticulocytopenia; and the absence of erythroblasts from an otherwise normal bone marrow. Pure red cell aplasia is classified by the clinical course (acute or chronic) and underlying etiology (idiopathic or secondary).

PATHOBIOLOGY

Although pure red cell aplasia has numerous causes, the underlying etiology is thought to be immune-mediated.[10] Pure red cell aplasia may represent a primary hematologic disorder in the absence of any other disease or may develop secondary to parvovirus infection (Chapter 342), human immunodeficiency virus infection, a collagen vascular disease, leukemia, lymphoma, thymoma, solid tumors, treatment with recombinant human erythropoietin or other drugs, ABO-incompatible hematopoietic stem cell transplantation, and pregnancy.

CLINICAL MANIFESTATIONS

The acquired form of pure red cell aplasia presents either as an acute self-limited disease, predominantly seen in children, or as a chronic illness that is more frequently seen in adults. In adults, pure red cell aplasia presents as isolated anemia with normal (or slightly low) white blood cell and platelet counts. Large granular lymphocytes may be increased.

DIAGNOSIS

Evaluation for the possible causes of pure red cell aplasia includes assessing for a history of drug use, toxin exposure, or infections; abnormalities in liver and kidney function; immunologic examination for auto-antibodies; virologic studies to detect parvovirus B19 DNA, especially in patients with immunodeficiency and/or hemolytic anemia; and computed tomographic scanning

to assess for a thymoma. Peripheral-blood flow cytometry should also be performed to quantify the concentration of large granulocytic lymphocytes.

However, the diagnosis of pure red cell aplasia requires a bone marrow biopsy and is often a diagnosis of exclusion. Bone marrow biopsies show normal to hypocellular marrow with absent or nearly absent erythroid precursors. Colony formation assays specifically for burst forming unit-erythroid may be informative. Increased colony formation assay growth is often seen in pure red cell aplasia, in keeping with the immune-mediated nature of this disorder, and higher growth correlates with a positive response to immunosuppressive therapy.

TREATMENT

During the initial evaluation, red cell transfusions can be given as necessary. Since about 10% of patients who have primary idiopathic pure red cell aplasia will have self-limited disease, other treatments can be delayed for about 1 month while watching for signs of recovery of erythropoiesis.

Immunosuppression is the mainstay of therapy for persistent pure red cell aplasia.[11] Corticosteroids (e.g., prednisone 20 to 60 mg) produce about a 75% response rate, but relapse occurs in up to 80% of patients when the dosage is tapered during the 24 months after remission. Cyclosporine under expert oversight yields an overall response rate of about 65%, but many patients do not remain in remission when cyclosporine is discontinued. Cyclophosphamide can provide an overall response rate of 40 to 60% after approximately 11 to 12 weeks of treatment.

For secondary pure red cell aplasias, removal of the inciting factor is critical. Pure red cell aplasia that is secondary to parvovirus B19 can be treated with intravenous immunoglobulin under expert oversight. About 25 to 30% of causes of thymoma-associated pure red cell aplasia show a hematologic response after surgical resection.

PROGNOSIS

Depending on the cause, the course can be acute and self-limiting or chronic with rare spontaneous remissions. In patients who have spontaneous remissions, no specific therapy is required other than transfusion for symptomatic anemia and cessation of possible offending drugs. For acquired chronic pure red cell aplasia, remissions can be attained with treatment, but the aplasia commonly recurs when therapy is discontinued.

INHERITED BONE MARROW FAILURE SYNDROMES

The inherited bone marrow failure syndromes are heterogeneous disorders in which at least one clinically significant cytopenia is present.[12] Many of the inherited bone marrow failure syndromes are associated with characteristic physical findings as well as notably increased risks of both solid and hematologic neoplasms.

FANCONI ANEMIA

Fanconi anemia is a genetic disorder that manifests as developmental abnormalities, progressive bone marrow failure, and an increased risk of developing both hematologic malignancies and carcinomas of the head, neck, and anogenital region at a relatively young age. The vast majority of families with Fanconi anemia exhibit autosomal recessive inheritance, but about 2% of cases are X-linked recessive. Fanconi anemia has an incidence of about 1/200,000 to 400,000 in most populations, but the incidence is higher in Ashkenazi Jews (about 1/30,000) and Afrikaners from South Africa (about 1/22,000). Most patients are diagnosed in the first decade of life, though some cases with milder phenotypes present later in life. Abnormalities in at least 23 genes that participate in a common DNA repair pathway called the Fanconi anemia pathway can result in defective DNA repair, which, in turn, leads to an increased mutation rate and oncogenesis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Fanconi anemia is a very heterogeneous disease, with different mutations associated with different patterns of disease and severity. On physical examination, patients with Fanconi anemia show heterogeneous but characteristic physical findings, including café au lait spots, abnormalities of the thumbs, malformation of the ears and eyes, small stature, hypogonadism, and abnormalities of the gastrointestinal, genitourinary, cardiopulmonary, and central nervous systems. Patients typically present with an unusual macrocytosis and then later develop pancytopenia, thrombocytopenia, and ultimately bone marrow failure. Diagnosis is based on chromosomal fragility in blood lymphocytes, especially after exposure to alkylating agents, diepoxybutane, or mitomycin C.[13] Skin fibroblasts are often required for conclusive diagnosis.

TREATMENT

Approximately 50% of patients with Fanconi anemia initially respond to androgens under expert supervision, but androgen therapy has significant side effects such as liver toxicity, acne, and behavioral anomalies. Allogeneic hematopoietic stem cell transplantation provides a potential cure.

PROGNOSIS

Patients with low blood counts or cytogenetic abnormalities in the marrow have a relatively poor prognosis. By age 25 years, approximately 10% of patients develop acute leukemia (Chapter 168) and approximately 5% develop myelodysplastic syndrome. Even after a successful hematopoietic stem cell transplantation, patients remain at an increased risk of developing solid tumors[14] and should be regularly monitored.

DYSKERATOSIS CONGENITA AND SHORT TELOMERE SYNDROMES

Telomeres, which are tandem TTAGGG repeats at the ends of eukaryotic chromosomes, protect the integrity of the genetic material. Telomeres decrease in length with cell division. When the telomeres become too short, the resulting genomic instability allows for an increased rate of mutations and predisposes to oncogenesis. Nine proteins are currently known to participate in the maintenance of telomeres, and approximately 60% of patients with dyskeratosis congenita have a mutation in one of these genes.

The inheritance of dyskeratosis congenita may be autosomal dominant, autosomal recessive, or X-linked, and some patients also have de novo germline mutations. The median age at diagnosis is at about 15 years (range 0 to 75), and males are disproportionately affected, with a male:female ratio of approximately 3:1.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Dyskeratosis congenita is most often associated with a triad of characteristic skin and nail changes, bone marrow failure, and a predisposition for the development of cancers, particularly squamous cell carcinomas of the head and neck and anogenital region. Additional clinical findings may include premature graying, pulmonary fibrosis, short stature, immune deficiencies, avascular necrosis of the femur or humerus, and liver cirrhosis. Short telomere syndromes encompass a broader spectrum of disorders with both marrow failure and other systemic manifestations.[15]

The bone marrow is initially cellular, but all three lineages demonstrate gradual aplasia. Patients may progress to develop myelodysplastic syndrome or acute myeloid leukemia. Verification of shortened telomeres in white blood cells evaluated by flow cytometry with fluorescent in situ hybridization can confirm the diagnosis.

TREATMENT AND PROGNOSIS

Allogeneic hematopoietic stem cell transplantation, which is the only curative option, should be offered if the platelet count is 3000/μL, the absolute neutrophil count is <1000/μL, and the hemoglobin concentration is <8 g/dL. Without successful transplant, mean survival is 30 years, with most deaths related to infections, bleeding, and malignancy.[16]

DIAMOND–BLACKFAN ANEMIA

Diamond-Blackfan anemia is a rare congenital hypoplastic anemia that usually presents early in infancy. In familial cases, the pattern of inheritance is generally autosomal dominant, but a significant number of cases represent new mutations.

Diamond-Blackfan anemia is a ribosomopathy, and approximately 50% of patients carry known mutations that result in defective ribosomal function, especially mutations in the large or small subunit gene *RPS19*. The clinical disease is caused by insufficient production of a particular ribosomal protein (haploinsufficiency).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Very young patients present with anemia and reticulocytopenia, with an increase in mean corpuscular volume, hemoglobin F, and red cell adenosine deaminase. The hematologic findings are often accompanied by facial

deformities (characterized by a short nose with a broad nasal bridge, widely spaced eyes, and thick upper lip), triphalangeal thumbs, microcephaly, congenital cataracts, and genitourinary and cardiac defects.

The bone marrow shows a selective loss of erythroid precursors. The myeloid lineage shows a full range of maturation, and megakaryocytes are normal in number and morphology. The finding of an elevated adenosine deaminase level in the serum is strongly suggestive of this disease, and the genetic diagnosis usually can be made with a Diamond-Blackfan anemia panel.

TREATMENT AND PROGNOSIS

Up to 80% of patients respond to corticosteroids (e.g., prednisone starting at 2 mg/kg/day, followed by a 0.5 mg/kg/day maximum maintenance dose).[17] Patients who do not respond within a month are considered steroid-refractory and require RBC transfusion support. Hematopoietic stem cell transplantation improves red cell production but does not protect against the development of the myelodysplastic syndrome or acute myeloid leukemia; as a result, matched unrelated hematopoietic stem cell transplantation is best reserved for steroid-refractory patients who require regular transfusions.

The outcomes of Diamond-Blackfan anemia are usually excellent, in particular for patients younger than age 10 years. However, Diamond-Blackfan patients have a marked increased risk for colon cancer, and all patients should be referred to a gastroenterologist for appropriate screening at around age 20 years.

OTHER MARROW FAILURE DISORDERS

Other extremely rare marrow failure disorders that can be seen, especially in children, typically require specific genetic panels or whole exome sequencing by an expert hematologist. Examples include mutations in *SAMD9* (sterile alpha motif domain protein 9) and *SAMD9L* (its paralogue SAMD9-like), sideroblastic anemia (Chapter 145), monosomy 7 predisposition syndromes, thrombocytopenia-absent radii syndrome, Pearson syndrome, and MonoMac (*GATA2*) syndrome.[18]

152 POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

JASON GOTLIB

DEFINITION

In the 2022 International Consensus Classification, the major category of myeloproliferative neoplasms comprises seven diseases (Table 152-1), including polycythemia vera, essential thrombocythemia, and primary myelofibrosis.[1]

TABLE 152-1 2022 INTERNATIONAL CONSENSUS CLASSIFICATION OF MYELOPROLIFERATIVE NEOPLASMS

DISEASE
Chronic myeloid leukemia
Chronic neutrophilic leukemia
Polycythemia vera
Primary myelofibrosis Prefibrotic/early primary myelofibrosis Overt primary myelofibrosis
Essential thrombocythemia
Chronic eosinophilic leukemia, not otherwise specified
Myeloproliferative neoplasm, unclassifiable

The umbrella term "*BCR::ABL1*-negative myeloproliferative neoplasms" is used to distinguish these disorders from chronic myeloid leukemia (CML), which is also included in the myeloproliferative neoplasm category and molecularly defined by the *BCR::ABL1* fusion oncogene. (CML is discussed in Chapter 170.) Polycythemia vera, essential thrombocythemia, and myelofibrosis are chronic myeloid stem cell disorders characterized by excessive production of terminally differentiated cells and variable potential to evolve into acute myeloid leukemia (AML), also referred to as blast-phase myeloproliferative neoplasm. Although these neoplasms exist along a continuous disease spectrum, they each exhibit heterogeneous molecular, biologic, and clinical features that translate into unique natural histories.

EPIDEMIOLOGY

According to a meta-analysis of 34 studies, the combined annual incidence rates (IRs) for polycythemia vera, essential thrombocythemia, and primary myelofibrosis were 0.84, 1.03, and 0.47 per 100,000, respectively. Data from 2001 to 2012 found that the age-adjusted IRs were highest for polycythemia vera (10.9 per 1 million person-years) and essential thrombocythemia (IR = 9.6), and relatively lower for primary myelofibrosis (IR = 3.1). The median ages at diagnosis ranged from 65 to 70 years for the three myeloproliferative neoplasms. Excluding essential thrombocythemia, which predominates among females especially younger than 60 years of age, polycythemia vera and primary myelofibrosis are more commonly diagnosed in males. For all three myeloproliferative neoplasms, IRs are significantly lower among Hispanic Whites, Asian-Pacific Islanders, and Blacks compared to non-Hispanic Whites. Based on data from two large U.S. health plans spanning 2008 to 2010, prevalence rates ranged from 44 to 57 per 100,000 individuals for polycythemia vera, 38 to 57 per 100,000 for essential thrombocythemia, and 0.3 to 5.7 per 100,000 for myelofibrosis.

Risk factors associated with the development of myeloproliferative neoplasms require further study but have included Jewish descent, autoimmune conditions (e.g., Crohn disease), and male-predominant occupations including agricultural or other rural-sector workers with potential exposure to benzene or petroleum. The individual genetic background can influence the propensity for developing a myeloproliferative neoplasm. A five- to seven-fold increased risk of myeloproliferative neoplasm development was identified in first-degree relatives of patients with a myeloproliferative neoplasm.

PATHOBIOLOGY

A point mutation at base pair 1849 (G→T) in the *JAK2* gene results in substitution of the normal valine to phenylalanine in codon 617 (V617F) of exon 14. The somatic V617F mutation has been identified as a highly recurrent mutation in polycythemia vera, essential thrombocythemia, and primary myelofibrosis.[2,3] The mutation affects the autoinhibitory pseudokinase domain of *JAK2*, relieving inhibition of JAK2 kinase activity, and resulting in constitutive JAK-STAT signaling (Fig. 152-1). *JAK2* V617F is found in ≈95 to 98% of polycythemia vera patients and 50 to 60% of essential thrombocythemia and primary myelofibrosis patients; other myeloid neoplasms rarely exhibit *JAK2* mutations. Small in-frame insertions and deletions in exon 12 of the *JAK2* gene (e.g., codons 530 to 540 s) are restricted to ≈2% of polycythemia vera patients who are negative for the V617F mutation (Fig. 152-2).

The *JAK2* V617F mutation arises in a multipotent hematopoietic progenitor or hematopoietic stem cell. It is identified in all cells derived from the myeloid lineage but can also be found in B and NK cells and, more rarely, in

For all three myeloproliferative neoplasms, IRs are significantly lower among Hispanic Whites, Asian-Pacific Islanders, and Blacks compared to non-Hispanic Whites. Based on data from two large U.S. health plans spanning 2008 to 2010, prevalence rates ranged from 44 to 57 per 100,000 individuals for polycythemia vera, 38 to 57 per 100,000 for essential thrombocythemia, and 0.3 to 5.7 per 100,000 for myelofibrosis.

Risk factors associated with the development of myeloproliferative neoplasms require further study but have included Jewish descent, autoimmune conditions (e.g., Crohn disease), and male-predominant occupations including agricultural or other rural-sector workers with potential exposure to benzene or petroleum. The individual genetic background can influence the propensity for developing a myeloproliferative neoplasm. A five- to seven-fold increased risk of myeloproliferative neoplasm development was identified in first-degree relatives of patients with a myeloproliferative neoplasm.

PATHOBIOLOGY

A point mutation at base pair 1849 (G→T) in the *JAK2* gene results in substitution of the normal valine to phenylalanine in codon 617 (V617F) of exon 14. The somatic V617F mutation has been identified as a highly recurrent mutation in polycythemia vera, essential thrombocythemia, and primary myelofibrosis.[2,3] The mutation affects the autoinhibitory pseudokinase domain of *JAK2*, relieving inhibition of JAK2 kinase activity, and resulting in constitutive JAK-STAT signaling (Fig. 152-1). *JAK2* V617F is found in ≈95 to 98% of polycythemia vera patients and 50 to 60% of essential thrombocythemia and primary myelofibrosis patients; other myeloid neoplasms rarely exhibit *JAK2* mutations. Small in-frame insertions and deletions in exon 12 of the *JAK2* gene (e.g., codons 530 to 540 s) are restricted to ≈2% of polycythemia vera patients who are negative for the V617F mutation (Fig. 152-2).

The *JAK2* V617F mutation arises in a multipotent hematopoietic progenitor or hematopoietic stem cell. It is identified in all cells derived from the myeloid lineage but can also be found in B and NK cells and, more rarely, in

ABSTRACT

The major clinical disorders that are grouped under the heading of "*BCR::ABL1*-negative myeloproliferative neoplasms" are polycythemia vera, essential thrombocythemia, and primary myelofibrosis. (*BCR::ABL1*-positive chronic myeloid leukemia [CML]) is covered in Chapter 170). These are all neoplasms arising in a pluripotent hematopoietic stem cell with differences in phenotypic expression being driven, at least in part, by now well-established somatic mutations. These genomic alterations include the *JAK2* V617F mutation (which is the driver mutation in 95 to 98% of patients with polycythemia vera but also occurs in 50 to 60% of patients with essential thrombocythemia and myelofibrosis), *JAK2* exon 12/13 mutations, and mutations in *MPL* and *CALR*. Polycythemia vera must be differentiated from many other (secondary) causes of erythrocytosis; essential thrombocythemia must be differentiated from other, secondary (reactive) causes of thrombocytosis, and marrow fibrosis can be found in conditions other than myelofibrosis. The characteristic genomic alterations that occur primarily in the myeloproliferative neoplasms have made the differential diagnosis easier. The only curative treatment for myeloproliferative neoplasms is allogeneic hematopoietic stem cell transplantation which, because of its high risk of morbidity and mortality, is reserved for only a select group of patients, particularly those with myelofibrosis. In other cases, treatment is directed at palliation of symptoms and/or control of the high blood counts to prevent thrombotic, vascular, and bleeding complications.

JAK2 V617F

T cells. It has been identified in endothelial cells of the spleen and of splanchnic veins in patients with myelofibrosis or patients with a myeloproliferative neoplasm and the Budd-Chiari syndrome. *JAK2* V617F can evolve from a heterozygous to homozygous state due to uniparental disomy (copy-neutral loss of heterozygosity) involving the short arm of chromosome 9 (9p loss of heterozygosity) where the *JAK2* gene is located. The *JAK2* V617F variant allele frequency in granulocytes from myeloproliferative neoplasm patients can vary widely. The variant allele frequency is usually low (e.g., below 50%) in essential thrombocythemia and higher in polycythemia vera and primary myelofibrosis (frequently over 50%, attributable to loss of heterozygosity). Similarly, very high variant allele frequencies are commonly observed in myelofibrosis that evolves from polycythemia vera (post-polycythemia vera myelofibrosis) or myelofibrosis that evolves from essential thrombocythemia (post-essential thrombocythemia myelofibrosis).

Activating mutations in the gene encoding the thrombopoietin receptor *MPL* (most commonly *MPL* W515 L/K) are found in less than 5% of patients with essential thrombocythemia and up to 10% of individuals with myelofibrosis (see Fig. 152-2). These mutations in exon 10 (including the rare S505N variant) occur in the juxtamembrane, intracytosolic portion and stabilize the receptor in an active dimeric configuration. Mutations in exon 9 of the calreticulin (*CALR*) gene have been found in the overwhelming majority of nonmutated *JAK2*/*MPL* patients and account for 20 to 35% of all patients with essential thrombocythemia and myelofibrosis (see Fig. 152-2). Although more than 50 types of mutations have been described, *CALR* variants fall into two predominant subtypes: type 1 (52 base-pair deletion), which is more common in patients with myelofibrosis, and type 2 (5 base-pair insertion) mutations, which is more prevalent in essential thrombocythemia. All exon 9 mutations result in a +1 frameshift in the coding sequence, resulting in a modified carboxy terminus which lacks a KDEL motif responsible for preventing secretion of the protein from the endoplasmic reticulum (ER). The mutant CALR C-terminus also acquires a greater positive charge that leads to loss of multiple calcium-binding sites. Recent investigations have uncovered that mutant CALR binds to the extracellular domain of the thrombopoietin receptor, MPL (Chapter 142), resulting in activation of the JAK-STAT axis. The positive charge of the mutant CALR C-terminus and the protein's lectin activity are required to mediate this neomorphic oncogenic activity.[4] These findings highlight a new paradigm of a mutated ER chaperone protein activating a cytokine receptor, leading to cellular transformation.

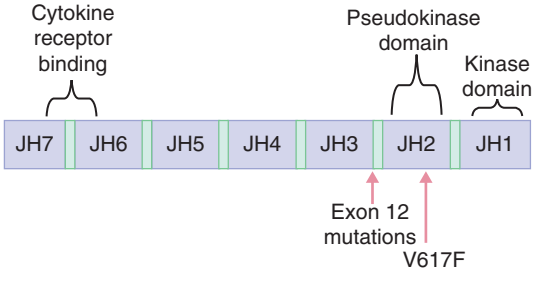

FIGURE 152-1. Exon 12 and *JAK2* V617F gene mutations. Scheme of the *JAK2* gene showing the positions of the V617F (exon 14) and exon 12 mutations. (From Levine RL, Gilliland DG. Myeloproliferative disorders. *Blood.* 2008;112:2190-2198. Fig. 2.)

LNK (SH2B3) is a negative regulator of JAK2 and normally functions to inhibit downstream STAT activation. Mutations in *LNK* have been found in 1 to 2% of patients with essential thrombocythemia or myelofibrosis, and rarely in patients with idiopathic erythrocytosis or polycythemia vera. Secondary *LNK* mutations may also occur during disease progression in *JAK2*- or *CALR*-mutant patients.

Approximately 10% of patients with essential thrombocythemia or primary myelofibrosis do not exhibit the canonical *JAK2*, *MPL*, or *CALR* driver mutations (so-called "triple-negative" myeloproliferative neoplasm patients) (see Fig. 152-2). Some of these patients exhibit cytogenetic abnormalities without evidence for a driver mutation, but no evidence of clonal hematopoiesis can be found in other patients. Rare patients exhibit alternative *JAK2* or *MPL* mutations that are present in the germline, consistent with a hereditary thrombocytosis.

Additional Molecular Abnormalities

Exome sequencing of a large cohort of patients with myeloproliferative neoplasm revealed that the median number of mutations in both polycythemia vera and essential thrombocythemia was 6.5, compared with 13 in myelofibrosis, consistent with it being a more advanced, genetically heterogeneous disease (Table 152-2). Besides *JAK2*, *CALR*, and *MPL*, mutations are found in genes encoding epigenetic regulators (*TET2*, *DNMT3A*, *ASXL1*, *EZH2*, *IDH1*, and *IDH2*), components of the splicing machinery (*SF3B1*, *SRSF2*, *U2AF1*), signal transduction (*CBL*, *SH2B3 [LNK]*), and tumor suppressor function (*TP53*).[5] Although identified in chronic-phase myeloproliferative neoplasms, acquisition of *TP53* mutations is commonly associated with disease acceleration, including transformation of myelofibrosis to blast-phase disease.

Genotype-Phenotype Correlations

The high prevalence of the *JAK2* V617F mutation in three clinically distinct myeloproliferative neoplasms raises the question of which factors contribute to the phenotypic diversity among polycythemia vera, essential thrombocythemia, and primary myelofibrosis. Differences in mutant allele burden of *JAK2* V617F likely modulate phenotype. Murine retroviral transplant models resulting in high levels of *JAK2* V617F expression produced a polycythemia vera–like phenotype with marked erythrocytosis. In contrast, transgenic models with more physiologic levels of *JAK2* V617F expression resulted in phenotypes resembling essential thrombocythemia and primary myelofibrosis. These animal models corroborate findings in patients, in whom the frequency of the *JAK2* V617F variant allele tends to be the highest in polycythemia vera and primary myelofibrosis, with lower levels in essential thrombocythemia. For patients with essential thrombocythemia, positivity for *JAK2* V617F tends to confer a polycythemia vera–like phenotype, with higher hemoglobin and lower platelet counts than in *JAK2* V617F–negative essential thrombocythemia patients.

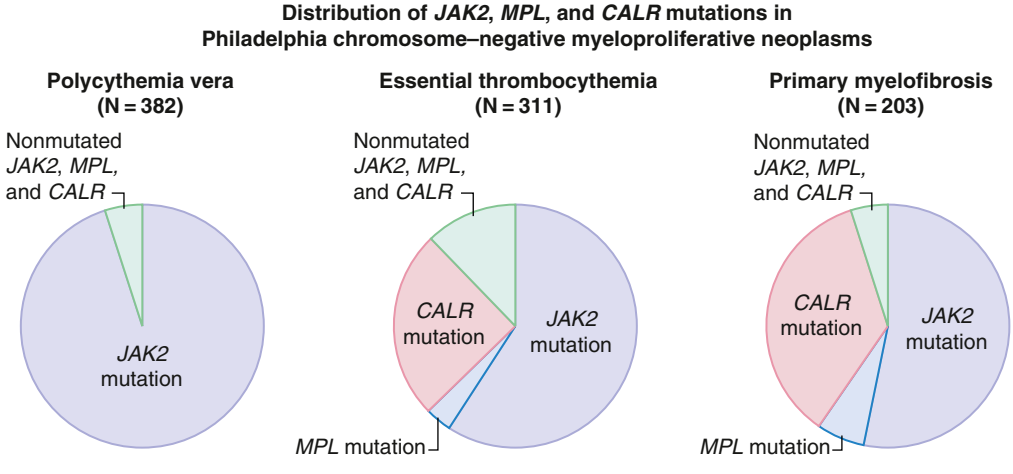

FIGURE 152-2. Distribution of canonical *JAK2*, *MPL*, and *CALR* mutations in polycythemia vera, essential thrombocythemia, and primary myelofibrosis. Relative distribution of *JAK2*, *CALR*, and *MPL* mutations in polycythemia vera, essential thrombocythemia, and primary myelofibrosis. All three mutations lead to constitutive activation of the Janus kinase/signal transducer and activator of transcription (JAK-SKAT) signaling axis. (From Klampfl T, Gisslinger H, Harutyunyan AS, et al. Somatic mutations of calreticulin in myeloproliferative neoplasms. *N Engl J Med*. 2013;369:2379-2390, Fig. 1a.)

TABLE 152-2 MUTATIONAL LANDSCAPE OF CHRONIC- AND BLAST-PHASE MYELOPROLIFERATIVE NEOPLASMS AND PROGNOSTIC RELEVANCE OF MOLECULAR ABNORMALITIES

MUTATION	CHROMOSOME LOCATION	FREQUENCY	PATHOGENETIC RELEVANCE	PROGNOSTIC ASSOCIATIONS
JAK2 (Janus kinase 2): *V617F*	9p24	PV: ≈96% ET: ≈55% PMF: ≈65%	Contributes to abnormal myeloproliferation and progenitor cell growth factor hypersensitivity	Intermediate prognosis and higher risk of thrombosis compared to patients with *CALR* mutation (PMF)
JAK2 exon 12 mutation	9p24	PV: ≈3%	Contributes to primarily erythroid myeloproliferation	Younger age, increased mean hemoglobin/hematocrit, and lower mean white blood cell and platelet counts at diagnosis compared to those with *JAK2* V617F-mutated PV. Both *JAK2* mutations are associated with similar rates of thrombosis, evolution to myelofibrosis or leukemia, and death in PV
CALR (Calreticulin): exon 9 deletions and insertions	19p13.2	PMF: ≈25% ET: ≈20% PV: 0%	Wild-type *CALR* is a multifunctional Ca^{2+} binding protein chaperone mostly localized in the endoplasmic reticulum	Improved survival compared to *JAK2* mutation and "triple-negative" PMF. Lower risk of thrombosis compared to *JAK2* mutation (ET, PMF) No difference in overall survival or myelofibrotic or leukemic transformation compared to *JAK2*-mutated ET *CALR* type 1/type 1-like with improved overall survival compared to *CALR* type 2/type 2-like and *JAK2* V617F mutation (PMF)
MPL (myeloproliferative leukemia virus oncogene): MPN-associated *MPL* mutations involve exon 10	1p34	ET: ~3% PMF: ~10%	Contributes to primarily megakaryocytic myeloproliferation	Intermediate prognosis and higher risk of thrombosis compared to patients with *CALR* mutation (PMF)
LNK, or *SH2B3* (a membrane-bound adaptor protein): MPN-associated mutations are monoallelic and involve exon 2	12q24.12	PV: rare ET: rare PMF: rare BP-MPN: ≈10%	Wild-type *LNK* is a negative regulator of JAK2 signaling	Inferior overall survival in ET
TET2 (TET oncogene family member 2): mutations involve several exons	4q24	PV: ≈16% ET: ≈5% PMF: ≈17% BP-MPN: ≈17%	TET proteins catalyze conversion of 5mC to 5hmC, which favors demethylated DNA. Both TET1 and TET2 display this catalytic activity. *IDH* and *TET2* mutations might share a common pathogenetic effect.	
ASXL1 (additional sex combs-like 1): exon 12 mutations	20q11.1	ET: ≈3% PMF: ≈13% BP-MPN: ≈18%	Wild-type *ASXL1* is needed for normal hematopoiesis and might be involved in coactivation of transcription factors and transcriptional repression	Independently associated with inferior overall survival and leukemia-free survival (PMF) Survival longest for *CALR* (+)/*ASXL1*(−) patients (median 10.4 years) and shortest in *CALR*(−)/*ASXL1*(+) patients (median 2.3 years). Intermediate survival (median 5.8 years) for *CALR*(+)/*ASXL1*(+) or *CALR*(−)/*ASXL1*(−) patients (PMF); worse overall and MF-free survival in PV
IDH1/IDH2 (isocitrate dehydrogenase): exon 4 mutations	2q33.3/15q26.1	PV: ≈2% ET: ≈1% PMF: ≈4% BP-MPN: ≈20%	*IDH* mutations induce loss of activity for the conversion of isocitrate to 2-KG and gain in function in the conversion of 2-KG to 2-HG. 2-HG might be the mediator of impaired TET2 function in cells with mutant *IDH* expression	Independently associated with inferior leukemia-free survival (PMF); worse overall (*IDH1*) and leukemia-free survival (*IDH2*) in PV; inferior overall survival in ET (*IDH2*)
EZH2 (enhancer of zeste homolog 2): mutations involve several exons	7q36.1	PV: ≈3% PMF: ≈7% MDS: ≈6%	Wild-type *EZH2* is part of a histone methyltransferase (polycomb repressive complex 2 associated with H3 Lys-27 trimethylation). MPN-associated *EZH2* mutations might have a tumor suppressor activity, which contrasts with the gain-in-function activity for lymphoma-associated *EZH2* mutations	Independently associated with inferior overall survival (PMF); inferior overall and leukemia-free survival in ET
DNMT3A (DNA cytosine methyltransferase 3a): most frequent mutations affect amino acid R882	2p23	PV: ≈7% PMF: ≈7% BP-MPN: ≈14%	DNA methyl transferases are essential in establishing and maintaining DNA methylation patterns in mammals	
CBL (Casitas B-lineage lymphoma proto-oncogene): exon 8/9 mutations	11q23.3	PV: rare ET: rare MF: ≈6%	CBL is an E3 ubiquitin ligase that marks mutant kinases for degradation. Transforming activity requires loss of this function.	
IKZF1 (IKAROS family zinc finger 1): mostly deletions including intragenic	7p12	CP-MPN: rare BP-MPN: ≈19%	IKZF1 is a transcription regulator and putative tumor suppressor	
TP53 (tumor protein p53): exons 4 through 9	17p13.1	PMF: ≈4% BP-MPN ≈27%	A tumor suppressor protein that targets genes that regulate cell cycle arrest, apoptosis, and DNA repair	Associated with leukemic transformation (PMF and ET)

TABLE 152-2 MUTATIONAL LANDSCAPE OF CHRONIC- AND BLAST-PHASE MYELOPROLIFERATIVE NEOPLASMS AND PROGNOSTIC RELEVANCE OF MOLECULAR ABNORMALITIES—cont'd

MUTATION	CHROMOSOME LOCATION	FREQUENCY	PATHOGENETIC RELEVANCE	PROGNOSTIC ASSOCIATIONS
SF3B1 (splicing factor 3B subunit 1): mostly exons 14 and 15	2q33.1	PMF: ≈7%	SF3B1 is a component of the RNA spliceosome. *SF3B1* mutations are closely associated with ring sideroblasts.	Inferior overall and MF-free survival in ET
SRSF2 (serine/arginine-rich splicing factor 2): exon 2	17q25.1	PMF: ≈17%	SRSF2 is a component of the RNA spliceosome, whose dysfunction promotes defects in alternative splicing	Independently associated with inferior overall survival and leukemia-free survival (PMF); worse overall survival in PV, ET
U2AF1 (U2 small nuclear RNA auxiliary factor 1)	21q22.3	PMF: ≈16%	U2AF1 is a subunit of the U2 small nuclear ribonucleoprotein auxiliary factor involved in pre-mRNA processing	Independently associated with anemia (PMF); inferior overall survival with *U2AF1* Q157 compared to *U2AF1*-unmutated PMF; worse overall and MF-free survival in ET
Triple-negative (negative for *JAK2*, *MPL*, or *CALR* mutations)				Inferior leukemia-free survival compared to patients with *JAK2*- and/or *CALR*-mutated PMF. Inferior overall survival compared to patients with *CALR*-mutated PMF.

2-HG = 2-hydroxyglutarate; 2-KG = 2-ketoglutarate; 5hmC = 5-hydroxymethylcytosine; 5mC = 5-methylcytosine; BP-MPN = blast-phase MPN; CP-MPN= chronic-phase MPN; ET = essential thrombocythemia; MDS = myelodysplastic syndrome; MF includes both PMF and post-ET/PV myelofibrosis; MPN = myeloproliferative neoplasms; PMF = primary myelofibrosis; PV = polycythemia vera.

CLINICAL MANIFESTATIONS

Essential Thrombocythemia

Up to one half of patients may present with incidental thrombocytosis (defined as platelet count >450,000/μL) without symptoms. The frequency of vasomotor symptoms differs widely between series; such microvascular disturbances can manifest as headaches, lightheadedness, syncope, chest pain, visual disturbances (amaurosis fugax, scintillating scotomata, ophthalmic migraine), and erythromelalgia (Fig. 152-3) which manifests as burning pain of the hands or feet associated with erythema and warmth.[6] Incidence rates of arterial (e.g., cerebrovascular event, myocardial infarction, peripheral arterial disease) and venous (deep vein thrombosis, pulmonary embolism, superficial thrombophlebitis) thrombosis as well as hemorrhage also vary; however, rates of major thrombosis or bleeding are less than 10% at diagnosis and follow-up. Thrombosis of unusual sites such as the abdomen (e.g., mesenteric, portal, hepatic vein thrombosis [Budd-Chiari syndrome]) and central nervous system (e.g., cerebral venous sinus thrombosis; retinal vein or artery thrombosis) may also be observed. Differences in diagnostic criteria used for essential thrombocythemia as well as the potential for inclusion of patients with prefibrotic myelofibrosis may account for the variability in reported rates of splenomegaly (typically mild), which range from <10% to approximately 50% of patients.

In one study of 150 patients with essential thrombocythemia, the median platelet count ranged from 454,000 to 3,460,000/μL. There is no correlation between the degree of thrombocytosis and risk of thrombosis; however, patients with a platelet count higher than about 1.5 million/μL are at an increased risk for bleeding, attributable, in part, to acquired von Willebrand disease. Acquired von Willebrand disease is due to increased binding of large von Willebrand factor multimers, which are the most hemostatically effective components of the von Willebrand factor protein, to platelets and their removal from the plasma; the finding of decreased ristocetin cofactor activity (e.g., <30%) and loss of high-molecular-weight von Willebrand multimeric proteins on multimer analysis can help establish the diagnosis (Chapter 159).

Polycythemia Vera

Most patients with polycythemia vera are incidentally discovered to have an elevated hemoglobin (defined as hemoglobin >16.5 g/dL in men or >16.0 g/dL in women) and elevated hematocrit (defined as >49% in men or >48% in women). Increased blood hyperviscosity can lead to a constellation of physical examination findings, including hypertension, facial plethora, injection of the conjunctival small vessels and engorgement of the retinal veins on funduscopic examination, erythromelalgia (similar to essential thrombocythemia), splenomegaly (more frequent than hepatomegaly), and tophaceous gout.[7] Relatively common complaints include fatigue, aquagenic pruritus (itching following a warm bath or shower), headache, difficulty concentrating, lightheadedness/dizziness, and nondescript gastrointestinal symptoms such as epigastric discomfort and abdominal fullness/early satiety (E-Table 152-1). Neurologic symptoms, including tinnitus, paresthesias, and the aforementioned visual disturbances, are also encountered in polycythemia vera. In a large international study of patients with polycythemia vera, arterial thrombotic complication, venous thrombosis, or major hemorrhage were noted prior to or at the time of diagnosis in 16, 7, and 4% of patients, respectively.

FIGURE 152-3. Erythromelalgia of the hands in a patient with polycythemia vera characterized by an exon 12 *JAK2* mutation.

Primary Myelofibrosis

The major clinical issues related to primary myelofibrosis include debilitating constitutional symptoms, splenomegaly, progressive cytopenias, potential for evolution to AML (15 to 20% of patients), and reduced survival. With advancing disease, the spleen can become massive in size (filling the left side of the abdomen and to the pelvic brim), resulting in abdominal pain (sometimes with referred left shoulder pain), early satiety, weight loss, and complications including splenic infarction.[8] Extramedullary hematopoiesis resulting in hepatomegaly is also common; complications of extramedullary hematopoiesis include portal hypertension, esophageal or gastric varices, and ascites. Myelofibrosis-associated anemia may be due to several causes, including ineffective hematopoiesis, splenic sequestration, gastrointestinal bleeding, autoimmune hemolytic anemia, or nutritional deficiencies (e.g., vitamin B_{12}). Extramedullary hematopoiesis may involve other sites besides the liver and spleen, such as the paravertebral space, lymph nodes, retroperitoneum, lungs or pleura, genitourinary organs, skin, and bowel. Pulmonary hypertension may be underdiagnosed in myelofibrosis and other myeloproliferative neoplasms and has been associated with increased symptoms (e.g., fatigue and dyspnea) and decreased survival. The incidence of arterial and venous thrombosis is similar to that of essential thrombocythemia.

E-TABLE 152-1 ALL-INCLUSIVE AND GENDER-STRATIFIED PRESENTING FEATURES IN 1545 PATIENTS WITH POLYCYTHEMIA VERA

	N EVALUABLE	ALL PATIENTS (N = 1545)	FEMALES, N = 785 (51%)	MALES, N = 760 (49%)	P-VALUES
Median age, years (range)	1545	61 (18-95)	62 (18-92)	59 (19-95)	**<0.01**
Ages below 40/50 years	1545	10/24%	10/23%	10/26%	0.58
Hemoglobin, median in g/dL (range)	1545	18.4 (15.1-26.5)	17.7 (15.1-24.5)	18.9 (17.1-26.5)	**<0.01**

History of hypertension, *n* (%)	1388	638 (46%)	339 (48%)	299 (43.7%)	0.09

Bold numerals indicate differences that were statistically relevant.
EEC = endogenous erythroid colony; Epo = erythropoietin.
From Tefferi A, Rumi E, Finazzi G, et al. Survival and prognosis among 1545 patients with contemporary polycythemia vera: an international study. *Leukemia*. 2013;27:1874-1881, Table 1.

TABLE 152-3 2022 INTERNATIONAL CONSENSUS CLASSIFICATION DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

CRITERIA	POLYCYTHEMIA VERA*	ESSENTIAL THROMBOCYTHEMIA†	PRIMARY MYELOFIBROSIS‡
Major criteria	1. Elevated hemoglobin concentration (>16.5 g/dL in men; >16.0 g/dL in women) or elevated hematocrit (>49% in men; >48% in women) or increased red blood cell mass (>25% above mean normal predicted value) 2. Bone marrow biopsy showing age-adjusted hypercellularity with trilineage growth (panmyelosis), including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes 3. Presence of *JAK2* V617F or *JAK2* exon 12 mutation	1. Platelet count ≥450,000/μL 2. Bone marrow biopsy showing proliferation mainly of the megakaryocytic lineage, with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei, no significant increase or left shift in neutrophil granulopoiesis or erythropoiesis; very rarely or minor (grade 1) increase in reticulin fibers 3. ICC criteria for *BCR::ABL1*-positive chronic myeloid leukemia, polycythemia vera, primary myelofibrosis, or other myeloid neoplasms are not met 4. *JAK2*, *CALR*, or *MPL* mutation	1. Megakaryocytic proliferation and atypia, without reticulin fibrosis grade >1, accompanied by increased age-adjusted bone marrow cellularity, granulocytic proliferation, and (often) decreased erythropoiesis (**PREFIBROTIC**)§ 2. Megakaryocytic proliferation and atypia, accompanied by reticulin and/or collagen fibrosis grades 2 or 3 (**OVERT**)‖ 3. ICC criteria for *BCR::ABL1*-positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndromes, or other myeloid neoplasms are not met 4. *JAK2* or *CALR* or *MPL* mutation, or presence of another clonal marker,¶ or absence of reactive myelofibrosis**
Minor criteria	Subnormal erythropoietin level	Presence of a clonal marker¶ or absence of reactive thrombocytosis	Presence of at least one of the following, confirmed on two separate determinations: • Anemia not attributed to a comorbid condition • Leukocytosis ≥11,000/μL • Palpable splenomegaly • LDH above the upper limit of normal • Leukoerythroblastosis (only in overt primary myelofibrosis)

*The diagnosis of polycythemia vera requires either all three major criteria or the first two major criteria plus the minor criteria. Major criterion 2 (bone marrow biopsy) may not be required in patients with sustained absolute erythrocytosis (hemoglobin concentration in men >18.5 g/dL or >16.5 g/dL in women and hematocrit values >55.5% in men and >49.5% in women) if the major criterion 3 and the minor criteria are present. However, initial myelofibrosis (present in as many as 20% of patients) can only be detected by bone marrow biopsy, and this finding may predict a more rapid progression to overt myelofibrosis (post–polycythemia vera myelofibrosis).

†The diagnosis of essential thrombocythemia requires that all major criteria or the first three major criteria plus the minor criteria are met.

‡The diagnosis of primary myelofibrosis requires that all three major criteria and at least one minor criterion are met.

§First major criterion definition for prefibrotic/early myelofibrosis only (not applicable to overt myelofibrosis).

‖First major criterion definition for overt myelofibrosis only (not applicable to prefibrotic/early myelofibrosis).

¶In the absence of any of the three major clonal mutations, a search for other mutations associated with myeloid neoplasms (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1*, *IDH2*, *SRSF2*, and *SF3B1* mutations) may be of help in determining the clonal nature of disease.

**Minor (grade 1) reticulin fibrosis secondary to infection, autoimmune disorder, or other chronic inflammatory conditions, hairy cell leukemia, or another lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

ICC = International Consensus Classification; LDH = lactate dehydrogenase.

Patients with myelofibrosis exhibit the greatest symptom burden among the Philadelphia chromosome–negative myeloproliferative neoplasms. In addition to mechanical symptoms referable to splenomegaly, hypercatabolic signs and symptoms such as fatigue, night sweats, low-grade fevers, weight loss, pruritus, gout, and joint or bone pain (most commonly involving the lower extremities) tend to become more omnipresent and severe with disease evolution.

DIAGNOSIS

Diagnostic Criteria for Polycythemia Vera, Essential Thrombocythemia, and Primary Myelofibrosis

The International Consensus Classification uses a combination of histopathologic, laboratory, and molecular data to establish major and minor criteria for the diagnosis of polycythemia vera, essential thrombocythemia, and primary myelofibrosis (Table 152-3). To mitigate the risk of periprocedural bleeding, testing for acquired von Willebrand disease (Chapter 159) should be considered in patients who have elevated platelet counts (e.g., 1 to 1.5 million/μL) associated with major bruising or bleeding or in patients undergoing surgery or delivery of a pregnancy.

Other Causes of Erythrocytosis and Thrombocytosis

For patients presenting with an elevated hemoglobin, history taking should first try to determine whether a spurious erythrocytosis may be present due to hemoconcentration (seen in patients with volume depletion related to conditions such as burns, diarrhea, and diuretics). Family history is important for evaluating congenital forms of erythrocytosis, including causes associated with a decreased p50 (the oxygen tension at which hemoglobin is 50% saturated) such as a high-oxygen-affinity hemoglobin, 2,3-bisphosphoglycerate (2,3-BPG) deficiency, or methemoglobinemia (Chapter 144). Congenital forms of erythrocytosis associated with a normal p50 include mutations in the genes encoding *EPO*[9] or the *EPO* receptor and mutations of genes involved in the oxygen-sensing pathway (e.g., *VHL*, *HIF2A*, and *PHD2*) (Table 152-4). Erythrocytosis mutation panels are now commercially available to test for such variants.

In secondary types of acquired erythrocytosis (see Table 152-4), only red blood cells are increased, whereas in polycythemia vera, red blood cells, as well as the white blood count and platelet count, may be increased because only the latter is a pluripotent hematopoietic stem cell disorder. Molecular testing has greatly facilitated the evaluation of acquired forms of erythrocytosis; in this clinical context, identification of *JAK2* V617F (in 95 to 98% of patients with polycythemia vera) or an exon 12 *JAK2* mutation establishes the diagnosis of polycythemia vera. Iron deficiency and a subnormal EPO level (the latter is a minor diagnostic criterion) are common laboratory findings in polycythemia vera.

Similar to erythrocytosis, the evaluation of thrombocytosis is first directed to ruling out reactive causes, which are much more common than essential thrombocythemia (see Table 152-5). Hereditary forms of thrombocytosis are rare and may be related to germline mutations in the genes encoding thrombopoietin (*THPO*), gelsolin, or *MPL* and *JAK2*, which are distinct from the somatic *MPL* W515 L/K and *JAK2* V617F variants.

If essential thrombocythemia or primary myelofibrosis is suspected and molecular testing is negative for *JAK2* V617F, screening for *CALR* and/or *MPL* mutations is undertaken. Bone marrow examination with expert pathology interpretation is critical to distinguish between essential thrombocythemia (Fig. 152-4), prefibrotic myelofibrosis, and overt primary myelofibrosis (Fig. 152-5) and between clonal and reactive forms of myeloproliferation, particularly in cases where a clonal marker cannot be found (e.g., triple-negative patients). The peripheral blood smear may demonstrate large or giant platelets in all three myeloproliferative neoplasms. In primary myelofibrosis, variable degrees of leukoerythroblastosis may be observed, consisting of circulating immature granulocytes and nucleated and teardrop red blood cells (dacrocytes) (Chapter 143). Increased numbers of circulating $CD34^+$ cells can be detected in the blood, and their numbers increase with disease severity. The bone marrow reveals myeloid hyperplasia, clustered atypical megakaryocytes, and variable degrees of reticulin (or collagen) fibrosis (as well as osteosclerosis) depending on disease stage (see Fig. 152-5). Specific clinical and laboratory criteria have been codified for a diagnosis of post–polycythemia vera myelofibrosis

TABLE 152-4 DIFFERENTIAL DIAGNOSIS OF ERYTHROCYTOSIS

SPURIOUS ERYTHROCYTOSIS (also referred to as relative polycythemia, stress erythrocytosis, stress polycythemia, benign polycythemia, Gaisböck syndrome, and pseudopolycythemia)

A. Cases are characterized by an increased hematocrit and normal or decreased red blood cell (RBC) total mass resulting from a decreased plasma volume. Hemoconcentration can result from vomiting or diarrhea, burns, aggressive diuretic therapy, decreased fluid intake, diabetic ketoacidosis, and renal disease. Stress and hypertension can also be associated with a decreased plasma volume.

CONGENITAL ERYTHROCYTOSIS

A. Associated with reduced p50 (partial pressure of oxygen at which 50% of hemoglobin is saturated with oxygen)
  i. Mutant high-oxygen-affinity hemoglobinopathy
  ii. 2,3-Bisphosphoglycerate deficiency
  iii. Methemoglobinemia
B. Associated with normal p50
  i. *VHL* mutations (Chuvash polycythemia)
  ii. *PHD2* mutations
  iii. *HIF2A* mutations
  iv. *EPO* receptor mutations
  v. *EPO* gain-of-function mutation

ACQUIRED ERYTHROCYTOSIS

A. Primary (clonal): Polycythemia vera (associated with low EPO level)
B. Secondary (associated with normal to high EPO levels)
  i. Chronic hypoxia states
    (1) Chronic lung disease
    (2) Right-to-left cardiopulmonary shunts
    (3) High-altitude habitat
    (4) Tobacco use or carbon monoxide poisoning
    (5) Sleep apnea or hypoventilation syndrome
    (6) Renal artery stenosis
  ii. Hypoxia-independent
    (1) Use of androgens (e.g., testosterone; danazol)
    (2) Use of erythropoietin
    (3) Post–renal transplant
    (4) Anti-VEGF therapy
    (5) Erythropoietin-secreting tumors: hepatocellular carcinoma, renal cell carcinoma, (cerebellar) hemangioblastoma, uterine leiomyoma, meningioma, carcinoid tumor, metanephric adenoma, pheochromocytoma, parathyroid adenoma
    (6) POEMS

EPO = erythropoietin; POEMS = polyneuropathy, organomegaly, endocrinopathy, M protein, and skin (changes) syndrome; VEGF = vascular endothelial growth factor.

TABLE 152-5 DIFFERENTIAL DIAGNOSIS OF THROMBOCYTOSIS

PRIMARY (CLONAL)	SECONDARY (REACTIVE)
ESSENTIAL THROMBOCYTHEMIA	**INFECTION**
OTHER MYELOID NEOPLASMS	Acute bacterial/viral infections
Primary myelofibrosis	Chronic infections (e.g., tuberculosis)
Chronic myeloid leukemia	**NONMALIGNANT BLOOD CONDITIONS**
Del(5q) myelodysplastic syndrome	Iron deficiency anemia
Myelodysplastic/myeloproliferative neoplasms with ring sideroblasts and thrombocytosis (MDS)/MPN-RS-T	Acute blood loss
	Acute hemolytic anemia
	Rebound following use of chemotherapy
	Rebound following treatment of ITP
	Rebound from ETOH-related thrombocytopenia
	AUTOIMMUNE/INFLAMMATORY CONDITIONS
	Inflammatory bowel disease
	Vasculitides
	Rheumatoid arthritis
	Celiac disease
	MALIGNANCIES
	Lymphoma
	Metastatic cancer
	POEMS
	MEDICATIONS
	Thrombopoietin receptor agonists
	All-trans retinoic acid (ATRA)
	Interleukin-1β
	Vincristine
	Epinephrine
	Glucocorticoids
	TISSUE DAMAGE
	Severe trauma, burns
	Acute pancreatitis
	Myocardial infarction
	Postsurgical period (e.g., CABG)
	ALLERGIC REACTION
	EXERCISE

CABG = coronary artery bypass graft; ETOH = alcohol; ITP = immune (or idiopathic) thrombocytopenic purpura; MDS = myelodysplastic syndrome; POEMS = polyneuropathy, organomegaly, endocrinopathy, M protein, and skin (changes) syndrome.

and post–essential thrombocythemia myelofibrosis, including confirmation of a prior diagnosis of polycythemia vera or essential thrombocythemia and minimal thresholds of bone marrow fibrosis. Table 152-6 lists other causes of fibrosis involving the bone marrow.

TREATMENT

Essential Thrombocythemia and Polycythemia Vera

For patients with essential thrombocythemia and polycythemia vera, no therapy has been shown to alter the natural history of disease (e.g., transformation to post–polycythemia vera or post–essential thrombocythemia myelofibrosis, acute myeloid leukemia, or overall survival), and therapies are aimed at mitigating the risk of future vascular events and disease-related constitutional symptoms.[10] The therapeutic approaches to the two conditions have many similarities (Table 152-7).

Aspirin

Low-dose aspirin (100 mg daily), which is foundational to the treatment of polycythemia vera regardless of risk group, results in an approximately 60% reduction in the relative risk of the composite end point of nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes, without significantly increasing the risk of major bleeding.

In essential thrombocythemia, treatment decisions are based on the classification of patients into very low-, low-, intermediate-, and high-risk groups according to the revised International Prognostic Score for Essential Thrombocythemia (IPSET)–thrombosis risk stratification. For patients with very low-risk essential thrombocythemia (age ≤60 years, no *JAK2* mutation, no prior history of thrombosis), aspirin or observation alone may be considered. Pharmacologic data suggest an optimal aspirin regimen of 100 mg twice daily to maximize platelet inhibition without adverse effects.[A1] For a patient with low-risk essential thrombocythemia (age ≤60 years, with *JAK2* mutation, no prior history of thrombosis) or intermediate-risk essential thrombocythemia (age >60 years, no *JAK2* mutation, no prior history of thrombosis), only aspirin (81 mg daily) is recommended.

Cytoreductive Therapy

Cytoreductive therapy should be administered to patients who have high-risk essential thrombocythemia (history of thrombosis at any age or age >60 years with *JAK2* mutation), patients who have high-risk polycythemia vera, and patients who have lower-risk forms of essential thrombocythemia or polycythemia vera but who develop any signs or symptoms of new thrombosis, acquired von Willebrand disease, disease-related major bleeding, symptomatic progressive splenomegaly, progressive leukocytosis or thrombocytosis, worsening disease-related symptoms (pruritus, night sweats, fatigue), or vasomotor/microvascular disturbances (headaches, chest pain, erythromelalgia) refractory to aspirin.[11]

For polycythemia vera, intensive treatment to maintain a hematocrit target of less than 45% results in an almost four-fold reduction in the risk of cardiovascular death and major thrombosis compared with a hematocrit target of 45 to 50%. A lower hematocrit cutoff (42%) may be appropriate for females (attributed to their lower red blood cell mass compared with males) or for patients with progressive symptoms, but no randomized data are available to support this recommendation.

Hydroxyurea or pegylated interferons are generally considered front-line therapy, but interferons have become increasingly preferred in younger patients due to their ability to elicit high rates of hematologic remissions and molecular responses, without evidence of leukemogenicity.

Hydroxyurea

In high-risk essential thrombocythemia, hydroxyurea can reduce the risk of thrombosis from about 25% to about 5%. Hydroxyurea plus low-dose aspirin is at least as good as anagrelide plus low-dose aspirin and is recommended as first-line therapy for essential thrombocytopenia.[12] Initial and subsequent dosing of hydroxyurea is tailored to individual blood counts and tolerance. A typical starting dose is 500 to 1000 mg daily.

TABLE 152-7 RISK-BASED STRATIFICATION OF TREATMENT OPTIONS IN ESSENTIAL THROMBOCYTHEMIA AND POLYCYTHEMIA VERA

RISK GROUP*	ESSENTIAL THROMBOCYTHEMIA	POLYCYTHEMIA VERA
Very-low	Observation	N/A
Low	Low-dose aspirin	Low-dose aspirin + phlebotomy
Intermediate	Low-dose aspirin	N/A
High	Low-dose aspirin + cytoreduction Cytoreduction options: Hydroxyurea† or Interferons (based on patient-specific variables)‡ or Anagrelide	Low-dose aspirin + phlebotomy + cytoreduction Cytoreduction options: Hydroxyurea or Interferons (based on patient-specific variables)‡ Ruxolitinib for hydroxyurea-resistant or intolerant patients
	Manage cardiovascular risk factors; monitor for new thrombosis or bleeding; progressive disease-related signs and symptoms (e.g., splenomegaly, leukocytosis, thrombocytosis, pruritus, night sweats, fatigue)	

*Risk groups are defined in the text.
†For older patients, busulfan may be considered in patients not responding to or tolerating hydroxyurea.
‡Interferon alfa-2b, peginterferon alfa-2a, or ropeginterferon alfa-2b (approved in the European Union and United States).
N/A = not applicable.

In polycythemia vera, the use of hydroxyurea plus phlebotomy as needed significantly reduces the risk of thrombosis compared with phlebotomy alone, probably without increasing the risk for leukemic transformation. As a result, hydroxyurea is a first-line cytoreductive therapy for polycythemia vera.[13]

Interferons

For patients with essential thrombocythemia or polycythemia vera, interferons (interferon alfa-2b, PEG-interferon alfa-2a, or PEG-interferon alfa-2b) are an alternative first-line treatment to hydroxyurea, particularly for younger patients or for pregnant women who need cytoreductive therapy (see Table 152-7). The addition of a polyethylene glycol (PEG) moiety to IFN-α results in a longer half-life, which translates into less frequent administration, more drug stability, less immunogenicity, and less toxicity and is favored by most practitioners. Nevertheless, depending on the study, PEG-interferons have resulted

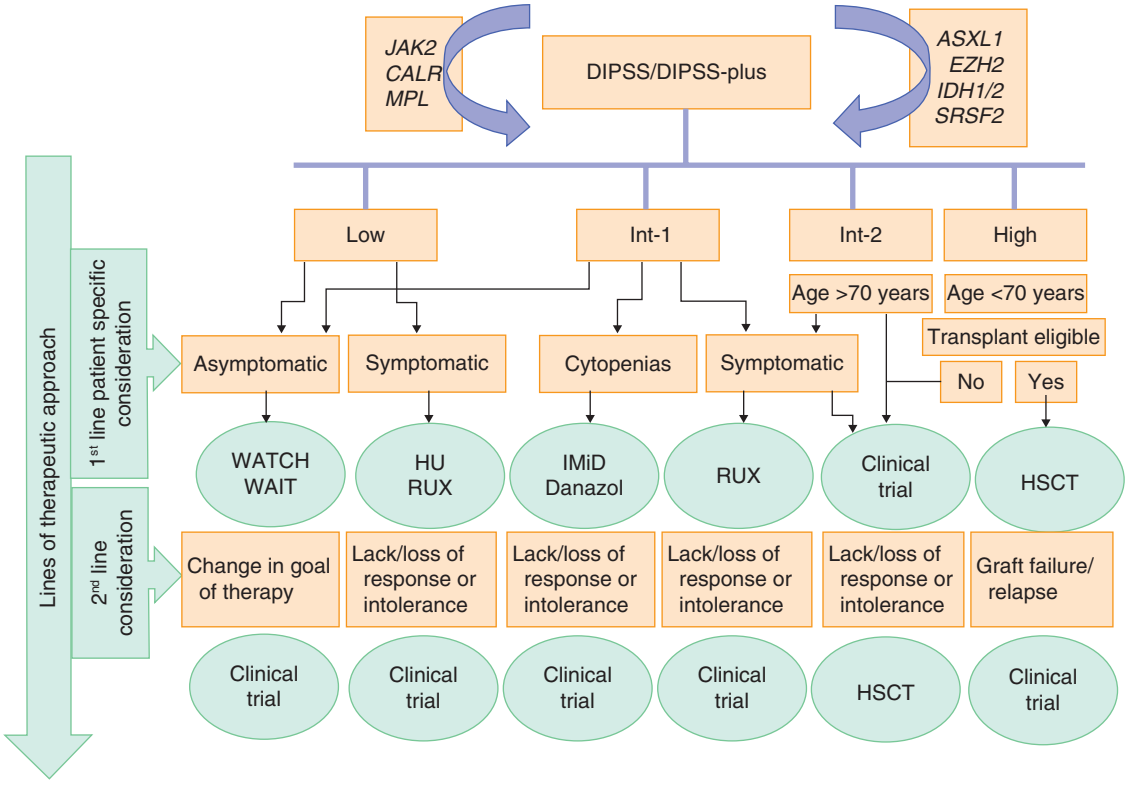

FIGURE 152-6. Risk-based stratification for treatment decision making in myelofibrosis. DIPSS = Dynamic International Prognostic Scoring System (see text under "Prognosis" for "Primary Myelofibrosis"); HSCT = hematopoietic stem cell transplant; HU = hydroxyurea; IMiD = immunomodulatory agents; Int = intermediate; RUX = ruxolitinib. (From Mascarenhas J. Looking forward: novel therapeutic approaches in chronic and advanced phases of myelofibrosis. *Hematology Am Soc Hematol Educ Program*. 2015;2015:329-339, Fig 3.)

in treatment discontinuation rates of 15 to 40%. Toxicities include myelosuppression, flulike symptoms (e.g., fatigue, myalgias/arthralgias), transaminitis, autoimmune phenomena, hypothyroidism, and depression.

Studies of PEG-interferon-alfa-2a in patients with polycythemia vera and essential thrombocythemia reveal complete hematologic remission rates of 75 to 95% and complete molecular remission of the *JAK2* V617F mutation in 17 to 24% of patients. The presence of *TET2, ASXL1, EZH2, DNMT3A*, and *IDH1/2* mutations is associated with failure to achieve a complete molecular remission.

In a randomized trial of pegylated IFN-alfa-2a compared with hydroxyurea in high-risk polycythemia vera and essential thrombocythemia, no significant differences were noted in response rates after 24 months.[A2] However, ropeginterferon-alfa-2b provides superior and durable hematologic and molecular response rates compared with hydroxyurea at 5 years.[A3] In low-risk polycythemia vera patients, ropeginterferon-alfa-2b can also increase the ability to maintain the hematocrit <45% in about 85% of patients compared with 60% of patients with phlebotomy alone (p = .0075).[A4]

Anagrelide

Anagrelide (starting at 1 mg twice daily and not to exceed 10 mg/day), which inhibits the maturation of megakaryocytes, can reduce the platelet count in essential thrombocythemia.[A5] However, it may be associated with more thrombotic and bleeding events than hydroxyurea.[A6] As a result, it is a second-line agent.

Ruxolitinib

Ruxolitinib, a *JAK1/JAK2* inhibitor (starting dose 10 mg twice daily), is useful in patients who have phlebotomy-dependent polycythemia vera with or without splenomegaly and an inadequate response to or intolerance of hydroxyurea. It can provide durable responses and improvement of disease-related symptoms, with generally good tolerability.[A7]

Other Agents

Busulfan is an alkylating agent that can be used as an alternative cytoreductive agent in older patients with polycythemia vera or essential thrombocythemia. Special care has to be given to adjusting the dose based on blood counts because prolonged severe myelosuppression/aplasia has been reported.

In polycythemia vera, iron deficiency and increased red blood cell production result in suppression of the master iron homeostasis hormone hepcidin, which in turn leads to increased iron availability for erythropoiesis. Clinical trials are now in progress evaluating whether hepcidin mimetics can reduce phlebotomy requirements in patients with polycythemia.[14]

Primary Myelofibrosis

The Dynamic International Prognostic Scoring System (DIPSS)-(Plus) risk stratification scheme is used to guide decision making regarding treatment options (Fig. 152-6), with clinical trials encouraged in all risk groups. Allogeneic hematopoietic stem cell transplantation is the only curative modality, and all other therapies are used with palliative intent. Transplant generally should be recommended for patients with intermediate-2 or high-risk disease, nontransplant therapy should be recommended for low-risk disease, and more individualized risk counseling is required for patients with intermediate-1 risk disease for which the risk-benefit ratio is less clear. In such individuals, low platelet counts and identification of potentially high molecular–risk mutations (e.g., *ASXL1*) may assist with decision making.

Individuals with asymptomatic low-risk primary myelofibrosis do not require treatment and are monitored regularly for symptoms and signs of disease progression.[15,16] Symptomatic patients with low- or intermediate-risk disease have demonstrated responses in splenomegaly and constitutional symptoms with ruxolitinib in nonrandomized studies. Although interferons can elicit hematologic responses, reduction of splenomegaly, and improvement of bone marrow histopathology in earlier stages of myelofibrosis, responses in more advanced forms of disease are modest.

Medical Therapy

Ruxolitinib, with dosing based on platelet count under expert supervision, is recommended to treat patients with intermediate- to high-risk primary, post–polycythemia vera myelofibrosis and post–essential thrombocytopenia myelofibrosis to mitigate symptomatic splenomegaly (Fig. 152-7) and disease-related symptoms. Ruxolitinib also is associated with about a 30% reduction in the risk of death. Therapy is generally continued until loss of response (e.g., worsening splenomegaly and/or symptoms or unacceptable toxicity).

The majority of patients treated with ruxolitinib do not experience significant reductions in *JAK2* V617F allele burden or bone marrow fibrosis. High-grade anemia and thrombocytopenia are common with ruxolitinib, usually improve after the first 8 to 12 weeks of therapy, and require careful dose adjustment to maximize efficacy while minimizing myelosuppression. Ruxolitinib is also associated with an increased risk of opportunistic infections, including herpes zoster, reactivation of hepatitis B virus, tuberculosis, and rare cases of progressive multifocal leukoencephalopathy.

JAK inhibitors are useful and reasonably well-tolerated.[17] The JAK2 inhibitor fedratinib (400 mg daily) is first- or second-line therapy for adult patients with intermediate-2 or high-risk primary or secondary (post–polycythemia vera or post–essential thrombocythemia) myelofibrosis and a baseline platelet count of ≥50,000 μL based on its ability to reduce splenic volume.[A8] However, it has a black box warning because of a potential increased risk of serious and fatal Wernicke encephalopathy. Thiamine levels must be checked in all patients prior to starting fedratinib and periodically during treatment.

Another *JAK1/JAK2* inhibitor, momelotinib (200 mg daily), is noninferior to ruxolitinib in reducing splenic volume,[A9] but is not as good for reducing the

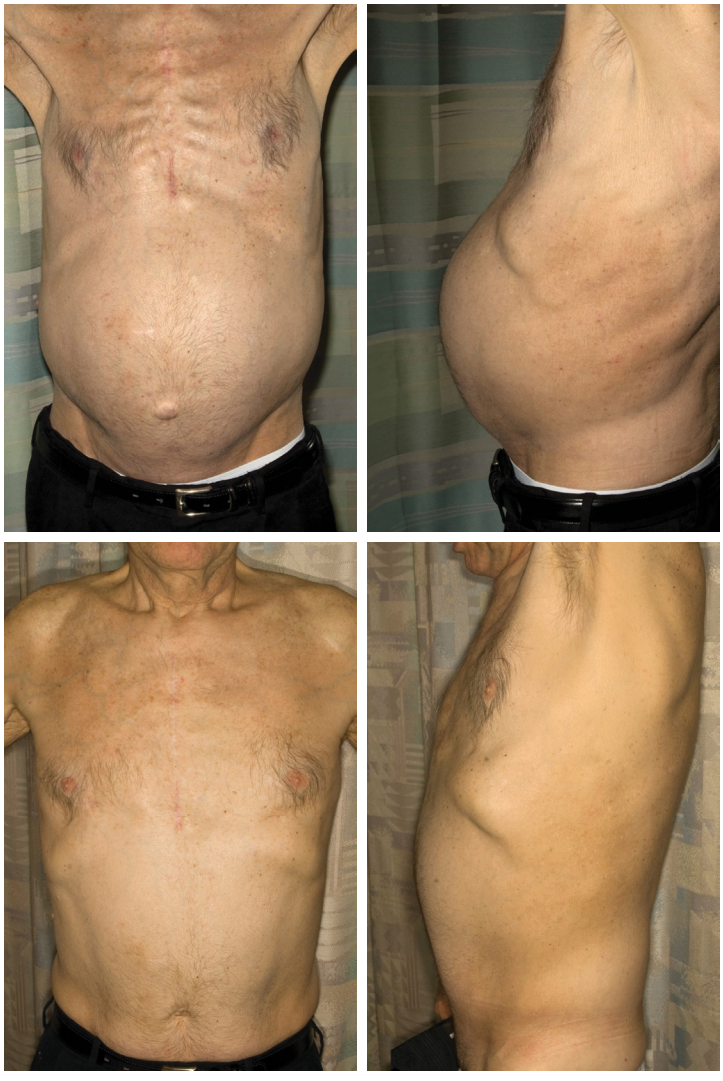

FIGURE 152-7. JAK inhibition in myelofibrosis. Marked reduction in massive splenomegaly after 2 months of JAK inhibitor therapy. (Photos courtesy Dr. Srdan Verstovsek, MD Anderson Cancer Center.)

symptomatic burden. In patients previously treated with ruxolitinib, momelotinib is not superior to best available therapy in reducing spleen volume.[A10] However, momelotinib may be useful to mitigate myelofibrosis-associated anemia by reducing hepcidin levels.

Pacritinib (200 mg twice daily)[A11,A12] is an oral multikinase inhibitor that targets JAK2 (as well as FLT3, CSF1R, and IRAK1) that can reduce splenic volume and improve symptoms, even in patients with severe baseline cytopenias. It is FDA-approved for myelofibrosis patients with a platelet count <50,000/μL.

Other drugs being evaluated as monotherapy or in combination with JAK inhibitors in the front- or second-line therapy include telomerase inhibitors (imetelstat), BET inhibitors (e.g., CPI-06010), BCL-2 inhibitors (e.g., navitoclax), lysine-specific demethylase 1 (LSD1) inhibitors (e.g., bomedemstat), MDM2 blockade (e.g., KRT-232), and various antifibrotic agents that target the bone marrow microenvironment.

Anemia is an unmet need not served (and often worsened) with ruxolitinib treatment. In addition to support with red blood cell transfusions, erythropoiesis-stimulating agents under expert supervision have exhibited responses in about one-third of patients with myelofibrosis. Androgens such as danazol (200 to 300 mg twice daily) can improve anemia in 20 to 30% of individuals, more commonly in non–transfusion-dependent patients. Prostate cancer screening and monitoring of liver function tests are recommended for patients receiving danazol. Luspatercept, which is an erythroid maturation agent that acts as an activin receptor type IIB fusion protein ligand trap that targets the transforming growth factor beta pathway, is currently under evaluation in myelofibrosis patients with anemia.

Splenectomy

The need for splenectomy has probably decreased since the availability of ruxolitinib. Nevertheless, patients who have symptomatic splenomegaly refractory to JAK inhibitors and hydroxyurea may respond to splenectomy, with about a 67% response rate for splenomegaly-related discomfort, a 50% response rate for portal hypertension, and a 23% response rate for transfusion-dependent anemia. However, surgical-related mortality is about 9%, and surgical-related morbidity is about 30%. Postsplenectomy complications (Chapter 154) include infection, bleeding, thrombosis, hepatomegaly, and extreme thrombocytosis or leukocytosis.

Radiation Therapy

Radiation therapy is an option for both hepatosplenic and nonhepatosplenic extramedullary hematopoiesis, which can be associated with complications such as spinal cord compression, pleural effusion or ascites, pulmonary hypertension, cardiac tamponade, and hydronephrosis. Splenic irradiation (100 to 500 cGy in 5 to 10 fractions) induces transient reduction in splenomegaly but can be associated with persistent, life-threatening pancytopenia. Lower doses of radiation (100 cGy total dose in four daily fractions of 25 cGy) have been shown to be safe and effective.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (Chapter 163) is the only potentially curative therapy for myelofibrosis. Candidacy for transplantation is based on age, performance status, major comorbid conditions, psychosocial status, patient preference, and availability of caregiver(s). Myeloablative conditioning is associated with higher rates of treatment-related nonrelapse mortality compared with reduced-intensity conditioning, whereas the latter is associated with a higher risk of disease relapse. Long-term survival is observed in approximately 30 to 60% of patients and depends on the conditioning regimen and the source of stem cells (e.g., matched-sibling compared with unrelated donor). In prospective trials and retrospective analyses of reduced-intensity allogeneic transplantation, the respective 5-year overall survival and nonrelapse mortality rates have ranged from 47 to 67% and 16 to 24%.

For patients with accelerated-phase myelofibrosis (10 to 19% circulating blasts), reduced-intensity allogeneic hematopoietic stem cell transplantation can provide an estimated 5-year overall survival of 65% and a 5-year incidence of relapse of 30%.[18]

Special Situations

Pregnancy in the setting of polycythemia vera and essential thrombocythemia is a higher-risk clinical situation that warrants consultation with a high-risk obstetrician. Patients with essential thrombocythemia have an increased risk of first trimester pregnancy loss. The *JAK2* V617F mutation is an adverse prognostic factor for pregnancy outcome, and retrospective analyses have shown that low-dose aspirin is associated with a reduction in pregnancy complications, especially in patients with *JAK2*-mutated essential thrombocythemia. In low-risk pregnancy, low-dose aspirin is recommended throughout pregnancy, and low-molecular-weight heparin for 6 weeks postpartum; for high-risk pregnancy (previous microcirculatory disturbances, presence of two or more hereditary thrombophilic factors, severe complications in a previous pregnancy, age >35 years, and platelet count >1,000,000/μL), prophylactic low-molecular-weight heparin with low-dose aspirin is recommended throughout pregnancy and the postpartum period. Interferon is generally considered safe during pregnancy and is the preferred agent when cytoreduction is required and its benefits to the mother outweigh potential risks to the fetus. Hydroxyurea should be avoided, including during the breast-feeding period.

Given the thrombohemorrhagic diatheses observed in myeloproliferative neoplasms, optimization of blood counts (e.g., with phlebotomy or cytoreduction) is a high priority before elective surgery. Multidisciplinary collaboration with the surgical team is recommended to evaluate the type and duration of prophylactic antiplatelet or anticoagulation therapy needed in the perioperative setting, in conjunction with close surveillance of thromboembolism.

PROGNOSIS

Polycythemia Vera and Essential Thrombocythemia

Survival

In polycythemia vera, older age, leukocytosis, venous thrombosis, and abnormal karyotype adversely affect survival, with median survivals ranging from about 11 years to about 28 years. The cumulative incidence of transformation to leukemia is 2.3% at 10 years, 5.5% at 15 years, and 7.9% at 20 years. Resistance to hydroxyurea is associated with a 5.6-fold increase in the risk of death and a 6.8-fold increase in the risk of transformation to post–polycythemia vera myelofibrosis and AML.

In patients with essential thrombocythemia, age 60 years or older, leukocyte count of ≥11,000/μL, and prior thrombosis are associated with poorer survival. Based on weighted points assigned to these variables, patients were allocated to three risk categories: low (0 points; median survival not reached); intermediate (1 to 2 points; median survival 24.5 years); and high (3 to 4 points; median survival 13.8 years) (E-Table 152-2). The incidence of leukemic transformation is less than 5% in patients with essential thrombocythemia.

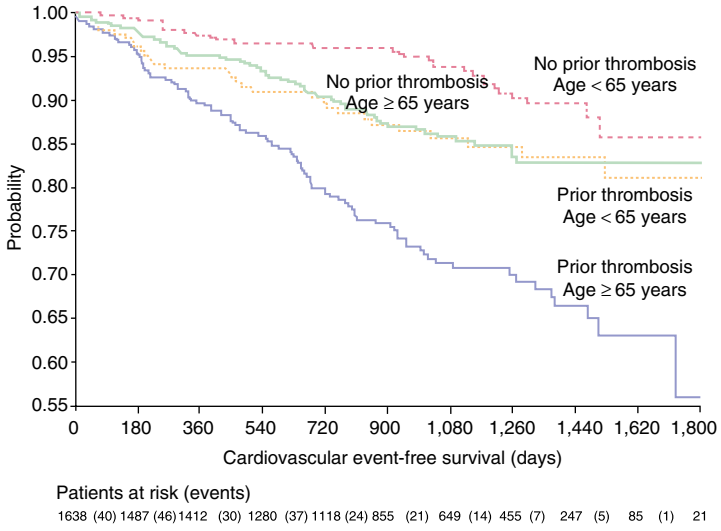
E-TABLE 152-2 PROGNOSTIC MODELS OF SURVIVAL AND THROMBOSIS IN ESSENTIAL THROMBOCYTHEMIA

PROGNOSTIC MODEL	RISK GROUPS AND CLINICAL RELEVANCE
Conventional score for prediction of vascular complications (European LeukemiaNet recommendations)	
At least one of the following risk factors: • Age ≥60 yr • Previous thrombosis or major bleeding • PLT count ≥1,500,000/μL	Low risk: age <60 yr AND no history of thrombosis or major bleeding AND PLT count <1,500,000/μL, that is, none of the three major risk factors High risk: age ≥60 yr AND/OR history of thrombosis or major bleeding AND/OR PLT count ≥1,500,000/μL, that is, at least one of the three major risk factors While low-risk patients are just followed (observation alone) or given low-dose aspirin, high-risk patients are given a cytoreductive treatment plus low-dose aspirin
IPSET-thrombosis (International Prognostic Score for Essential Thrombocythemia: estimates the risk of thrombosis)	
Risk factors (weight): • Age ≥60 yr (1 point) • Previous thrombosis (2 points) • Cardiovascular risk factors* (1 point) • *JAK2*(V617F) mutation (2 points)	Low risk: 0-1 point (probability of thrombotic events: 1.03% of patients/year) Intermediate risk: 2 points (2.35% of patients/year) High risk: ≥3 points (3.56% of patients/year) Potential therapeutic implications: (1) observation alone may be adequate in patients with no risk factors; (2) low-dose aspirin should be used in all patients with *JAK2* (V617F) and/or cardiovascular risk factors; (3) older patients (≥60 yr) without additional risk factors may not need a cytoreductive treatment; (4) conversely, a cytoreductive treatment may be considered in younger patients (<60 yr) with *JAK2*-mutant essential thrombocythemia and concomitant cardiovascular risk factors, even in the absence of previous thrombosis
IPSET (International Prognostic Score for Essential Thrombocythemia: predicts survival)	
Risk factors (weight): • Age ≥60 yr (2 points) • Previous thrombosis (1 point) • Leukocyte count >11 × 10^9/L (1 point)	Low risk: 0 (median survival not reached) Intermediate risk: 1-2 points (median survival, 24.5 yr) High risk: 3-4 points (median survival, 13.8 yr)

*Cardiovascular risk factors include hypertension, diabetes, and tobacco use.

PLT = platelets.

From Rumi E, Cazzola M. Diagnosis, risk stratification, and response evaluation in classical myeloproliferative neoplasms. *Blood*. 2017;129:680-692, Table 4.



Risk group	# events/ 100 persons/year
Age <65 without prior thrombosis	2.5
Age ≥65 without prior thrombosis	4.9
Age <65 with prior thrombosis	5.0
Age ≥65 with prior thrombosis	10.9

FIGURE 152-8. Cardiovascular event–free survival of 1638 patients with polycythemia vera according to age and history of thrombosis.

Thrombosis

Conventional assessment of thrombosis risk in essential thrombocythemia (and polycythemia vera) separates patients into low- and high-risk categories based on the absence or presence of either age older than 60 years or history of thrombosis (Fig. 152-8). Marked thrombocytosis (e.g., platelet count >1.5 million/μL) is associated with a higher risk of bleeding than thrombosis.

An international study of patients with essential thrombocythemia identified cardiovascular risk factors and *JAK2* V617F mutation status as additional independent risk factors that were used to validate a three-tiered prognostic model (IPSET-thrombosis) consisting of low-, intermediate-, and high-risk patients with respective thrombosis risks of 1.03%, 2.35%, and 3.56% of patients/year (see E-Table 152-2). IPSET-thrombosis outperformed the two-tiered (low-risk 0.95% of patients/year vs. high-risk 2.86% of patients/year) risk stratification in predicting future vascular events.

Subsequent analysis of IPSET-thrombosis revealed that among low-risk patients, thrombosis risk was significantly lower in patients with nonmutated *JAK2* in the absence of cardiovascular risk factors (0.44%) compared with when they are present (1.05%). In addition, the risk of thrombosis in the presence of the *JAK2* mutation without cardiovascular risk factors and in the presence of both *JAK2* mutation and cardiovascular risk factors were 1.59% and 2.57%, respectively. These observations led to the development of the revised IPSET-thrombosis scoring system, which has been independently validated and stratifies patients into four risk groups: very low risk (age ≤60 years, no prior history of thrombosis, and no *JAK2* mutation); low risk (age ≤60 years, no prior history of thrombosis, and having a *JAK2* mutation); intermediate risk (age >60 years, no prior history of thrombosis, and no *JAK2* mutation), and high risk (prior history of thrombosis and/or age >60 years with a *JAK2* mutation).

Primary Myelofibrosis

The Dynamic International Prognostic Scoring System (DIPSS)-Plus utilizes eight clinical and laboratory parameters to refine risk prognostication in patients with primary myelofibrosis: age >65 years, hemoglobin <10 g/dL, leukocyte count >25,000/μL, circulating blasts ≥1%, constitutional symptoms, unfavorable karyotype, red cell transfusion need, and platelet count <100,000/μL. Four risk categories were generated based on the number of adverse points: low

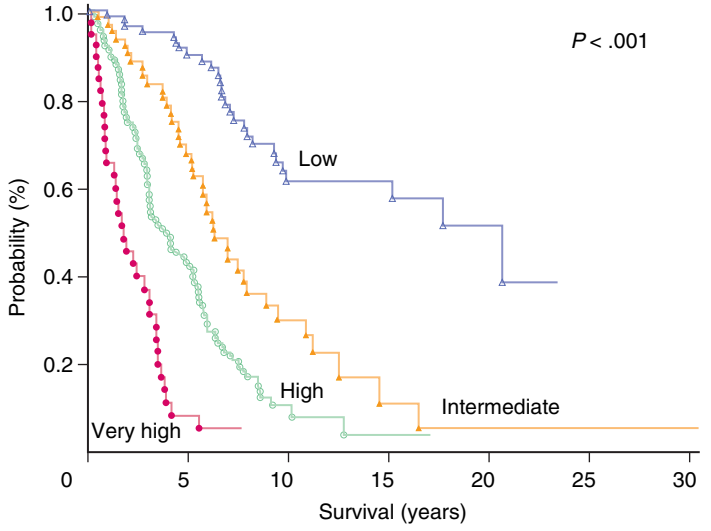


FIGURE 152-9. Mutation-enhanced International Prognostic Score System 70-Plus: mutation-enhanced international prognostic score system for patients with primary myelofibrosis. Mayo training cohort. (Adapted from Guglielmelli P, Lasho TL, Rotunno G, et al. MIPSS70: mutation-enhanced international prognostic score system for transplantation-age patients with primary myelofibrosis. *J Clin Oncol*. 2018;36:310-318, Fig 1 and Table 3.)

risk (zero adverse points); intermediate-1 risk (1 adverse point); intermediate-2 risk (2 to 3 adverse points); and high risk (4 to 6 adverse points), with respective median survivals of 180, 80, 35, and 16 months. In a multivariate analysis, platelet count <100,000/μL and unfavorable cytogenetics were independent predictors of leukemia-free survival. The Mutation-enhanced International Prognostic Scoring System (MIPSS)-Plus prognostic scoring system integrates mutational data (absence of *CALR* type-1 mutation, presence of a high–molecular risk mutation [i.e., *ASXL1*, *EZH2*, *SRSF2*, *IDH1/2*], and presence of two or more high–molecular risk mutations) in addition to clinical and cytogenetic information to improve risk stratification in transplantation-eligible patients (Fig. 152-9).[19] The MIPSS70+ version 2.0 prognostic scoring system provides additional information about risk with the addition of a very high-risk cytogenetic category and the high-risk *U2AF1* Q157 mutation.

153 LEUKOCYTOSIS AND LEUKOPENIA

NANCY BERLINER

The normal peripheral white blood cell count (WBC) ranges between 4500/μL and 10,000/μL, with a mean of 7500/μL, and is composed of neutrophils, lymphocytes, monocytes, basophils, and eosinophils. Because neutrophils usually represent about 60% of the peripheral WBC, derangement in the WBC usually reflects elevation or reduction in the absolute neutrophil count. Leukocytosis (an elevated WBC) and leukopenia (a depressed WBC) may be secondary to an underlying disease or exposure, or they may be manifestations of a primary hematologic disorder.

NORMAL NEUTROPHIL DYNAMICS

Neutrophils arise in the bone marrow from multipotent progenitor cells that also give rise to erythrocytes, megakaryocytes, eosinophils, basophils, and monocytes. Neutrophil precursors in the marrow mature over 6 to 10 days to form a storage pool of mature neutrophils (Fig. 153-1). Acetylation of C/EBPε, a member of the CCAAT/enhancer binding protein family of transcription factors, is required for secondary and tertiary granule formation and for terminal neutrophil differentiation. Together, the marrow populations make up about 95% of the body's total granulocyte mass (20% neutrophil precursors, 75% mature bands and neutrophils). The circulating neutrophil pool thus represents only the remaining approximately 5% of the body's total neutrophils, just over half of which at any given time are adherent to the vascular endothelium and pooled in the spleen, a phenomenon termed *margination*. Marginated neutrophils are poised for immediate release into the circulation during stress. The lifespan of neutrophils in the peripheral blood is up to 3 to 4 days. Once in the circulation, neutrophils subsequently migrate into tissues, where they can survive for 1 to 4 days. Changes in neutrophil number reflect these dynamics.

Neutrophilia can occur as the result of increased marrow production, increased release of neutrophils from the storage pool, or mobilization of neutrophils from the marginated pool. Neutropenia may be due to decreased marrow production, increased margination with or without sequestration by the spleen, or increased destruction of peripheral cells.

NEUTROPHILIA

Neutrophilia is usually reactive or secondary to an underlying inflammatory process such as infection, chronic inflammation, stress, drugs, nonhematologic malignancy, marrow stimulation (as in hemolysis or idiopathic thrombocytopenic purpura), or splenectomy. Primary causes of neutrophilia may be congenital, including hereditary neutrophilia, Down syndrome, and leukocyte adhesion deficiency, or they can be acquired, as in chronic myelogenous leukemia (CML) (Chapter 170) and other myeloproliferative neoplasms (Chapter 152) (Table 153-1).

EPIDEMIOLOGY AND PATHOBIOLOGY

Secondary Causes of Neutrophilia

Infection

Many acute bacterial infections can present with leukocytosis with a "left shift," referring to the circulation of more immature myeloid cells. This left shift most commonly is restricted to release of an increased number of band forms; however, in severe stress, one may also see circulating metamyelocytes and even earlier cells ("leukemoid reaction") (see Fig. 153-1) in the peripheral blood. Leukocytosis occurs within minutes to hours of infection owing to release of neutrophils from both the marrow and marginated pools. Examination of these neutrophils on peripheral smear may reveal evidence

TABLE 153-1 DIFFERENTIAL DIAGNOSIS OF NEUTROPHILIA

- Primary hematologic etiologies
  - Congenital neutrophilia
    - Hereditary neutrophilia
    - Chronic idiopathic neutrophilia
    - Down syndrome
    - Leukocyte adhesion deficiency (LAD)
      - LAD-1
      - LAD-2
  - Acquired hematologic neoplasms
    - Myeloproliferative neoplasm
      - Chronic myelogenous leukemia
      - Polycythemia vera
- Secondary to other disease entities
  - Infection
    - Acute via release from marginated and storage pools
    - Chronic via increased myelopoiesis (e.g., tuberculosis, fungal infection, chronic abscess, other chronic infections)
  - Chronic inflammation
    - Rheumatic disease: juvenile rheumatoid arthritis, rheumatoid arthritis, Still disease, and others
    - Inflammatory bowel disease
    - Granulomatous disease
    - Chronic hepatitis
  - Cigarette smoking
  - Stress
  - Myocardial infarction
  - Drug induced
    - Corticosteroids
    - β-Agonists
    - Lithium
    - Recombinant cytokine administration
  - Nonhematologic malignancy
    - Cytokine-secreting tumors (lung, tongue, kidney, urothelial tumors)
    - Marrow metastasis (myelophthisis)
  - Marrow stimulation
    - Hemolytic anemia, immune thrombocytopenia
    - Recovery from marrow suppression
    - Recombinant cytokine administration
  - Post-splenectomy

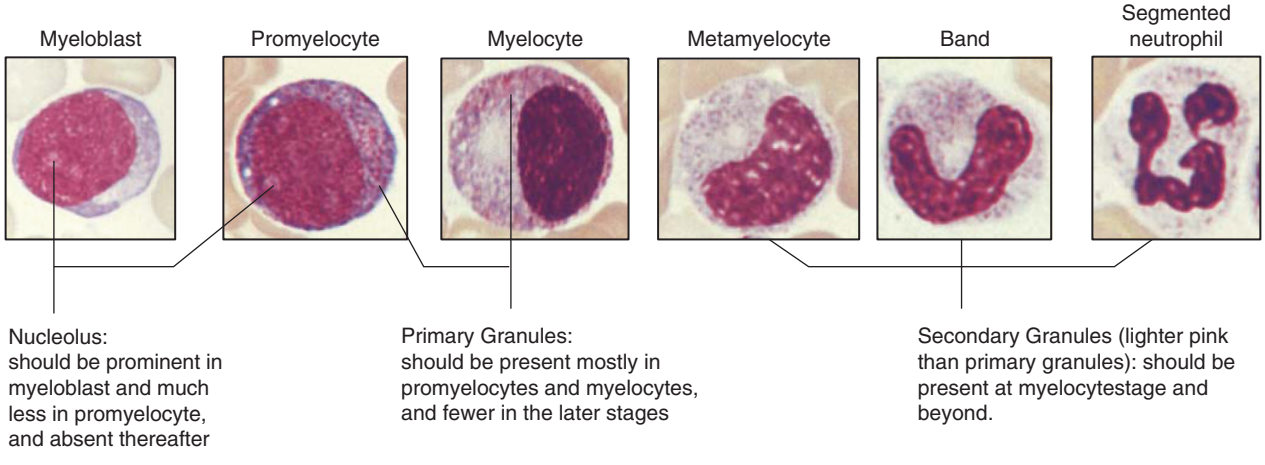

FIGURE 153-1. Myeloid maturation in the bone marrow. Nucleoli are prominent in myeloblasts, much less frequent in promyelocytes, and absent in more mature forms. Primary granules are present in the cytoplasm of promyelocytes and myelocytes, and secondary granules predominate beyond the myelocyte stage.

ABSTRACT

Disruption of the normal peripheral white blood cell count may reflect primary hematologic disease or may be secondary to a host of other diseases. Leukocytosis and leukopenia usually reflect disorders of neutrophils since neutrophils are the primary component of the white blood cell compartment. Leukocytosis is most commonly reactive and secondary to nonhematologic disorders, thereby reflecting the normal response of a healthy bone marrow to infectious or inflammatory stress. Evaluation should focus on identifying the underlying disorder, and bone marrow examination is rarely necessary. Primary myeloproliferative neoplasms leading to leukocytosis are much less common but can largely be identified by molecular testing for pathognomonic mutations on peripheral blood. By contrast, neutropenia is often a primary disorder, either congenital or acquired, and requires more intensive hematologic evaluation. Outside of chronic neutropenic disorders, leukopenia may also occur because of immune-mediated destruction of neutrophils, either as a reaction to a drug or toxin, or in the setting of autoimmune disease. Age of onset and chronicity can help guide the evaluation of patients with leukopenia. Most patients with unexplained neutropenia require bone marrow examination, although repeated examination is not indicated in patients with chronic idiopathic neutropenia.

congenital neutropenia

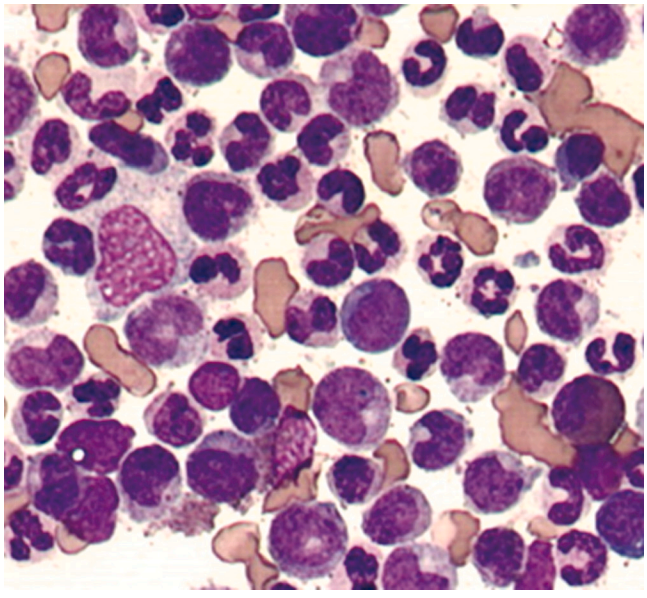

FIGURE 153-2. Peripheral blood from a patient with leukemoid reaction. From this smear, it would be impossible to distinguish a leukemoid reaction from chronic phase chronic myelogenous leukemia (Chapter 170). Distinction would depend on determination of the presence or absence of *BCR-ABL* fusion.

of toxic granulation (see Fig. 143-18), Döhle bodies (see Fig. 143-19), and cytoplasmic vacuoles. Certain infections (e.g., *Clostridioides difficile* or tuberculosis in particular) are known to cause elevations in the WBC to greater than 30,000/μL in about one fourth of infected patients and may result in a *leukemoid reaction*,[1] defined as a WBC greater than 50,000/μL with a pronounced left shift (Fig. 153-2).

Chronic Inflammation

Leukocytosis due to chronic inflammation results from increased leukocyte (specifically neutrophil and monocyte) production as opposed to altered neutrophil distribution. Mature neutrophil pools become depleted with ongoing inflammation, and the marrow myeloid compartment expands to increase neutrophil production. Myriad cytokines, including tumor necrosis factor-α (TNF-α), granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage inflammatory protein-1 (MIP-1), interleukin-1 (IL-1), IL-6, and IL-8, have been implicated in this marrow stimulation. Chronic inflammatory conditions that are commonly associated with leukocytosis and neutrophilia include juvenile rheumatoid arthritis, rheumatoid arthritis, Still disease, Crohn disease, ulcerative colitis, granulomatous infection, and chronic hepatitis. The WBC and neutrophil elevation in these cases is typically more modest than that seen in acute infection or inflammation.

Cigarette Smoking

Cigarette smoking can cause a neutrophilia in about 25 to 50% of chronic smokers and can persist for up to 5 years after smoking cessation. The mechanism of neutrophilia is unknown, although evidence suggests that cigarette smoke slows neutrophil apoptosis.

Stress

Within minutes of exercise, surgery, or stress, the number of circulating neutrophils increases, presumably because catecholamines stimulate the demargination of neutrophils. Some cases of stress-induced neutrophilia can be prevented by pretreatment with β-adrenergic antagonists (e.g., propranolol), thereby supporting the role of catecholamines in the demargination process. Exercise-induced neutrophilia, however, is not blocked by propranolol, thereby suggesting that it may instead be due to flow and mechanical perturbation of neutrophils in the lungs.

Myocardial Infarction

An elevated WBC has been described in the setting of acute myocardial infarction. The etiology of this leukocytosis is likely multifactorial and related, in part, to inflammation. Data suggest that individuals with higher white blood cell counts have poorer short- and long-term prognoses.

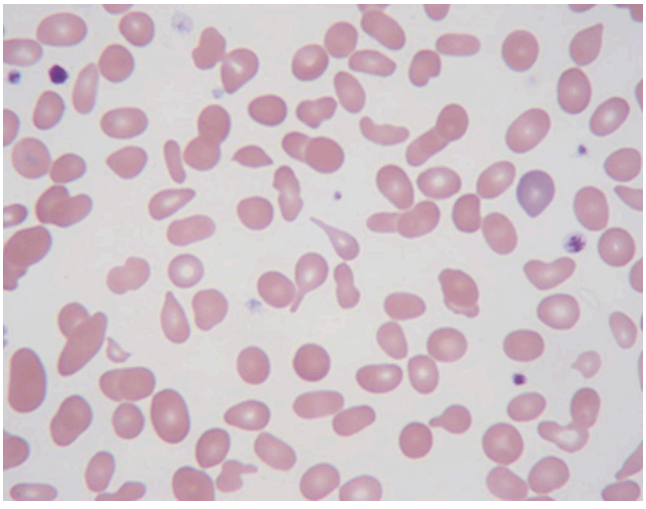

FIGURE 153-3. Myelophthisic changes in erythrocyte morphology. Note prominent teardrop forms. (From Rose M, Berliner N. Disorders of red blood cells. In: Andreoli TE, Benjamin IJ, Griggs RC, et al, eds. *Andreoli and Carpenter's Cecil Essentials of Medicine*, 8th ed. Philadelphia: Saunders; 2010:522, Fig. 49-2.)

Drug Induced

The most well-known and widely used drugs associated with leukocytosis are corticosteroids. Other drugs that elevate the neutrophil count include β-agonists and lithium. Lithium causes neutrophilia by increasing the production of endogenous colony-stimulating factors (CSFs). G-CSF or GM-CSF treatment (Chapter 142) likewise causes neutrophilia, and although this is the desired effect, the neutrophilia can be quite pronounced.

Nonhematologic Malignancy

Leukocytosis can be seen in a number of nonhematologic malignancies. Some tumors (lung, head and neck, kidney, bladder) may secrete G-CSF as an ectopic hematopoietic growth factor. In cancer patients with hyperleukocytosis, genomic testing can discriminate myeloproliferative neoplasms from a paraneoplastic leukemoid reaction. Other tumors (lung, stomach, breast), when metastatic to the bone marrow, can cause a *leukoerythroblastic reaction*, characterized by left-shifted leukocytosis, thrombocytosis, and red cell abnormalities including nucleated and teardrop-shaped red blood cells (Fig. 153-3). The presence of nonhematopoietic entities invading the bone marrow (metastatic cancer, fibrosis, granulomatous disease) is termed *myelophthisis*.

Marrow Stimulation

Peripheral destruction of red cells and platelets, as seen with hemolytic anemia and idiopathic thrombocytopenic purpura, can result in stimulation of the bone marrow and a "spillover" leukocytosis. Recovery of cell counts following marrow suppression, as in the case of chemotherapy, can result in a rebound leukocytosis that may last several weeks.

Primary Causes of Neutrophilia

Hereditary Neutrophilia

Hereditary neutrophilia is an autosomal dominant genetic disease that is characterized by an elevated WBC in the 20,000 to 100,000/μL range with splenomegaly and widened diploe of the skull. The neutrophils function normally, and patients have no increased risk for bacterial infection or other sequelae. Hereditary neutrophilia can be caused by an autosomal dominant *GCSF3* gene mutation, which leads to constitutive activation of the G-CSF receptor.

Chronic Idiopathic Neutrophilia

Chronic idiopathic neutrophilia is a condition marked by leukocytosis in the 11,000 to 40,000/μL range with a normal bone marrow biopsy. In one series with a 20-year follow-up, patients with this condition had no medical sequelae from the elevated WBC.

Pelger-Huët Anomaly

Patients with the Pelger-Huët anomaly are often misdiagnosed as having a left-shifted WBC because many of their mature neutrophils are misinterpreted as band forms. Although these patients do not have leukocytosis, the Pelger-Huët anomaly often raises suspicion for an acute infection because of this apparent left shift. Pelger-Huët anomaly is due to a mutation in the lamin B

receptor gene and manifests with mature neutrophils and condensed, clumped chromatin within a bilobed nucleus (see Fig. 143-20). A number of drugs can reversibly induce pseudo–Pelger-Huët anomaly, including colchicine, sulfonamides, ibuprofen, taxoids, and valproate. Pseudo–Pelger-Huët anomaly is also seen in some patients with myelodysplasia (Chapter 167). Vitamin B_{12} or folate deficiency can cause increased nuclear lobation of neutrophils in patients with Pelger-Huët anomaly, perhaps leading to a missed diagnosis. With correction of the vitamin deficiency, however, the aberrant neutrophil nuclear morphology returns.

Down Syndrome

Up to 10% of patients with Down syndrome develop a transient myeloproliferative disorder manifesting as peripheral blood leukocytosis with blasts in association with an accumulation of megakaryoblasts in the blood, liver, and marrow. Similar reactions have also been reported in phenotypically normal individuals with trisomy 21 mosaicism. Transient myeloproliferative disorder usually resolves spontaneously but can progress to acute megakaryoblastic leukemia in 23 to 30% of affected patients. This disorder is attributable to acquisition of mutations in the *GATA1* gene, which encodes a key transcription factor for hematopoietic regulation, leading to loss of normal GATA-1 expression and expression of a truncated GATA-1 protein. Evidence supports that these mutations are acquired during fetal life, and patients present in early infancy with transient myeloproliferative disorder. The pathogenesis of progression to acute megakaryoblastic leukemia presumably involves additional genetic and epigenetic events and is the focus of intense study.

Leukocyte Adhesion Deficiency

Patients with leukocyte adhesion deficiency also have persistent leukocytosis, defects in stimulus-dependent activation of neutrophils, recurrent infections, and delayed separation of the umbilical cord. Leukocyte adhesion deficiency is an abnormality of leukocyte adhesion reflecting the loss of surface adhesion molecules. Leukocyte adhesion deficiency-1 is due to absence or marked reduction in the common β chain of β2 integrins, resulting in loss of expression of leukocyte function–associated antigen 1 (LFA-1), the C3bi receptor, and GP150;95. This results in a failure to ingest and kill microbes opsonized by C3bi. In leukocyte adhesion deficiency-2, neutrophils lack sialyl Lewis X, the ligand for L-selectin expressed on endothelial cells. Neutrophils appear morphologically normal but are defective in chemotaxis, adherence, and phagocytosis.

Familial Cold Urticaria

Familial cold urticaria is marked by episodic fevers, leukocytosis, urticaria, rash, conjunctivitis, and muscle and skin tenderness with cold exposure. The rash is composed of infiltrating neutrophils. The syndrome appears to be related to decreased levels of C1-esterase inhibitor and is associated with mutations in the *CIAS1* gene on chromosome 1q.

Chronic Myelogenous Leukemia and Other Myeloproliferative Neoplasms

Chronic myelogenous leukemia (CML; Chapter 170), chronic neutrophilic leukemia, and the other myeloproliferative neoplasms (namely polycythemia vera and essential thrombocythemia; Chapter 152) are the principal acquired primary hematologic disorders associated with neutrophilia. CML on presentation should be distinguished from a leukemoid reaction. In contrast to a leukemoid reaction, CML is characterized by the presence of abnormalities of other blood cell lines ("panmyelosis") and by the presence of specific abnormalities. Therefore, the peripheral blood smear in CML (but not leukemoid reaction) demonstrates increased numbers in all cells of the neutrophilic series, classically with a greater proportion of myelocytes to metamyelocytes, and may display concomitant basophilia, eosinophilia, anemia, and thrombocytosis. Chronic neutrophilic leukemia, a rare myeloproliferative neoplasm, is characterized by hepatosplenomegaly and leukocytosis of at least 25,000/μL, with more than 80% of leukocytes being segmented neutrophil/band forms and less than 10% being immature granulocytes.[3] At least 50% of patients with chronic neutrophilic leukemia harbor mutations in the receptor for CSF-3 (*CSF3R; GCSFR*). Polycythemia vera and essential thrombocythemia, on the other hand, are notable for also having a marked increase in red cell mass and a marked thrombocytosis, respectively, which is often accompanied by leukocytosis.

Post-splenectomy

Patients develop leukocytosis following splenectomy, often long-standing, reflecting the loss of a major site of neutrophil margination. This is of no clinical importance, except insofar as it leads to unnecessary evaluation for other pathology.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

As outlined previously, acquired leukocytosis is most commonly the result of acute or chronic infection or inflammation. When leukocytosis occurs in the absence of fever, aberrations in acute phase reactants, effusions, edema, or other signs and symptoms of inflammation, it may be secondary to drugs or an underlying nonhematologic malignancy. As such, leukocytosis should be seen as the sign of a healthy hematopoietic system responding to an outside stress. Bone marrow evaluation is therefore rarely indicated. However, persistence of leukocytosis in the absence of signs and symptoms of inflammation or infection, nonhematologic malignancy, and offending drugs should prompt an evaluation for a primary myeloproliferative disease or clonal hematologic neoplasm, particularly when there is evidence of a leukoerythroblastic reaction. CML and other myeloproliferative neoplasms can be ruled out by molecular diagnosis on the peripheral blood, as described in Chapter 170. In this setting of unexplained leukocytosis, bone marrow examination is indicated to evaluate for marrow infiltration by infection, tumor, or fibrosis and should include cultures for tuberculosis and fungal infection as well as cytogenetics and flow cytometry (Fig. 153-4).

LEUKOCYTOSIS DUE TO EXPANSION OF OTHER CELL LINES

Monocytosis and lymphocytosis can also elevate the WBC. Monocytosis, defined by an absolute monocyte count of greater than 500/μL, usually occurs in chronic inflammation resulting from infections (e.g., tuberculosis, syphilis, some viruses, and subacute bacterial endocarditis), autoimmune or granulomatous disease, and sarcoidosis.[3] Monocytosis can also be seen in malignancies, (e.g. preleukemic states, nonlymphocytic leukemia including acute myelomonocytic and monocytic leukemia, histiocytosis, Hodgkin disease, non-Hodgkin lymphoma, and various carcinomas).[4] Finally, monocytosis can be seen in the setting of chronic neutropenia, after splenectomy, and in the setting of recovery from marrow suppression (Table 153-2).

Lymphocytosis is defined by an absolute lymphocyte count of more than 5000/μL. The most common causes of lymphocytosis are viral infections such as Epstein-Barr virus (Chapter 348) and the hepatitis viruses (Chapter 134 and 135). Although most bacterial infections cause neutrophilia, pertussis and cat-scratch disease due to *Bartonella henselae* can cause lymphocytosis. Other infections that may cause a secondary lymphocytosis include toxoplasmosis and babesiosis. Hypersensitivity reactions due to drugs or serum sickness may also be associated with lymphocytosis.

Primary disorders causing lymphocytosis include chronic lymphocytic leukemia and monoclonal B-cell lymphocytosis (Table 153-3; see also Chapter 169). Low-count monoclonal B lymphocytosis can be detected in about 5% of adults over age 40 years and rarely progresses to chronic lymphocytic leukemia. By comparison, high-count monoclonal B lymphocytosis progresses to chronic lymphocytic leukemia at a rate of 1 to 2% per year.[5]

Eosinophilia (Chapter 156) is defined by an absolute eosinophil count of more than 400/μL.[6] Eosinophils proliferate under the influence of IL-5 and play a role in phagocytosis and modulating toxicity due to mast cell degranulation in hypersensitivity reactions. Eosinophilia is therefore most often seen in the setting of drug reactions, allergy, atopy, and asthma. A variety of infections, particularly parasitic infections and, to a lesser degree, fungal infections, can cause eosinophilia. Eosinophilia can also be the result of autoimmune and inflammatory conditions, as in eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss vasculitis). Atheroembolic disease and adrenal insufficiency may also cause eosinophilia. A number of cancers have been associated with polytypical expansion of eosinophils, including lymphomas and solid tumors. Clonal disorders of eosinophils have been observed in the setting of some leukemias. Finally, there is a heterogeneous group of disorders termed *hypereosinophilic syndromes* (Chapter 156). A *FIP1L1-PDGFRA* fusion gene has confirmed that some of these are primary clonal disorders of eosinophils; the clonality of other hypereosinophilic syndromes can be difficult to establish (see Table 156-1).

NEUTROPENIA

The risk for infection with neutropenia is highly dependent on the size of the neutrophil storage pool. Although neutropenia is defined by an absolute neutrophil count of less than 1500/μL, patients with neutrophil counts below this number have different risks and rates of infection depending on

the cause of neutropenia. Patients who are neutropenic from chemotherapy, marrow failure, or marrow exhaustion experience infection at much higher rates than those with chronic neutropenic syndromes and immune-mediated neutropenia. Neutropenia may be congenital or acquired. The following sections first discuss congenital neutropenic disorders, the study of which has provided critical insights into normal myelopoiesis, and then the secondary causes of neutropenia (Table 153-4).

EPIDEMIOLOGY AND PATHOBIOLOGY

Primary Causes of Neutropenia

Normal Neutrophil Count for Duffy A-B- Individuals

The normal range of the neutrophil count is genetically determined and is variable. Several racial and ethnic groups have a relatively large proportion of individuals who are neutropenic by comparison to the published normal range, usually based on young, largely White individuals.[7] Single-nucleotide polymorphisms in the gene for the Duffy antigen receptor for chemokine are postulated to explain racial and ethnic differences in neutrophil counts. This polymorphism is seen among a variety of ethnic groups, including Blacks, Yemenite Jews, Falasha Jews, and African Bedouins.[8] Blood bank testing for Duffy A and B will demonstrate negativity for both antigens, thereby confirming this normal variant. An autosomal dominantly inherited condition called *benign familial neutropenia* is characterized by neutrophil counts in the 800 to 1400/μL range. Neither of these two forms of neutropenia is associated with *any* increased risk for infection.

Severe Congenital Neutropenia

Severe congenital neutropenia presents in the neonatal period with recurrent bacterial infections and neutrophil counts of less than 500/μL. Infections usually occur in the first months of life and often include omphalitis and perirectal abscesses. There is often an increase in monocytes and eosinophils. Bone marrow biopsy reveals a "maturation arrest" with an absence of mature neutrophil elements. Severe congenital neutropenia can follow autosomal

Hermansky-Pudlak syndrome type 2	Autosomal recessive	*AP3B1*

ELANE = neutrophil elastase gene; *G6PC3* = glucose-6-phosphatase catalytic subunit 3 gene; G-6-PT = glucose-6-phosphatase translocase; *G-CSFR* = granulocyte colony-stimulating factor receptor gene; *LYST* = lysosomal trafficking regulatory gene; SBDS = Shwachman-Bodian-Diamond syndrome; *WASP* = Wiskott-Aldrich syndrome protein gene.

dominant and recessive and X-linked patterns of inheritance and is associated with mutations in a variety of genes (Table 153-5).[9]

Neutrophil elastase (ELANE) is a serine protease that is synthesized at high levels in the promyelocyte stage of neutrophil maturation and is packaged in primary granules. Though originally hypothesized to cause defective cellular trafficking and cytoplasmic accumulation leading to neutrophil apoptosis, newer evidence supports that ELANE mutations lead to accumulation of mutant elastase in the endoplasmic reticulum, with apoptosis resulting from activation of the unfolded protein response. Severe congenital neutropenia due to ELANE mutations is inherited in an autosomal dominant fashion.

Hax-1 is a mitochondrial protein with weak homology to bcl-2, and its absence results in mitochondrial-dependent apoptosis. Although all severe congenital neutropenia cases were originally referred to as Kostmann syndrome, that term is now reserved for this subgroup of autosomal recessive cases.

Wiskott-Aldrich syndrome protein regulates actin polymerization in hematopoietic cells, and deficiency of this protein results in the Wiskott-Aldrich syndrome, characterized by small platelets in low number, sinopulmonary infections, and eczema. Another phenotype of mutated Wiskott-Aldrich syndrome protein, however, is X-linked thrombocytopenia and neutropenia. Mutations in the glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) are a more recently discovered cause of severe congenital neutropenia; homozygous loss of this metabolic enzyme also appears to lead to activation of the unfolded protein response and increased apoptosis of neutrophil precursors.

Severe congenital neutropenia was formerly a disease of infancy and early childhood because few, if any, patients survived to adulthood. However, G-CSF can raise neutrophil counts and prevent infection in most patients, thereby allowing most patients with severe congenital neutropenia to survive. Some patients require very high doses of G-CSF, but responses are seen in 80 to 90% of individuals. Increased survival led to the realization that severe congenital neutropenia predisposes to the development of myelodysplasia and acute myeloid leukemia (myelodysplasia/AML), with the development of myelodysplasia/AML at a rate of approximately 2% per year and a cumulative risk of about 20 to 30% over 10 years. Patients refractory to, or requiring very high doses of, G-CSF have a higher risk for leukemic transformation. The development of myelodysplasia/AML is often associated with the acquisition of a G-CSF receptor gene mutation. Considerable controversy exists concerning the role of lifelong G-CSF administration in the acquisition of other mutations and their contribution to malignant transformation in patients with severe congenital neutropenia (see Treatment later).

Two classes of G-CSF receptor mutations have been associated with severe congenital neutropenia and either hyper-responsiveness or hyporesponsiveness of the receptor. Initial studies aimed at demonstrating that severe congenital neutropenia was caused by mutation of the G-CSF or G-CSF receptor gene did not implicate such mutations in its pathogenesis. However, a small number of patients have been shown to have mutations in the G-CSF receptor gene that block ligand binding and produce a G-CSF–resistant form of severe congenital neutropenia. More important, however, the studies identified an acquired missense mutation that introduces a stop codon that leads to the deletion of the distal intracellular domain of the receptor known to be responsible for differentiation signaling. This mutation has been shown to cause hypersensitivity to G-CSF, suggesting that the mutation may play a role in the development of myelodysplasia/AML. However, whether this mutation in fact influences the development of myelodysplasia/AML and whether G-CSF increases the risk for developing the mutation remain subjects of significant controversy. Even in the presence of the G-CSF mutation, development of AML is associated with the acquisition of other myeloid leukemia–associated gene mutations.[10]

Cyclic Neutropenia

Cyclic neutropenia is defined by periods of neutropenia (≤200/μL) lasting 3 to 5 days and occurring at approximately 21-day intervals. Neutropenic periods may be marked by recurrent fevers, mouth sores, and infections of the skin, upper respiratory tract, and ears. Cyclic neutropenia can be dominantly inherited or sporadic, and it is associated with ELANE mutations in virtually all cases. Acquired cyclic neutropenia has been rarely associated with systemic diseases such as large granular lymphocytosis or T-cell lymphoma.

Other Congenital Syndromes with Associated Neutropenia

Several congenital disorders are associated with neutropenia.[11] These include Shwachman-Diamond syndrome, Fanconi anemia, dyskeratosis congenita, glycogen storage disease Ib, myelokathexis, Chédiak-Higashi syndrome, Griscelli syndrome II, and Hermansky-Pudlak syndrome II.

Shwachman-Diamond syndrome usually begins as an isolated neutropenia but progresses to marrow failure and is also associated with pancreatic dysfunction and skeletal abnormalities. The responsible gene, the Shwachman-Bodian-Diamond syndrome gene (*SBDS*), is involved in the regulation of ribosomal RNA. These patients carry an increased risk for leukemic transformation.

Fanconi anemia (Chapter 151) is due to mutations in genes involved in DNA repair, and as such, marrow failure develops later in these patients (median age, 7 years). Patients with Fanconi anemia often have concomitant short stature with upper limb anomalies and hyperpigmented café-au-lait spots, although about one third have no physical abnormalities. Screening is done by chromosomal fragility testing following exposure to diepoxybutane or mitomycin C and by direct assessment for known Fanconi gene mutations.

Dyskeratosis congenita (Chapter 151) is a syndrome of nail dystrophy, leukoplakia, and skin pigmentation abnormalities with associated neutropenia or aplastic anemia that typically does not present until the second decade of life. It is inherited in an autosomal dominant or recessive or X-linked fashion and is associated with mutations in genes involved in telomere maintenance. Dyskeratosis congenita is one of several diseases associated with telomere abnormalities, with wide-ranging manifestations including pulmonary fibrosis and hepatic cirrhosis as well as bone marrow failure.

Glycogen storage disease Ib (Chapter 191) is inherited as an autosomal recessive disorder characterized by intermittent neutropenia due to defects in the neutrophil respiratory burst with subsequent apoptosis of circulating neutrophils. Hepatomegaly and metabolic crises are also the hallmarks of this disease and are due to mutations in the gene for the glucose-6-phosphatase translocase enzyme.

The neutropenia of *myelokathexis* is due to retention of mature neutrophils in the bone marrow. During infection, however, patients with myelokathexis typically have a sudden rise in their neutrophils, making their clinical course relatively more benign. There is an association between this condition and hypogammaglobulinemia and warts: WHIM syndrome (*w*arts, *h*ypogammaglobulinemia, *i*mmunodeficiency, and *m*yelokathexis). Myelokathexis is caused by heterozygous mutations in the gene encoding chemokine receptor CXCR4.

Chédiak-Higashi syndrome, Griscelli syndrome II, and *Hermansky-Pudlak syndrome II* are all syndromes of albinism and neutropenia due to defects in vesicular trafficking. Chédiak-Higashi syndrome is due to mutations in a lysosomal trafficking regulatory gene (*LYST*) and is characterized by oculocutaneous albinism, bleeding, progressive neurologic disease, and increased susceptibility to hemophagocytic syndrome. Griscelli syndrome II, with nearly identical clinical manifestations as Chédiak-Higashi syndrome, is caused by mutations in the gene encoding the small guanosine triphosphatase RAB27A, which is involved in the release of myeloperoxidase from the primary granules of neutrophils. Hermansky-Pudlak syndrome II is due to mutations in the *AP3B1* gene, which encodes a part of a protein transport complex involved in vesicular trafficking and appears to be involved in the trafficking of neutrophil elastase. It is also marked by albinism, platelet abnormalities, and pulmonary fibrosis.

Barth syndrome is an X-linked autosomal recessive disorder characterized by neutropenia, cardiomyopathy, and growth retardation, with a high early childhood mortality from the associated heart disease. The causative mutation is in the *TAZ* gene, which encodes the tafazzin protein that is critical to remodeling cardiolipin in the mitochondrial membrane.

Secondary Causes of Neutropenia

Infection-Related Neutropenia

Several viral infections cause a transient neutropenia that typically resolves as the viremia abates. These include varicella, measles, rubella, hepatitis A and B, Epstein-Barr virus, influenza, parvovirus, and cytomegalovirus. The mechanisms are diverse and involve redistribution, decreased production, and immune destruction of neutrophils. Human immunodeficiency virus and acquired immunodeficiency syndrome also cause multifactorial leukopenia and neutropenia (Chapter 355). Patients often have splenomegaly and sequestration, but more commonly, the neutropenia reflects immune-mediated destruction. A myriad of atypical infections like *Mycobacterium tuberculosis*, ehrlichiosis, rickettsia, tularemia, brucellosis, and some staphylococcal infections can cause moderate neutropenia. Any infection leading to overwhelming sepsis can cause neutropenia, but this usually reflects consumption of marrow neutrophil reserves and is typically seen in newborns and elderly patients with limited marrow reserves. There is also increased margination of neutrophils during sepsis due to systemic activation of complement, exacerbating the neutropenia.

Drug-Induced Neutropenia and Neutropenia Due to Marrow Injury

Drug-induced neutropenia is the most common cause of neutropenia. Multiple drugs have been implicated in neutropenia and agranulocytosis, in both predictable and idiosyncratic patterns. Drug-induced neutropenias may reflect either suppression of marrow granulopoiesis or increased destruction of peripheral neutrophils. Many drugs cause direct dose-dependent marrow suppression, which is predictable and often mild. Others incite an idiosyncratic immune-mediated destruction that can present with profound agranulocytosis. Drug-induced neutropenia typically presents with a marked decline in neutrophils occurring after 1 to 2 weeks of exposure to the drug with recovery within 3 to 10 days of stopping the drug. However, atypical cases can present long after drug initiation, and others may be associated with a markedly delayed recovery (Fig. 153-5). Patients with drug-induced agranulocytosis may present with acute sepsis, leading to significant acute mortality. Recovery is often preceded by the appearance of monocytes and immature neutrophil forms. The more hypercellular the marrow is at diagnosis, the earlier marrow recovery may occur. Some common drugs known to cause neutropenia, in addition to antineoplastic, antiviral, and immunosuppressive agents, include clozapine;

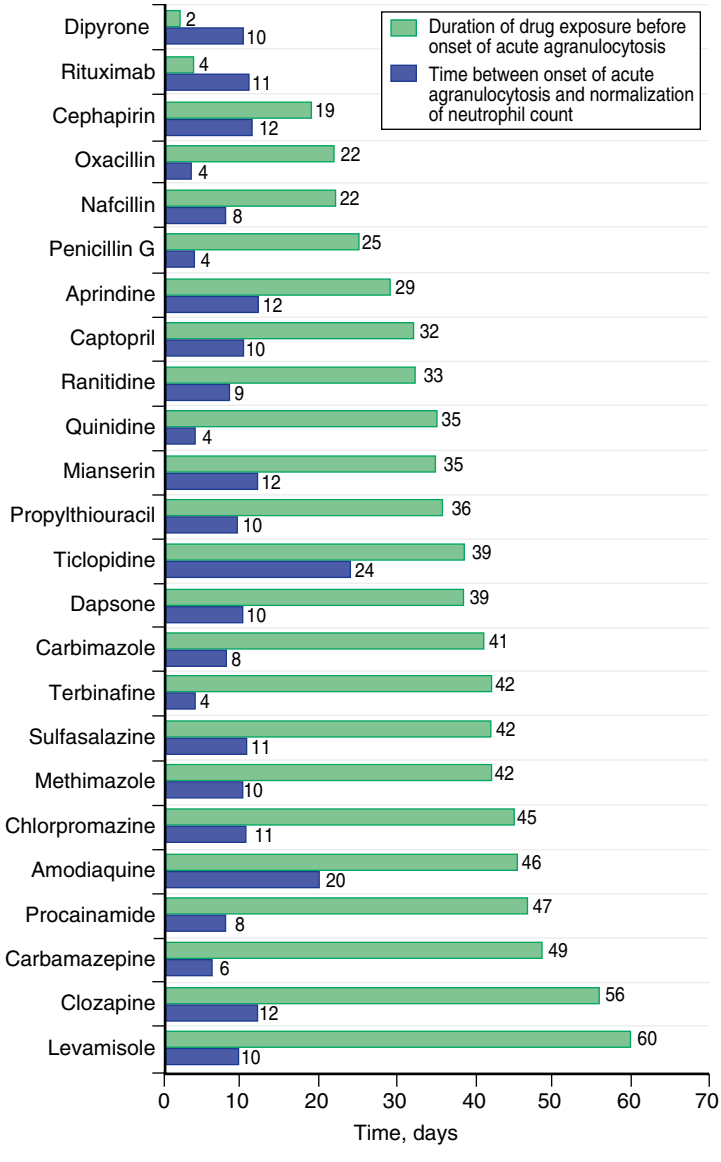

FIGURE 153-5. Median duration of treatment and neutropenia. Only drugs with more than three definite or probable reports of the time between onset of acute agranulocytosis and normalization of neutrophil count and the duration of treatment before onset of acute agranulocytosis were considered. (From Andersohn F, Konzen C, Garbe E. Systematic review: agranulocytosis induced by nonchemotherapy drugs. *Ann Intern Med*. 2007;146: 657-665.)

the antithyroidal thioamides including carbimazole, methimazole, and propylthiouracil; quinidine; procainamide; sulfasalazine; and levamisole, which is widely used as a cocaine adulterant and causes cocaine-associated neutropenia. Neutrophil recovery is speeded by G-CSF.

Radiation can induce marrow injury leading to acute or chronic marrow failure; in high doses, it is also a risk factor for the development of myelodysplasia and leukemia. These malignant hematopoietic diseases can themselves cause marrow failure because the malignant cells proliferate within the marrow and can also cause marrow fibrosis, both of which lead to cytopenias. These diseases are discussed in greater detail in Chapters 151 and 167, respectively. Likewise, metastatic carcinoma to the marrow can also cause marrow failure as the marrow becomes replaced by the metastatic cells.

Immune Neutropenia

Immune neutropenia can occur as an isolated phenomenon (primary immune neutropenia) or as a manifestation of an underlying systemic autoimmune disease (secondary immune neutropenia).[12] Primary autoimmune neutropenia is generally a disease of children, with a median age of onset of 6 to 12 months. Although infectious risk is increased, treatment is restricted to prophylactic antibiotics, with G-CSF reserved for acute infectious episodes. Ninety-five percent of patients undergo spontaneous remission within 2 years. Nearly all of these patients have antineutrophil antibodies directed against antigens derived from the FcγIIIb receptor; these antibodies mediate neutrophil destruction by either sequestration in the spleen or complement-mediated neutrophil lysis.

Secondary autoimmune neutropenia is a disease of adults and can be seen in association with hyperthyroidism, Wegener granulomatosis, rheumatoid arthritis, and systemic lupus erythematosus (SLE).[13] The role of antineutrophil antibodies in these patients is less clear. More than 50% of patients with SLE, for example, have antineutrophil antibodies, but many have normal neutrophil counts, and there is a poor correlation between the presence of the antibodies and neutrophil number.

Felty syndrome and *large granular lymphocyte syndrome* deserve separate mention. Felty syndrome occurs in association with long-standing rheumatoid arthritis (Chapter 243) and is characterized by splenomegaly and profound neutropenia. Large granular lymphocyte syndrome (Chapter 151) can occur either in the setting of rheumatoid arthritis or as an isolated phenomenon. Both Felty syndrome and large granular lymphocyte syndrome are associated with a proliferation of large granular lymphocytes, with a characteristic surface phenotype ($CD3^+$, $CD8^+$, $CD16^+$, and $CD57^+$). In rheumatoid arthritis, these two syndromes were originally thought to be separate diseases, with Felty syndrome being polyclonal and large granular lymphocyte syndrome representing a monoclonal proliferation. However, with increasing sensitivity of detection of monoclonal populations of lymphocytes, this distinction has become blurred. More than 90% of rheumatoid arthritis patients with either syndrome are human leukocyte antigen (HLA)-DR4-positive, leading to the postulate that the two entities represent the extremes of a single disease spectrum. This HLA restriction is not found among non–rheumatoid arthritis patients with large granular lymphocyte syndrome. Both syndromes cause immune-mediated neutrophil destruction by multiple mechanisms, including antineutrophil antibodies and cell-mediated destruction. Some patients may also have G-CSF resistance mediated by inhibitory G-CSF antibodies. The pathophysiology of large granular lymphocyte syndrome is incompletely understood. However, up to 50% of patients have activating mutations in Stat3, and all patients show constitutive activation of the Stat3 signaling pathway.

There are other rare forms of immune neutropenia. Isoimmune neonatal neutropenia is a moderate to severe neutropenia of the newborn due to transplacental passage of maternal antibodies against alleles inherited from the father, resulting in neutropenia in a manner similar to the development of anemia in Rh hemolytic disease. Pure white cell aplasia is a rare disease highlighted by a complete absence of myeloid precursors on bone marrow examination. The condition is associated with severe pyogenic infections and with thymoma in more than two thirds of cases. Pure white cell aplasia has also occurred following ibuprofen therapy.

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation can result in both acute and chronic neutropenia as a result of increased margination of the circulating neutrophil pool. The increased neutrophil margination has been attributed to the fact that C5a renders neutrophils more adherent and prone to aggregation within the pulmonary vasculature and has been seen in patients suffering from burns and transfusion reactions. Complement activation may also lead to neutrophil destruction, as in paroxysmal nocturnal hemoglobinuria. Neutropenia can also reflect hypersplenism, although this is typically less common and less pronounced than the anemia and thrombocytopenia seen in patients with splenomegaly.

Neutropenia Due to Nutritional Deficiency

B_{12}, folate (Chapter 150), and copper deficiency are each associated with neutropenia. Copper deficiency is an underrecognized cause of neutropenia (usually seen with anemia), found especially in situations like total parenteral nutrition without copper supplementation, protein-losing enteropathies, celiac disease, gastric bypass surgery and postgastrectomy, malabsorption syndromes, and zinc toxicity. In addition to low serum copper and ceruloplasmin levels, distinct morphologic findings include hypogranularity and hypolobated nuclei (Pelger-Huet anomaly) on peripheral smear and cytoplasmic vacuolization of myeloid, as well as erythroid precursors and ringed sideroblasts.

Deficiencies in these vitamins and minerals result in ineffective myelopoiesis, maturation arrest, and megaloblastic changes with nuclear-cytoplasmic dyssynchrony. The characteristic finding in the setting of megaloblastic anemia is hypersegmentation of the neutrophil (Fig. 153-6).

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia in adults is an acquired disorder characterized by prolonged neutropenia in the absence of any apparent underlying etiology. Chronic neutropenia is often an incidental finding on routine blood tests, making it impossible to know the duration of the neutropenia. Patients have no evidence of autoimmune disease, nutritional deficiency, or myelodysplasia. The syndrome is heterogeneous, with a wide range of neutrophil counts. A group of adults from Greece with chronic idiopathic neutropenia were found to have increased production of transforming growth factor-β (TGF-β), linked to a genetic polymorphism in the TGF-β locus, and consequent suppression of granulopoiesis by the bone marrow. These patients tend to have very mild neutropenia, with an absolute neutrophil count that is rarely less than 800. However, these patients should be distinguished from other adults with chronic idiopathic neutropenia, many of whom have an absolute neutrophil count below 200. The etiology of neutropenia in these patients is completely unknown, but the natural history of chronic idiopathic neutropenia in adults, even in the face of very low neutrophil counts, is generally benign. Most patients require no therapy, although those with very low counts may require G-CSF if they manifest severe infections. Some patients with recurrent infections or troublesome aphthous ulcers require chronic G-CSF treatment. These patients typically respond to low doses of G-CSF, and there is no increase in the development of myelodysplasia/AML.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neutropenia is not usually associated with clinical signs and symptoms other than those of the underlying condition causing the low WBC. It becomes

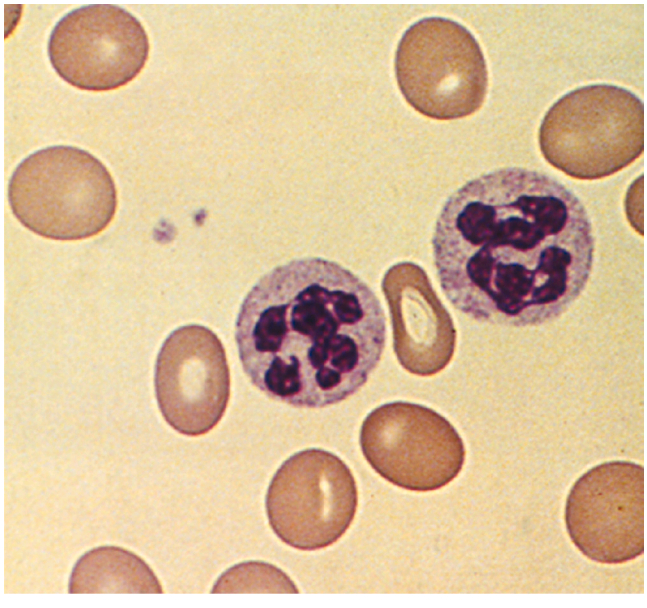

FIGURE 153-6. Peripheral blood with macrocytosis and hypersegmented neutrophils in megaloblastic anemia.

clinically evident, however, when it results in infection. Although patients with an absolute neutrophil count below 1000/μL have a slightly increased risk for infection, the risk increases substantially when the neutrophil count falls below 500/μL. With few neutrophils, the signs and symptoms of infection may be attenuated; pneumonia may be present with minimal infiltrate on chest radiograph, or a urinary tract infection may yield only a very mild pyuria. Therefore, fever in any neutropenic patient must be considered an emergency with prompt acquisition of cultures and rapid administration of empirical antibiotic therapy.
